
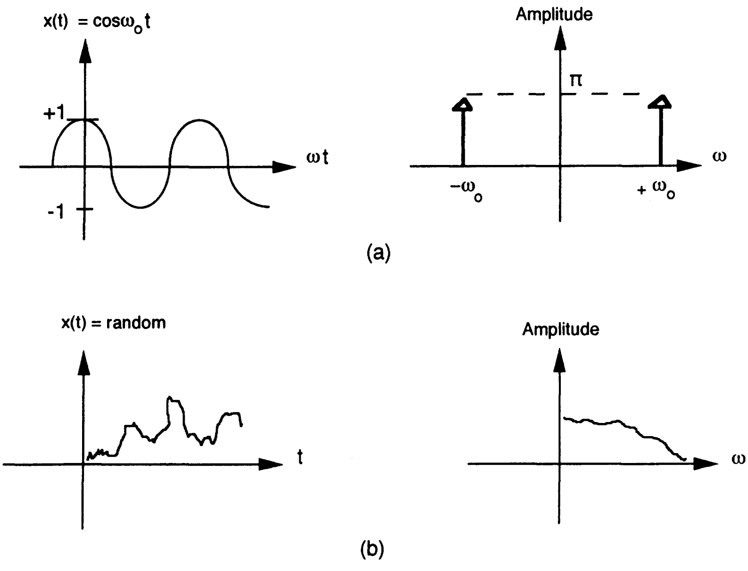

FIG. 13. Examples illustrating the frequency spectrum of periodic and nonperiodic functions: (a) periodic function; (b) nonperiodic function.

neously (not one at a time). Also, this analyzer provides both the magnitude and the phase information of each frequency component. The analyzer is useful for measuring signals from a few microhertz to about 100 kHz. In transient–wave-form analysis, signals can be sampled, digitized, and stored in internal memory or sent by one of several interfaces [e.g., general-purpose interface bus (GPIB), discussed in Sec. 2.3] to an external storage device. The stored information can be recalled and analyzed in time, frequency, and amplitude domains.

Some modern designs incorporate measurement of the statistical properties of signals as well as the joint properties of two or more signals. These measurements are made possible because of the availability of phase information afforded by the analyzer.

1.5.2 Spectrum Analyzers. For nonperiodic functions (signals), the spectrum is calculated on the basis of the power spectral density concept. For a complex, nonperiodic function $x(t)$, its power spectral density $S_{xx}(\omega)$ can be expressed as (Sydenham, 1982)

$$S_{xx}(\omega)=\frac{1}{2\pi}\lim_{T\to\infty}\frac{|X(j\omega)|^2}{2T}, \qquad (10)$$

where $X\ (j\omega)$ is the Fourier transform of $x(t)$ given by

$$X(j\omega)=\int_{-\infty}^{+\infty} x(t)e^{-j\omega t}dt. \qquad (11)$$

It is clear from Eq. (10) that the power spectral density is a real-valued function of ω and even, so that $S_{xx}(\omega)=S_{xx}(-\omega)$. The power P of the entire signal in the frequency domain is related to the power spectral density $S_{xx}(\omega)$ by Parseval's equation (Sydenham, 1982) as

$$P=\overline{x^2(t)}=\lim_{T\to\infty}\frac{1}{2\pi}\int_{-T}^{+T} x^2(t)dt$$
$$=\int_{-\infty}^{+\infty} S_{xx}(\omega)d\omega. \qquad (12)$$

Equation (12) shows that the spectrum of a signal at various frequencies is directly related to the signal power at these frequencies. Such a relationship provides the basic concept in spectrum analyzer design.

Design implementation of spectrum analyzers can be generally summarized in the following steps:

1. frequency filtering of the signal by a narrow-band–pass filter,
2. squaring the instantaneous value of the filtered signal,
3. averaging the squared instantaneous value over the sampling time, and
4. computing the rms value of the result.

As shown by Fig. 14, most modern spectrum analyzers perform the filtering function by a technique known as heterodyning, which al-

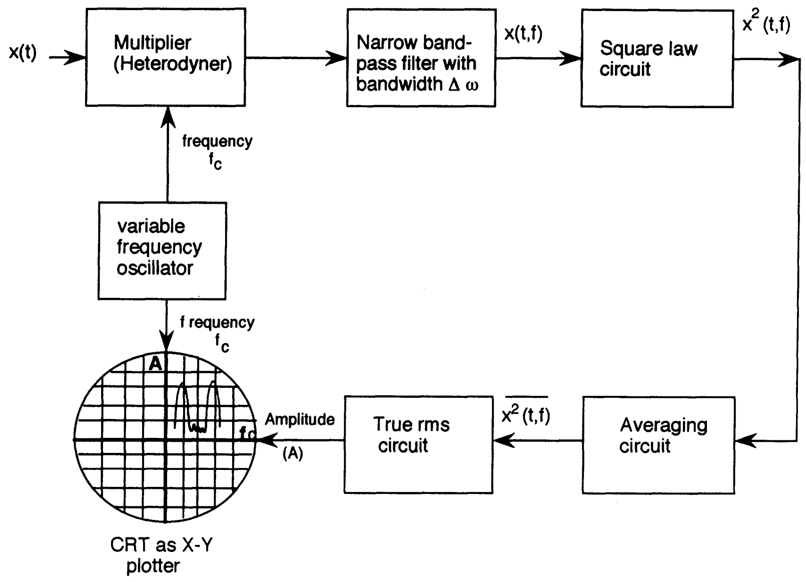

FIG. 14. Functional block diagram of a spectrum analyzer.

lows the use of a single fixed-band–pass filter throughout the entire range of frequencies. Without heterodyning, several filters of fixed bandwidth staggered in frequency would have to be used to cover the desired frequency range. The heterodyning operation consists of simply multiplying the signal with a sine wave whose frequency f_c can be accurately and quickly changed through a range of values. This multiplication process is equivalent to amplitude modulation that shifts any frequency content of the signal at, say, frequency f_s to f_c+f_s.

The filtered signal $x(t,f)$ is that part of $x(t)$ at frequency f. After squaring and averaging $x(t,f)$, the spectrum can be computed by using a calibrated TMS voltmeter circuit, as described in Sec. 1.1. The variable frequency from the oscillator provides the sweep signal for the synchronization with the x-axis sweep of the CRT to generate the amplitude spectrum on an oscilloscopelike display.

Spectrum analyzers can provide a broad frequency range from a few hertz to >300 GHz with a wide amplitude range from less than −100 to about +30 dBm. With the proper instrument interface protocol, the analyzers can be directly connected to plotters or printers to provide hard copies of the CRT displays.

1.6 Counters

A most convenient and widely used instrument for accurate measurement of frequency and time intervals is the electronic counter. Counters can perform a wide range of functions including high-accuracy frequency calibration of radio-frequency (rf) signals, frequency measurements on noisy signals, accurate propagation delay measurements, and phase shift in filter signals.

Modern counters employ the state of the art in digital technology and ICs by providing high-precision measurement and powerful analyzing capabilities—all in one compact, cost-effective instrument. With on-board microprocessors, counters can even provide some computational capabilities with built-in mathematical and statistical functions such as inversion, normalization, scaling, mean value, standard deviation, and minimum and maximum values. In addition to the integrated digital display of the measurement, the counter can have other outputs such as binary-coded decimal (BCD) (discussed below) and analog output for strip-chart recording. The versatility of the counter can also be extended by adding the IEEE-488 standard instrument interface bus for communication with other instruments and remote programmability of the counter.

FIG. 15. Clocked SR flip-flop using NOR gates: (a) circuit diagram; (b) block diagram; (c) state table.

The most basic element of the counter is a digital device called the *flip-flop* (FF). The flip-flop, also called a bistable multivibrator, is an extremely versatile logic device that is used extensively in most digital circuitry including digital computers. The basic FF, known as the RS FF, can be formed by cross-connecting two NOR gates or two NAND gates (Fig. 15 shows the NOR configuration to illustrate the basic operation of the FF). The RS FF device has three inputs: S (SET), R (RESET), and CP (CLOCK PULSE). The S and R inputs are normally at logic 0 (also referred to in the digital field as logic LOW or 0 state). If the input applied to S is changed from logic 0 to logic 1 (referred to in the digital field as logic HIGH or 1 state), the Q output goes to logic 1 and the complemented (inverted) output $\bar{Q}$ goes to logic 0. Even if the S input returns to the 0 state, Q remains at the 1 state because of the internal feedback between the two NOR gates. This operation is called *setting the FF.* Similarly, when the input applied to R changes to the 1 state, Q goes to the 0 state (and $\bar{Q}=1$ state) and remains in that state. This operation is called *resetting the FF,* as indicated by the table of Fig. 15(c). Important to note is that the S and R inputs should not go to logic 1 simultaneously, because the output state in this case is not defined. In practice, the FF would be one component in a digital circuit performing a specific function. Therefore, the operation of the FF must be synchronized with the rest of the circuitry. Synchronization is accomplished by a CLOCK PULSE at the CP input. This pulse is usually a square pulse with

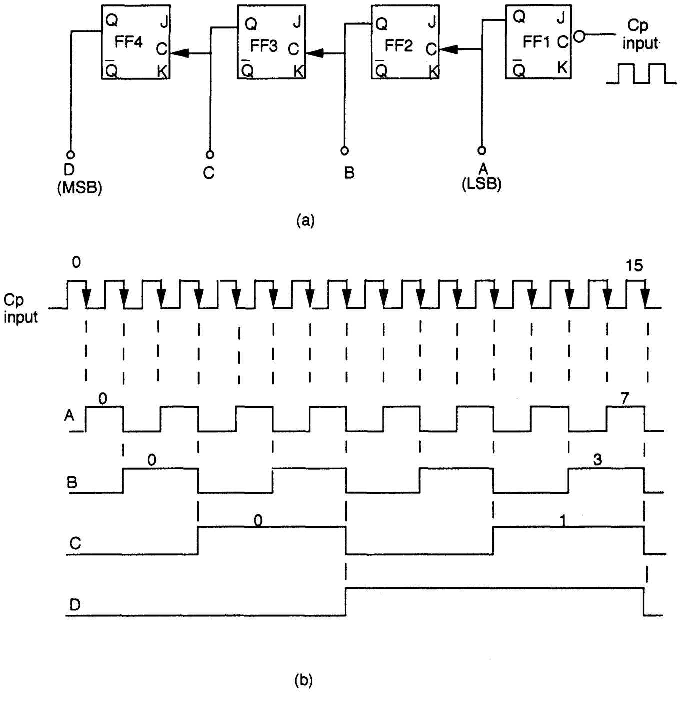

FIG. 16. Four flip-flops forming a 4-bit (MOD-16) binary counter: (a) interconnection diagram; (b) wave forms showing frequency division.

specific frequency. It allows the FFs to change states, on the basis of the present states of inputs R and S, only once for each clock pulse. Other FF forms exist, but their discussion is beyond the scope of this article. For further information on digital logic devices, refer to a textbook on the subject (e.g., Kohavi, 1978). A wide variety of counters (in their basic forms) are available as standard IC packages, and it is seldom necessary to construct a counter from individual FFs. Therefore, coverage of internal operation of counters will be limited to discussing external operating characteristics of currently available counters.

Flip-flops can be connected in various arrangements to function as binary counters that count input clock pulses or events. A 4-bit counter, for example, contains four FFs, one per bit, with the number of outputs equal to the number of bits (i.e., four). As shown by Fig. 16, the counter basically has one input, the clock pulse CP. It is assumed in this counter structure that the FFs are of a form known as JK, where J and K are the FF inputs, and that both J and K are kept at logic 1. In this configuration, the outputs of the JK FF change states on the high-to-low transition of the clock pulse, as indicated by the small circle at the input CP. Some counters trigger on low-to-high transition, in which case the input CP would not have the small circle. The states of the four FFs represent a binary number equal to the number of pulses that have been applied to the CP input. In the diagram, the A output represents the least significant bit (LSB) and D is the most significant bit (MSB) of the binary count. For example, after the fifth input pulse, the output DCBA=0101, which is the binary equivalent of five.

The 4-bit counter can count from 0000_2 (zero) to 1111_2 (fifteen), for a total of 16 distinct states. After the count reaches the maximum, the next input pulse causes the FF outputs to recycle to the 0000 count, and the counting sequence is then repeated with subsequent pulses. Generally, a counter with N FFs can count from 0 up to $2^N - 1$, for a total of 2^N distinct states.

The total number of states is known as the MOD number. The counting sequence can be cut short at any time by applying logic HIGH to a second input (RESET) that can be incorporated in the design. The decade counter is such an example, which counts from 0000 to 1001 (0 to 9) and then recycles to 0000. It has 10 distinct states and thus is referred to as a MOD-10 counter. It is also called a BCD counter because the FF outputs count through 10 in the common digital code known as the BCD code. The BCD is a weighted code where four bits are used to represent each decimal digit. The bits carry weights 8, 4, 2, 1 in the order from the MSB to the LSB, as shown in Table 3.

The counting capability of FFs can be demonstrated by examining the wave form in Fig. 16(a). It is evident that the frequency of the square wave (at CP) is divided by 2 successively by each FF. Therefore, cascading more FF units will produce division by 4, 8, 16,..., etc. In general, the wave form out of the MSB FF of a counter will divide the input frequency by the MOD number. For example, the MSB FF of a 4-bit counter has a frequency that is 1/16 of the clock input, as is evident by comparing waveform D to the clock pulse CP.

Counters can count up from zero to some maximum count and then reset to zero, and up/down counters can count in either direction. Some counters have a single CP input that is used for both count-up and count-down operations, whereas others have two separate CP inputs—one for counting up and another for counting down. For the latter type, only one input can be pulsed at one time to avoid

erratic operations. Some IC counters are designed to give the user the capability of varying the counting sequence through appropriate external connections. These types of counters are usually referred to as variable-MOD counters.

Commercially, counters are classified into frequency counters and general-purpose timer–counters. The frequency counter has a single input channel and sometimes an additional prescaled input for measuring high frequencies. In addition to frequency measurements, most frequency counters can also perform period measurements. The timer–counter version can perform time-interval measurements between two events in addition to frequency and period functions. For a given counter, a frequency can be used as a guide in deciding the suitability of frequency versus period measurement. For a 1-s sampling period, this frequency f_0 is given by (Doebelin, 1983)

$$f_0=(f_c)^{1/2}, \tag{13}$$

where f_c is the frequency of the crystal oscillator ("clock" frequency).

For example, a 10-MHz clock-frequency counter has $f_0=3160$ Hz, above which frequency measurements should be used and below which period measurement should be used.

A more advanced version can provide pulse-width measurements; totalizing capabilities (pulse counting); for the timer/counter type, rise/fall time computation; and phase delay between two events.

1.7 Boxcar Integrators

In some measuring applications, it is desirable to trigger a process repeatedly, such that on repetition, the resulting signal will be identical each time and will appear to be superimposed upon itself. To enhance the signal-to-noise ratio (SNR) of the repetitive signal, an averaging process is performed to smooth out the signal. Two known analog techniques used for this purpose are the signal averager and the boxcar integrator.

The signal averager, as shown in Fig. 17, consists of a bank of parallel capacitors connected to the output amplifier A2 through switch SW-A2. The capacitors are charged by closing in a specific sequence a set of electronic switches known as field-effect transistors (FETs), which are solid-state devices with very high input impedance. The sequence is determined by the timing control circuit controlling the FETs in response to an external trigger signal. The sequence always begins at a fixed time following application of the trigger signal. Consequently, upon repetition, each capacitor circuit receives part of the applied signal through amplifier A1 with the same phase each time by charging the capacitors through the resistance *R* by a small amount each time. The result after a large number of repetitions is that each capacitor contains an averaged sum corresponding to a point on the signal trace. The information stored on the capacitors can be retrieved by allowing switches SW1–SW*n* to be closed one at a time while SW-A1 is opened and SW-A2 is closed. The output resistance–capacitance combination R_0C_0 is used to smooth the final response, which otherwise would look like changing steps because of the switching action from one channel to the next in succession.

The boxcar integrator, also known as the boxcar averager or detector, performs the same function as that of the signal averager, except with a rather simpler circuit. Instead of using a bank of many capacitors, the boxcar employs a single capacitor circuit, as shown in Fig. 18, to take only one sample during each

FIG. 18. A simplified schematic of a boxcar integrator.

signal occurrence and requires a trigger signal at a fixed time interval.

The trigger pulse is used to delay by a fixed time interval the closing of the switch. The capacitor in this case is clearly taking an average of a set of readings for one single point. The entire process is then repeated with different delay-time increments until all points are averaged. [See Sydenham (1982) for more details.]

1.8 Lock-In Amplifiers

The lock-in amplifier is used to recover weak ac signals corrupted with noise. One common application of lock-in amplifiers is spectroscopy, where the generated signal is typically weak. By amplitude-modulating signals at some reference or carrier frequency, the noise often can be reduced and dc drift problems avoided. The main principle of signal recovery is based on the synchronous detector (also known as the phase-sensitive detector or PSD) part of the circuit, which in essence functions as a demodulator. As shown by Fig. 19, the PSD circuit consists primarily of a mixer (multiplier) followed by a low-pass filter. The output of the mixer is the product of two signals x and y. The phase difference between the two inputs can be adjusted precisely by the phase shifter. Mixer circuits used in lock-in amplifiers must be capable of withstanding large amounts of noise without overloading. The square wave used by the mixer is supplied by a sine-to-square-wave converter (this could be simply a comparator—sensing zero crossing). If the square-wave frequency is precisely the same as that of the input signal and if it coincides in phase with its zero crossing, the result would be a type of full-wave rectification. The SNR of the noisy amplitude-modulated signal can be improved by reducing the bandwidth with a band-pass filter tuned to the carrier frequency. The signal can finally be recovered by a low-pass filter, which removes all components of the mixer output that have frequencies beyond the filter cutoff frequency. Some lock-in amplifiers are commercially available with built-in oscillators that can be used to supply excita-

tion to an external system as well as the needed reference signal such as in strain gauge measurement (Vassos and Ewing, 1985; Sydenham, 1982).

1.9 Time-Domain Reflectometry

Time-domain reflectometry (TDR) is an echo technique used in transmission-line analysis to characterize and detect discontinuities in the line. This method also can identify the location and nature of the mismatch resulting from the discontinuity. This identification can be accomplished by applying a pulse of energy and monitoring the reflection of that energy by an oscilloscope. In the laboratory, the TDR is used primarily to test electrical cable (e.g., coaxial cable) and to check thermocouple characteristics in a thermopile.

The TDR system consists primarily of a step generator and an associated oscilloscope designed for this type of application, as shown by Fig. 20. The step generator produces a positive-going wave (incident wave) that is applied to the transmission system under test. The wave propagates through the transmission line at the velocity of propagation of the line. If the load impedance Z_L is equal to the characteristic impedance Z_0 of the line, then no wave reflection occurs, and the incident step voltage is displayed on the oscilloscope without change in its shape. If a mismatch exists at the load, part of the incident wave is reflected. The reflected wave is displayed on the oscilloscope's CRT as algebraically added to the incident wave, as depicted in Figs. 21 and 22 (Hewlett-Packard, 1988).

Analyzing the time delay, magnitude, and shape of the reflected wave form permits determination of location and nature of the mismatch whether the mismatch is at the load or somewhere along the transmission line.

Time-domain reflectometry is much more useful and advantageous than the classical standing-wave-ratio technique (frequency-domain measurement), which requires measurement at many frequencies to identify the mismatch—a rather tedious and time-consuming procedure. Also, with the technological advances in the optical field and the increased applications of fiber optics both in the laboratory and in industry, the optical TDR presents a powerful tool for testing the fiber. This device can analyze the reflected light energy to determine the existence and location of breaks in the fiber and losses at splices and connectors as well as the total loss of the system (Helfrick and Cooper, 1990).

2. DATA ACQUISITION INSTRUMENTATION

In many measurement situations, one is faced with vast quantities of information—mostly in analog form—generated by transducers. Gathering and processing the measured data with the speed and accuracy demanded by the challenging and complex scientific development tasks necessitates a more complex, more sophisticated type of instrumentation. Data acquisition systems (*q.v.*) (DASs) are used for that purpose. A DAS may be as simple as a DVM or it may be complex enough to contain a large-scale computer as part of its hardware. Ordinarily, DASs are digital systems since, with today's technology, complex circuits are low cost, accurate, and relatively simple to implement and easy to interface with human operators. As depicted by Fig. 23, the DAS generally accepts a wide mix of analog signals representing physical parameters; performs signal conditioning functions (filtering, linearization, scaling, and square root); converts the signals into digital form; performs various computations; analyzes data; and interfaces with many external peripheral devices (e.g., CRTs, digital recorders, printers, and mass storage devices). The analog multiplexer is a high-speed scanning device allowing inputs to be switched sequentially one at a time for processing and converted to digital form by using the same ADC.

2.1 Data Loggers

The data logger is a data acquisition system whose architecture resembles very closely that shown in Fig. 23. It provides an automated method of performing measurements and recording data as well as performing some computations with high speeds and accuracy. These functions can be performed at precise,

programmable intervals; once the logger is configured for the application, it will carry out the measurement precisely, unattended.

Data loggers offer good flexibility such as mixing signals representing various physical parameters and display each signal with the appropriate engineering units (pascals, liters per second, degrees Celsius or Fahrenheit). In addition, the same logger can be easily configured for different applications. Data loggers, however, have limitations compared with other DAS forms. Loggers are limited in their ability to provide histograms, trends, time function plots, and curve fits of data required for analyzing data. Although data loggers can interface with many external devices (output devices), they are still limited to some extent in their ability to interface directly with mass storage devices such as hard-disk drives. Some modern data-logger designs include microprocessors and two separate internal memories. One memory (RAM) for the system and user program can run without interference from a host, while the other memory can provide > 100 kbytes of data storage. In addition, an RS-232 or IEEE-488 interface can be included for communication with a host computer for data transfer and remote control of the logger. With a 12-bit ADC, the logger can provide up to 62 500 readings/s; while with a 16-bit ADC, it can provide up to 50 000 readings/s.

2.2 PC-Based Data Acquisition Systems

The high speed and low cost of personal computers (PCs) along with extensive hardware and software support made PCs an ideal choice for automated data acquisition systems in the laboratory and even in industrial applications. Most of today's PC-based DASs are based on either the IBM PC or the Apple Macintosh. As illustrated by Fig. 24, the basic elements of a PC-based DAS are listed below.

1. A PC with an operating system. The common operating system for the IBM PC is the PC-Disk Operating System (PC-DOS) and the Microsoft Disk Operating System (MS-DOS) for IBM-compatible PCs (commercially known as *clones*).
2. DAS boards for analog measurements and control. Analog input boards include an ADC, which is necessary to convert analog signals to digital form for further processing by the PC. Analog output boards also include a DAC, which is necessary to interface the DAS with the analog world. A host of other input/output (I/O) boards are available for practically any application. DAS boards are designed to be inserted directly into available expansion slots inside the PC chassis. In this case, the boards connect directly (through a standard connector, which is part of the board) into the PC bus. Some manufacturers offer stand-alone systems in which DAS boards can be inserted into a separate chassis, which in turn connects to the PC through an RS-232 or an IEEE-488 interface.
3. An instrument interface IEEE-488. This interface provides complete automated measurement and control capabilities of IEEE-type instruments such as DVMs.
4. Output devices. The PC can offer a wide choice of output devices from many differ-

ent manufacturers. In addition to the PC's own CRT, external devices such as printers, plotters, and many mass storage devices with various capacities are available from numerous manufacturing sources.

5. Application software. A wide range of software has been developed specifically for PC-based DASs for both the IBM PC and the Apple Macintosh at reasonable cost. Plug-in boards also are available that include the necessary hardware and resident software that can turn the PC into an oscilloscope, a DVM, a signal generator, a logic analyzer, etc. These simulated instruments, known as virtual instruments (VIs), can be controlled from the PC keyboard, which emulates the control knobs and buttons used with the actual instruments by means of software modules known as instrument drivers. These instrument drivers are essential building blocks in the construction of VIs. The drivers handle the details of controlling and communicating with specific instruments. With the instrument drivers, the user can create VIs by combining several instruments with data analysis, data presentation, and user interface code. A multitasking software development system for DOS called LabWindows is becoming the industry standard. LabWindows primarily serves three purposes. It provides an integrated development environment, a high-level interface to the instrumentation hardware, and the user interface to the virtual instruments. LabWindows also has extensive libraries of functions for data acquisition, data analysis, and data presentation along with tools for editing and debugging user programs written in BASIC or C (discussed in the following). PC-based DASs offer a high sampling rate [100 000 samples/s (i.e., 10-μs sample period)].

2.2.1 Software. Numerous programming languages have already been developed and exist in a variety of dialects (see COMPUTER PROGRAMMING LANGUAGES). Some of these languages were developed specifically for scientific applications such as those performed in the laboratory from customized PC-based DASs to data analysis routines.

BASIC (Beginner's All-purpose Symbolic Instruction Code) is an interpreting, high-level, unstructured, interactive, easy to learn and use language. It became popular among programmers because of its English-like commands. The difficulty of the original version of BASIC is the global internal structure, which does not lend itself to reusing or sharing parts of the program. Many PCs include improved versions of BASIC (e.g., Microsoft BASIC) by incorporating the BASIC interpreter in ROM, which is also available on disk. Another version of BASIC known as *QuickBASIC* was developed and became very popular for developing specialized DASs. Although QuickBASIC is an interpreting language, it is still considered fast enough in comparison with a compiled language such as FORTRAN.

Recently, a programming language called Visual Basic, for Windows, was introduced, primarily to improve users' interface development of virtual instrumentation as well as of general-purpose languages.

C is a block-structured, general-purpose programming language developed by Bell Laboratory. It has been closely associated with the UNIX system because it was developed on that system; also, UNIX and its software are written in C. However, the language is not tied to any one operating system or machine. Because of its portability, C can be used to compose programs that can run on a host of microcomputers with minimal alteration. C is quickly becoming the language of choice among professional application and system developers for the PC, other microbased systems, minicomputers, and mainframe computers. C can be used with LabWindows (for DOS) to develop customized PC-based ADSs. Recently, a programming language called C++ was introduced to improve users' ability to interface with virtual instrumentation as well as handling interfacing requirements of general-purpose languages.

Assembly generates the tightest code of any language and is considered to be the fastest to execute except for machine language. It is used to design programs such as the well-known spreadsheet software, Lotus 1-2-3. Assembly programs are generated from individual instructions represented by three- or four-letter mnemonics like MOV, JMP, and PUSH. When assembled, a program translates directly into machine code that the processor can read from memory and execute. Although the language is somewhat difficult to learn and use, once the programming is complete the results are hard to match.

2.3 Instrument Interfaces

Transmitting and capturing data among instruments in a measurement system requires some physical links or interface to integrate instruments from different manufacturers in a system. Also, the increased application of computers in test, measurement, and control in the instrumentation field requires some form of communication between instruments and computers. Several interface standards adopted by industry are discussed below (see also BUS SYSTEMS AND COMPUTER INTERFACES).

1. IEEE-488/GPIB interface: a standard communication bus adopted by the Institute of Electrical and Electronics Engineers (IEEE) in 1978. This interface was initially developed in 1972 by Hewlett-Packard (HP) as a computer–to–instrument-interface bus (HP-IB) to standardize interface configuration and operating protocol for all HP equipment supplied with digital control interfaces. The HP-IB was adopted by IEEE in 1975 and became IEEE Standard 488-1975 (Digital Interface for Programmable Instrumentation) and was later reissued as IEEE 488-1978 and 488-1987. The standard is also known as the general-purpose interface bus (GPIB). It defines the physical and data-link structure of a local area network for digital communications between a main controller (e.g., computer) and various pieces of instrumentation and laboratory equipment. Instruments (e.g., scopes, analyzers) equipped with this standard can be controlled remotely as part of automated test and measurement systems. The interface bus is available as a module (printed circuit board) containing all the necessary hardware and firmware to implement the specified communication protocol. The IEEE board includes a standard connector for interfacing with the IEEE instruments through a standard cable. The basic bus structure as it interfaces with the instruments is shown in Fig. 25. The diagram shows a typical computer-controlled measurement system in which the various instruments are connected by the IEEE-488 bus. The diagram clearly shows that all the instruments are connected in parallel to the 16 different bus lines. The various instruments can perform one or more of the following functions: (a)Talker, which can transfer data to other instruments by the data bus; (b) Listener, which can receive data from other instruments by the data bus; (c) Controller, which manages the operation of the bus system, primarily by sending addresses and commands over the data bus and sending control signals over the control bus. Only one Talker is allowed to put data on the data bus at a given time, but more than one Listener can receive data simultaneously. The Controller sends a Talk address out over the data bus while activating the appropriate control line. The instrument with that particular address is the only Talker that is activated, and all other Talkers are disabled. A similar procedure selects the one or more Listeners that can receive data from the active Talker.
2. VXIbus interface. The VXIbus interface is a modular instrument standard developed in 1987 to define a bus structure architecture that allows a wide range of instruments, interface cards, or computers from different manufacturers to coexist as modules in the same enclosure (cardcage). The VXIbus specification describes in detail the technical requirements of VXIbus-compatible components such as mainframes, backplanes, power supplies, and functional plug-in instrument and communication interface modules. The VXIbus standard is used in custom building powerful microcomputer-based DASs with distributed intelligence and extremely high data-transfer rates. The VXIbus instrument standard is an extension to the VMEbus that is open to all manufacturers and is compatible with present industry standards. The VMEbus architecture was developed primarily with focus on computer systems and with limited instrumentation capabilities. A new open architecture instrumentation bus, based on VMEbus, the Eurostandard (printed circuit board standard IEC 297-3), and other instrumentation standards such as IEEE-488.2, was created and became known as the VXIbus. A typical VXIbus (abbreviation for VMEbus eXtension for Instrumentation) system consists of a single frame [48.3-cm (19-in.) rack] with up to 13 modules plugged into numbered slots. A common configuration places into slot 0 a system resource module such as the VXIbus-

mandated timing generation or communication port such as IEEE-488 or RS-232. The other positions are general-purpose slots for the user to mix and match. Figure 26 shows some of the possible system configurations and illustrates the flexibility that is afforded by the VXIbus standard. [For more details, see *The System Engineer's Handbook,* a guide to building VMEbus and VXIbus systems (Black, 1992).]

3. RS-232C interface. The RS-232 serial (asynchronous) communication standard was developed initially by the Electronic Industries Association (EIA) to standardize the interface between modems and data terminal equipment (e.g., computers and termi-

nals) connected to them. The latest version, RS-232C, was adopted in 1969 and has become the serial interface standard when one microprocessor system communicates with another microprocessor system over long distances or with peripheral devices such as printers or CRT terminals. Serial transmission requires only two wires to carry all the necessary data, address, and control information. The information is transmitted one bit at a time, making serial transmission slower than parallel transmission. The RS-232C standard is typically used for baud rates up to 20 kb/s using signal lines up to 15 m (50 ft). For higher transmission rates over longer distances, EIA has adopted other standards such as the RS-422, RS-423, and RS-485, listed in Table 4 along with their electrical characteristics. Almost all modern instrumentation manufacturers offer serial interface as an option for their products to communicate with computers and other devices. An interface can be purchased as a card (printed circuit board), commonly known as a serial port, with all the necessary hardware and software (serial interface protocol). It is usually inserted into an open slot in the instrument or in the computer. The connection among devices equipped with RS-232C ports is through standard 25-wire cable that connects directly into a 25-pin connector mounted on the card.

4. CAMAC interface. The CAMAC is a modular instrumentation and digital interface system developed to address instrument incompatibility that results from employing instrumentation from various manufacturers in a given measurement system both in the laboratory and in industrial fields. An initialism for Computer-Automated Measurement And Control, the CAMAC is an ANSI/IEEE standard (Standard 583-1982) that is concerned with mechanical, electrical, and signal interfaces. As shown in Fig. 27, measurement devices are in modular units and are housed in a standard card enclosure (cage or crate) providing a common dc power required by these devices to function. Data input and output from the modules are handled by a specified bus called a data highway (Dataway) at the rear of the cage. The system initially has a 1-μs Dataway cycle time and a high address capability. The Dataway is a parallel bus with 24 read lines and 24 write lines so that words of 24 bits or less can be handled in a single data transfer. Additional levels of compatibility are achieved through the use of standardized parallel and serial highways that have been developed for use with the basic CAMAC system. The serial highway can be used to interconnect up to 62

Table 4. Communication Electronic Industries Association standards comparison.

	Interface			
Mode of operation	RS-232C Single-ended	RS-422 Single-ended	RS-423A Differential	RS-485 Differential
Number of drivers and receivers allowed on-line	1 driver, 1 receiver	1 driver, 10 receivers	1 driver, 10 receivers	32 drivers, 32 receivers
Maximum cable length [m (ft)]	15 (50)	1200 (4000)	1200 (4000)	1200 (4000)
Maximum common-mode voltage	±25 V	±6 V −0.25 V	±6 V	±12 V −7 V
Driver output	±5 V min ±15 V max	±2 V min	±3.6 V min ±6.0 V max	±1.5 V min
Driver load	3 to 7 KΩ	100 Ω min	450 Ω min	60 Ω min
Driver slew rate	30 V/μs max	NA[a]	Externally controlled	NA[a]
Driver output short-circuit current limit	500 mA to V_{cc} or ground	150 mA to ground	150 mA to ground	150 mA to ground

crates, providing a widely distributed system, and the parallel highway can handle up to 7 crates. (See CAMAC Instrumentation and Interface Standards, IEEE 1982, or latest version for more details.)

3. MEASUREMENT INTERFACE

Every measurement application consists of a number of components that together form a system used to perform a measurement and processes the result. The application could be data storage, recording, display, controlling functions, or analysis. The components within the measurement system are most likely to be a mix of analog and digital devices. Such a mix in interdomain devices gives rise to two important factors that must be considered and well understood for the measurement system to perform its intended function in the most satisfactory manner. These factors are data conversion from analog to digital and vice versa and signal transmission within the system.

The coverage in this section of interdomain conversion and signal transmission is intended to be brief and to serve as an introduction of this subject to the reader. A complete and more comprehensive coverage is provided in ELECTRICAL INSTRUMENTATION.

3.1 Digital-to-Analog Converters

The digital-to-analog converter (DAC), also known as the D/A converter, is an electronic device that accepts digital information and transforms it into an analog voltage. The digital information is in the form of a binary number with some fixed number of digits. In the digital field, the binary number is called a binary word, and the digits are called bits. For example, the 8-bit word 10101011_2 would be a binary number having eight digits consisting of 0s and 1s.

The DAC converts the digital word into an analog voltage by scaling the analog output to be zero when all bits are 0 and some maximum value when all bits are 1, as illustrated by the simplified functional diagram of Fig. 28. This function can be mathematically represented by expressing the binary number as a fractional number according to the relationship

$$V_x \simeq V_r(a_1 2^{-1} + a_2 2^{-2} + \ldots + a_n 2^{-n}), \quad (14)$$

where V_x is the analog voltage output, V_r is some voltage reference in the DAC internal

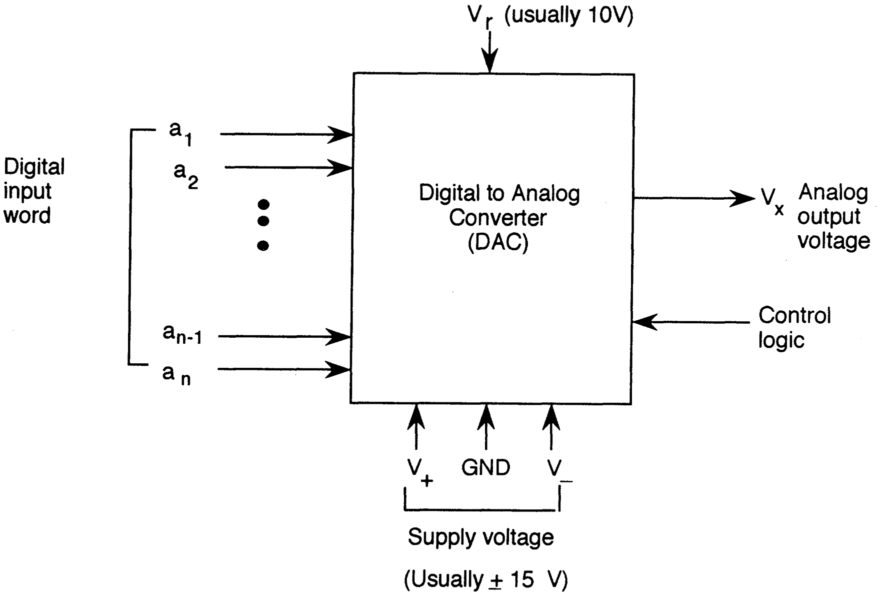

FIG. 28. Input/output diagram of an *n*-bit digital-to-analog converter.

circuit, and the coefficients $a_1,...,a_n$ represent the n-bit binary word. For a 10-bit DAC ($n=10$) with a 10-V reference, the output can have any of 1024 evenly spaced voltages, including 0 and 10.0 V, thus offering a resolution (1/1024) of slightly better than 0.1%.

DACs can be used in various applications other than for data conversion from digital to analog form. A DAC, for example, when driven by a binary counter, can produce a *staircase.* This staircase is useful in a variety of experiments. One form of DAC (based on a $R/2R$ resistor ladder network structure), when controlled with a BCD-coded input, can also be used as a digitally controlled voltage divider with high resolution. One such device is designed to provide an output between 0 and 1.999 times the input voltage, with a resolution of 0.001.

3.2 Analog-to-Digital Converters

The analog-to-digital converter (ADC), also known as the A/D converter, is an electronic circuit that accepts an analog voltage signal and transforms it into an encoded digital word, as illustrated by the simplified function diagram of Fig. 29. The relationship between the analog input voltage and the digital output sequence of the ADC is the same as that expressed by Eq. (14), where V_x is the analog input voltage, V_r is a reference voltage, and the coefficients $a_1,...,a_n$ represent the n-bit digital output (digital word). It is clear from Eq. (14) that the voltage, as expressed by the right-hand side, can change only by a finite step size given by

$$\Delta V = V_r 2^{-n}. \qquad (15)$$

The reference voltage V_r for the ADC also represents the full-scale value of the input voltage that can be applied to the converter. It is for that reason that Eq. (15) often appears in publications as

$$\Delta V = V_{\mathrm{fs}} 2^{-n}. \qquad (16)$$

The step size ΔV thus constitutes the smallest change in the analog input voltage that the ADC can resolve. Because of this resolution, the approximate equality in Eq. (14) is used rather than the equality sign. It is also clear that the resolution increases with an increase in the number of bits of the digital output. Historically, the first generation of ADCs was developed with 4-bit digital output. With the increased demand for higher performance, ADCs with 8, 10, 12, 14, and 16 bits offering superior resolution capabilities were developed.

The ADC sampling of the analog signal for conversion gives rise to two important considerations that could adversely affect its perfor-

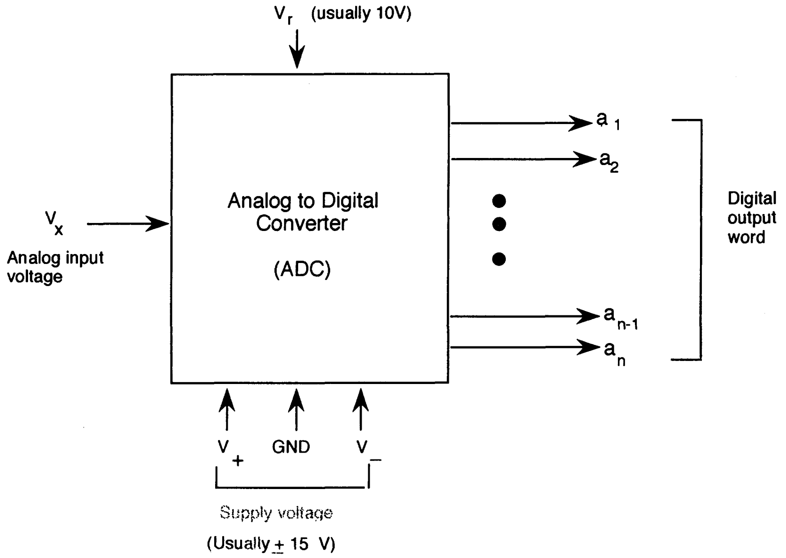

FIG. 29. Input/output diagram of an *n*-bit analog-to-digital converter.

mance if not properly addressed. The first is the sampling frequency, which must be at least twice the greatest frequency component of the signal to avoid the aliasing problem discussed in Sec. 1.2.3. Sampling the analog signal at a frequency less than that would lead to erroneous results when the sampled values are reconstructed. The second consideration concerns the finite time required for the ADC to complete its conversion. This time is known as aperture time, which is defined as the actual time the ADC requires to obtain an accurate reading of the analog signal. The aperture time must not be greater than the period of the greatest frequency component of the signal multiplied by the resolution. If the ADC is not fast enough to make a conversion within the aperture time for the given signal, then a circuit known as a sample-and-hold should be used. The sample-and-hold circuit, shown in its simplest form by Fig. 30, samples the signal by closing switch S1 long enough to charge capacitor C to the present signal value and hold that value for the time required by the ADC to make its conversion.

Many design methods exist for performing the ADC function. These methods vary in their techniques for realizing improvement in performance associated mainly with conversion speed and noise rejection. These designs resulted in the development of the following ADCs, which are listed for reference only because they are discussed in more details in ELECTRICAL INSTRUMENTATION:

1. successive approximation,
2. single-slope integrating,
3. dual-slope integrating,
4. servo,
5. ramp,

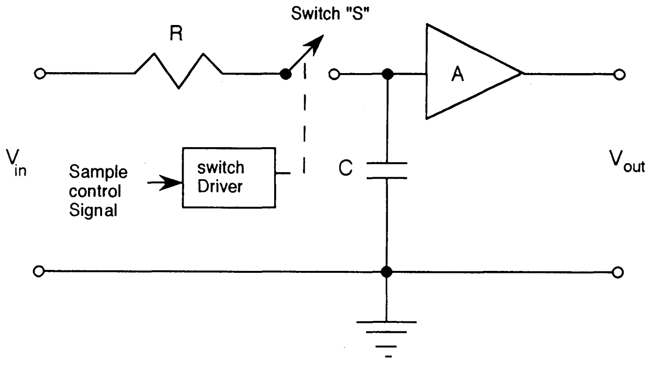

FIG. 30. Basic sample-and-hold circuit. The input is sampled periodically by closing switch S until capacitance C is charged to the new input value. The switch is then opened to hold the value to be delivered to the analog-to-digital converter through high-input-impedance amplifier A.

6. voltage-to-frequency,
7. parallel or flash,
8. cyclic, and
9. sigma-delta.

Until recently, the successive approximation and the dual-slope integrating-type ADCs have dominated because of their compromise in performance versus cost benefits. The dual-slope integrating-type ADC is not as fast as some of the others, but its inherent excellent noise immunity as well as its cost effectiveness due to design simplicity makes it ideal for many applications.

The most recent development in data-conversion technology is the sigma-delta ADC. It is considered state of the art and uses the latest development in digital technology to offer simplicity combined with powerful performance and resolution of up to 20 bits and high SNR.

3.3 Signal Transmission

Measurement starts with a transducer to quantify the physical measurement in terms of an electrical signal. Most transducers have analog outputs that need to be transmitted to other instrumentation for display, recording, analysis, or other purposes. It is crucial that the transmitting medium preserves signal integrity between the transmitting and the receiving instruments. Noise corruption from surrounding sources [e.g., electromagmetic interference (EMI)] and transmitting medium characteristics are two limitations that must be carefully considered.

The transmitting media can be classified in three categories: analog, digital, and optical. In industrial applications, the instruments within the same loop are separated by large distances, and the application environment is more noisy than the laboratory environment. Digital transmission methods [e.g., voltage-to-frequency (V/F), RS-232C, RS-422, RS-423, RS-425] offer a practical solution in industrial applications because of the inherent noise immunity and protection against signal degradation due to voltage drops along the transmitting media (wires). Analog transmission using a 4- to 20-mA current signal is also used for limited distances and when practical.

In laboratory applications, analog transmission of signals is the most practical and thus most commonly used method. Among the various signals used in analog data transmission (10–50 mA, 0–20 mA, 4–20 mA, 0–5 V, 0–10 V), the 4- to 20-mA current has been widely accepted as the industry standard signal because of the advantages that it has to offer. The 4- to 20-mA current is usually scaled to represent the signal range where the 4-mA current corresponds to the lowest range value, and the 20-mA current corresponds to the maximum range value. The 4-mA current, compared with the 0-mA current, value is recognized as the "live zero" because of the distinction it provides between loss of signal (electrical zero) due to physical interruption in the transmission medium and signal zero (representing the minimum range value). In addition to this advantage, current signals in general are less susceptible to noise pickup than voltage signals are, and degradation in signal due to voltage drops does not apply. The transmitting medium is typically a twisted pair of wires to reduce noise corruption further. Figure 31 illustrates a typical transmission configuration known as two-wire transmission. In this configuration, the 4- to 20-mA current is transmitted around a loop, allowing

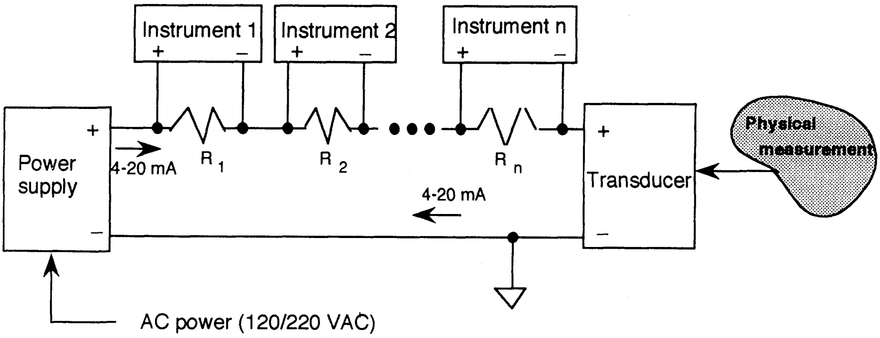

FIG. 31. Two-wire signal transmission configuration.

several instruments to share the same signal simultaneously. The signal is introduced to each instrument through an individual resistance R. The total number of instruments that can share the signal within the loop is limited by the sum of resistances around the loop. The maximum value of the total resistance in ohms is calculated by

$$R(\max)=R_1+R_2+\ldots+R_n$$
$$=(V_{\text{supply}}-12\text{ V})/(20\text{ mA}). \quad (17)$$

The transducer in the two-wire configuration is self-powered since its connection with the power supply serves to provide the dc power to and carry the signal from the transducer at the same time.

4. CONCLUSION

As was stated in the Introduction, this article is intended to acquaint readers within the scientific community with the kind of instruments and related technologies that are available to carry out scientific endeavors. In view of the rapidly changing technologies associated with the instrumentation industry, it is difficult to predict what will happen over the next few years. However, in observing the trend in the research and development in the electronics industry including the digital field and the their explosive markets, we can see that the basic ideas and theories will probably remain the same while details on device or instrument implementation will change. For example, in the area of instrument interface, our discussion of the VXIbus noted that the idea was not totally new, but it was an improvement over the VMEbus developed earlier. Another example is the future development in laboratory automation. PCs (such as the i386- and i486-based IBM-compatible PCs and the recently announced Pentium and the Macintosh) have invaded the workplace. Future development in this area is toward improving the processing power, networking [such as Ethernet and local area network (LAN)] capabilities, and data storage capacity. Workstations with 10^9 floating-point operations per second (Gflops) have evolved as a result of reduced instruction-set computer (RISC) processors.

GLOSSARY

ADC (Analog-to-Digital Converter): A device that changes analog voltage or current signal into a digitized number that can be digitally displayed or further analyzed by digital instruments.

Algorithm: A step-by-step procedure for solving a problem or performing a computation.

Analog device: A device that produces or processes analog signals.

Analog signal: A signal that varies continuously and can manage an infinity of values in any given range.

Aperture time: The time window, or time uncertainty, in making a measurement. For an analog-to-digital converter, it is the conversion time; for a sample-and-hold circuit, it is the signal averaging time during the sample-to-hold transition.

BCD (Binary Coded Decimal): A binary code used to represent decimal numbers in which each digit from 0 to 9 is represented by four bits weighted 8-4-2-1. Only 10 of the 16 possible states that are represented by the four bits are used.

Binary: A number representation system with a radix of 2.

Binary digit: In binary notation, either of the digits 0 or 1.

Bit: An abbreviation of "binary digit."

Bus: A group of wires used as a common path connecting various components within a microprocessor system (or computer) for transferring data by using control signals–for example, for interfacing the central processing unit of a digital computer to memory and inputs/outputs.

Byte: A group of adjacent binary digits operated on by the computer as a unit. The most common byte size is eight binary digits.

CRT (Cathode-Ray Tube): An electronic vacuum tube with a screen for graphical or alphanumeric visual display of information. Display is produced by means of proportionally deflected electron beams.

DAC (Digital-to-Analog Converter): A device that converts a digital signal, often from a computer, into a proportional analog signal (voltage or current).

Data Conversion: The process of changing the form of data representation. For example, converting analog signal to digital form and vice versa.

dB (Decibel): A logarithmic unit that expresses the magnitude of change in the level of a signal. The gain or attenuation of a device is commonly expressed in decibels defined in terms of output/input ratio as voltage (V): $dB_V = 20 \log V_{out}/V_{in}$; current ($I$): $dB_I = 20 \log I_{out}/I_{in}$; power ($P$): $dB_P = 10 \log P_{out}/P_{in}$. The decibel scale has the advantage of using small numbers to represent large ratios. Consecutive stages of amplification or attenuation lead to a sum (rather than a product) of individual gains.

dBm: A logarithmic measure in decibels of absolute signal level above or below some reference. For power measurement, m signifies a reference power of 1 mW. For example, 20 dBm is 100 mW. For other measurements (e.g., volts), the reference could be 1 V (dBV) or 1 mV (dBmV).

Digital Device: A device that produces or processes digital signals.

Digital Signal: A signal that varies in discrete steps and can manage only a finite number of different values in any given range.

EPROM (Erasable Programmable Read-Only Memory): A solid-state memory device that can be erased with ultraviolet light and reprogrammed by using equipment specialized for this purpose.

GPIB (General-Purpose Interface Bus): The IEEE-488 bus (HP-IB) designed by Hewlett-Packard in 1965 and adopted by the Institute of Electrical and Electronic Engineers in 1974.

LCD: Liquid crystal display.

LED: Light-emitting diode.

LSB (Least-Significant Bit): The rightmost binary digit in a digital word.

MSB (Most-Significant Bit): The leftmost binary digit in a digital word.

Peripherals: Auxiliary equipment that can be attached to and controlled by a central processing unit or a computer (e.g., CRTs, printers, magnetic tape transports).

Port: An electronic device that allows a computer to communicate with other external devices having communication capabilities.

Protocol: A formalized set of conventions including wiring arrangements necessary to establish and maintain communication between two devices.

RAM (Random Access Memory): This term, through common usage, refers to high-speed, volatile, solid-state (semiconductor) memory used to store and recall information. This type of memory can be read from or written to.

Refresh: Update information on the cathode-ray tube to maintain data on the screen.

Resolution: The magnitude of step changes distinguished by an instrument or device as the measured signal is continuously varied over the instrument range.

ROM (Read-Only Memory): A memory used for permanently stored computer programs and data.

Sampling Rate: The number of analog-to-digital conversions per second that are actually performed.

Sampling Theorem: A theorem by Nyquist that states that if a continuous bandwidth-limited signal contains no frequency components higher than clock frequency (f_c), then the original can be recovered without distortion if it is sampled at a rate of at least $2f_c$ samples per second.

Serial Communication: A form of communication that allows only one bit at a time to be sent or received between two communicating devices.

Serial Port: An electronic device that sends and receives data one bit at a time (also known as asynchronous communication port).

Spectrum: The spectrum of an analog signal is the amplitude versus frequency for all components within the signal.

Transducer: A primary device that converts physical measurements into low-level electrical signals.

Transmitter: A primary device that translates physical measurements into electrical signals, usually 4 to 20 mA.

Transmitter (Two-Wire): A device that is used to transmit data by a two-wire current loop. The loop usually has an external direct current power supply, and the transmitter acts as a variable resistor with respect to its input signal.

Volatility: An inability of memory to retain stored data during and after a power failure. An example of volatile memory is random access memory.

INTRODUCTION

Photochemistry transforms matter with energy in the form of light; laser photochemistry transforms matter with light from lasers. While most chemistry emphasizes the production of bulk materials, much photochemistry aims at the production of specialty materials, the manufacture of structures, or the processing of materials to obtain, transfer, or store information. Laser photochemistry retains these further emphases.

Manmade photons are expensive chemical reagents; economics restricts photochemistry to high-value–added processes, or to where only a few photons selectively initiate a process. Photons are very effective at causing chemical changes, but current photon sources are inefficient. While a mole of visible photons contains energy valued at only a cent at today's electric rates, inefficiencies of conventional light sources can quickly push the cost of photons to over a dollar per mole. These economics generally make photochemistry unattractive for the production of bulk chemicals. Photochemistry is more useful for high-value products such as drugs (currently vitamin D is produced photochemically), insecticides, perfumes, and polymer resins. Established photochemical technologies are found in photography, coating (especially of thermoplastics, such as used in magnetic recording or adhesive tapes), photocuring of optical and dental cements, drug phototherapy, uv disinfection, sterilization, and surface cleaning, printing, lithography, and photoresist masking in semiconductor and printed-circuit manufacturing.

The capital costs associated with most laser sources—particularly those operating in the photochemical uv—can bring the cost of photons up to $1000 per mole. Production of exceptionally valuable materials, such as isotopes or isotopically labeled molecules, can

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

benefit from laser photochemistry. More commonly, laser photochemical processes transfer or store information within materials. Lasers find applications in photographic rendering of computer-drawn images, laser marking, and photoresist masking. In stereolithography, laser photochemistry is used to realize complex three-dimensional plastic prototypes or mold models directly from computer-aided designs. The latter complements automated machining: solid material adds to an object held on a mandrel wherever a laser beam initiates curing of a polymer resin.

Lasers have found extensive application in the investigation of chemical processes themselves, where they have given us invaluable information about the details of chemical reactions. Photoinitiation is much more selective than thermal initiation of reactions and provides greater control in the investigation of chemical kinetics (now often called "chemical dynamics" to emphasize the higher precision afforded to prepare and investigate reactions of single quantum states). Lasers have moved into nearly every chemical kineticist's laboratory—if not to initiate reactions, then to analyze products. A whole field of "half reactions" has developed, in which a reaction intermediate, normally prepared by a precursor reaction or collision process, is instead prepared directly by a photoprocess. This allows the experimenter to prepare an intermediate of known chemical conformation, having a given energy, at a specified time.

The availability of short-duration (picosecond and femtosecond) pulses has shortened the time scale directly accessible for kinetic experiments in the time domain (Mukamel, 1990; Khundkar and Zewail, 1990). For example, nearly a dozen transient molecular states and conformers (different, relatively stable arrangements of atoms) have been identified by pump-probe laser experiments subsequent to the absorption of light by rhodopsin, the optical pigment in the retina (Birge, 1990).

Fundamental reaction dynamics also can be investigated in the frequency domain. For example, photoemissions from the dissociating states of the molecules methyl iodide and ozone have been observed. The structure of each intermediate, changing as it dissociates, is impressed upon the spectra as a series of resonances, while the dynamics and time scales of the reaction appear in the pattern of intensities and spectral widths of these features (Imre *et al.*, 1984). A laser provides a high flux of photons of a single frequency, making such investigation of weak emissions possible.

Information from the analysis of materials is becoming more in demand, and laser techniques have become more popular there. Laser spectroscopy is useful, but often lasers are used to prepare the sample by a mixture of physical and photochemical effects. Solid material may be introduced into the gas phase by laser ablation, for example. Photoionization of a sample may prepare ions for identification by mass spectrometry, or photodissociation may prepare atoms for atomic spectroscopy.

In much of photochemistry brought about by lasers, the fundamental uniqueness of laser radiation has not yet been used; lasers often represent specialized "light bulbs" that, in principle, could be replaced by thermal light sources. As such, much of this laser photochemistry is not qualitatively different from photochemistry conducted with weaker light sources, the subject of the article on PHOTOCHEMISTRY. The present article concentrates on the unique properties of laser radiation and focuses on the qualitative differences in the photophysics, energy partitioning, and chemistry that can appear when laser radiation is used.

1. PHOTOPHYSICS

1.1 Laser Light

The radiation field within a laser must stimulate emission in competition with spontaneous emission. This establishes a characteristic brightness of laser radiation.

Spontaneous emission can be viewed as emission stimulated by the random, zero-point fluctuations of the radiation field. The spectral density of these spontaneous fluctuations approximates that of the density of states per wavelength interval, $4\lambda^{-4}$. In terms of photon flux, or brightness, this is

$$\frac{d(\text{photons})}{dA\, d\Omega\, d\lambda\, dt} = \frac{c}{3\pi\lambda^4}, \tag{1}$$

or, in terms of flux power density M, solid angle Ω, and wavelength spread $\Delta\lambda$ of a laser beam,

$$M/\Omega\Delta\lambda = hc^2/3\pi\lambda^4. \qquad (2)$$

Laser light differs from light from lower-brightness, thermal sources in one or more of these quantities:

- high power flux density,
- low angular spread,
- narrow frequency distribution.

These give laser light several advantages for photochemistry.

1.2 Interaction with Matter

1.2.1 Linear Absorption. Until intense laser sources of radiation became available, the fundamental photochemical reaction step, absorption, depended linearly upon intensity. At low power density, light interacts with matter by the absorption of one quantum of radiation at a time.

Even without entailing direct multiphoton processes, lasers may still significantly enhance rates of photoabsorption. At low light levels, using thermal light sources, the absorption of light is usually the rate-limiting step in a sequence of steps that compose the mechanism of a photochemical process. At high light levels, resonant absorption may become the fastest step in a photochemical mechanism.

While the line shapes of individual transitions and the spectral distribution of transition bands depend upon numerous details of the molecule and its interaction with the radiation field, the overall line strengths, or band intensities, can be related to simple perturbation expressions. The absorption cross section σ for transition to the final state $|f\rangle$, when integrated over frequency ν, is given theoretically by the leading, first-order perturbation of the initial state $|i\rangle$ in the electric dipole approximation,

$$\int \sigma_{fi}(\nu)d\nu = 4\pi^2\alpha\bar{\nu}\left|\left\langle f\middle|\sum_e \mathbf{r}_e\cdot\mathbf{n}\middle|i\right\rangle\right|^2. \qquad (3)$$

The sum is taken over all charges e at distances $\mathbf{r}_e$; α is the fine-structure constant, and $\mathbf{n}$ is a unit polarization vector. The bar over the frequency indicates averaging.

Each electron contributes to the total integrated absorption cross section, averaged over orientations and summed over possible final states, one "electron oscillator," $\pi r_0 c \approx 0.03$ cm^2 s^{-1}; r_0 is the classical electron radius. Individual electronic absorption bands typically contain the transition strength corresponding to 0.01–0.5 of an electron oscillator, while weaker vibrational transitions contain perhaps 10^{-6}–10^{-4} of an electron oscillator in each band.

1.2.2 Multiphoton Absorption. At the high power densities achievable with lasers (easily 10^{18} W/m^2 in focused pulses), light interacts with matter through the additional mechanism of direct multiphoton absorption.

The second-order perturbation correction gives the two-photon contribution to the absorption. An absorption cross section $\sigma^{(2)}N_1$ for a photon of frequency ν_2 is induced by an off-resonance monochromatic field of frequency ν_1 and photon flux N_1. When integrated over the frequency of the second photon, the second-order cross section can be related to the dipole matrix elements:

$$\int \sigma_{fi}^{(2)}(\nu_1,\nu_2)N_1(\nu_1)d\nu_2 = \frac{4\pi^2\alpha^2}{\nu_1\bar{\nu}_2}\left|\sum_m \frac{\nu_{fm}\nu_{mi}\langle r_{fm}\rangle\langle r_{mi}\rangle}{\nu_{mi}-\nu_1}\right|^2, \qquad (4)$$

where

$$\langle r_{fm}\rangle = \left\langle f\middle|\sum_e \mathbf{r}_e\cdot\mathbf{n}_2\middle|m\right\rangle,$$
$$\langle r_{mi}\rangle = \left\langle m\middle|\sum_e \mathbf{r}_e\cdot\mathbf{n}_1\middle|i\right\rangle, \qquad (5)$$

and the sum is taken over intermediate states $|m\rangle$ having frequencies ν_{mi} and ν_{fm} for transitions to the initial and final states. The energy for the overall transition comes from two photons; hence the two-photon resonance condition $\nu_{fi} = \nu_1 + \nu_2$. A special case often occurs when only one radiation frequency is used: then $\nu_1 = \nu_2$ and two-photon resonance is achieved when the energy of the transition corresponds to twice the frequency of the radiation field.

This integrated induced cross section is roughly of the order $\alpha(\pi c r_0)^2 N_1/(\bar{\nu}_1\nu_2)$. Making the two-photon absorption comparable to the one-photon absorption requires off-resonance fields on the order of

$$N_1 \approx \nu_1\nu_2/\alpha\pi c r_0 \qquad (6)$$

or about 10^{21} photons s^{-1} cm^{-2} (10^{17} W m^{-2} s^{-1} for typical green light).

Expressions for higher-order, multiphoton cross sections are readily derived. Typical dipole-allowed molecular multiphoton absorption cross sections have been found on the orders of 10^{-58} m^4 s for two photons and 10^{-94} m^6 s^2 for three photons.

1.2.3 Level Shifts. High radiation powers can cause atomic and molecular resonant frequencies to vary, responding to the ac Stark effect (Carmichael and Walls, 1976; Li *et al.*, 1985).

In atoms and diatomic molecules, effects of high power can be rather striking, even at small laser powers. In sparse spectra, associated with atoms and small molecules, each individual resonance has a relatively large oscillator strength. Even moderate fields, tuned near resonance, interact strongly with an atom, which undergoes rapid excitation to, and stimulated emission from, excited states at a characteristic, power-dependent rate, the Rabi frequency. The fluorescence from such an interacting system has a characteristic "head and shoulders" appearance, best understood as radiation at the fundamental frequency undergoing amplitude modulation at the Rabi frequency (Mallow, 1969). Such a spectrum may be "smeared" to higher or lower wavelength by an ac Stark effect (Li *et al.*, 1985).

Large molecules, in contrast to small molecules, spread the oscillator strength of an electronic or vibrational transition over a large number of molecular "rovibronic" states. Especially when a number of initial states are populated at finite temperatures, transitions are heterogeneously broadened. Each individual state-to-state transition may have only a small fraction of the original oscillator strength; at any given frequency, many resonances with widely varying transition strengths are likely to overlap. Thus, power broadening and ac Stark shifts require much higher powers (and are less observable) in the multiphoton photochemistry of large polyatomic molecules. However, power-driven state "pulling," field-induced state mixing, and spontaneous and stimulated Raman effects often explain the excitation to higher states that would otherwise appear to be inaccessible.

1.2.4 Hole Burning. At high power densities, a general excitation of rotational and vibrational levels accompanies excitation and deexcitation of states by the radiation field. Absorbing states that interact resonantly with radiation become depleted as molecules enter and remain in "dark" states having weaker interactions with the radiation field. These optical-pumping effects can make resonance features in an absorption spectrum disappear at high power levels (Rothberg *et al.*, 1981).

Radiation at a particular frequency generally moves population out of states that interact strongly with that radiation. This depletion may appear as a "hole" in the absorption spectrum. "Hole burning" is the basis for Doppler-free Lamb-dip spectroscopy. Atoms or molecules having little or no velocity component along the axis of two counterpropagating beams are temporarily depleted from the population distribution of velocities. At exactly the frequency center of an absorption line, the absorption cross section acquires a power-dependent decrease or "dip." This technique is commonly used for laser frequency stabilization, such as the iodine-locked He-Ne laser. Recently, interest has shifted to permanent hole burning as a method of information storage in materials.

2. MULTIPHOTON PROCESSES

The most striking examples of new photophysics and photochemistry that occur when lasers are used in place of conventional light sources involve multiphoton absorption.

2.1 Electronic Multiphoton Absorption

Electronic multiphoton absorption, excitation to electronic states energetically inaccessable by one-photon absorption, was one of the first effects explored with lasers. Two-photon absorption was first reported for inorganic crystals containing europium ions (Kaiser and Garrett, 1961). Blue and ultraviolet fluorescence appeared in the interaction of red, ruby-laser light with organic compounds (Peticolas *et al.*, 1963; Peticolas and Reickhoff, 1963; Singh and Stoicheff, 1963; Weisz *et al.*, 1964). Others observed two-photon absorption directly (Hopfield *et al.*, 1963; Staginnus *et al.*, 1968).

2.1.1 Multiphoton Selection Rules. Using the symmetry of the absorbing molecule, and the electronic-state symmetry assignments, McClain (1974) derived explicit selection rules for two-photon electric-dipole interactions. Most notable in two-photon excitations, even-parity transitions appear for centrosymmetric molecules, normally forbidden in single-photon electric-dipole transitions. Light polarization characteristics may also affect absorption, even for collections of randomly oriented molecules, especially those possessing high molecular symmetry.

2.1.2 Multiphoton Ionization (MPI). One striking multiphoton effect, runaway electrical breakdown of air, often occurs at the focus of high-power, pulsed laser light. Initiated by direct multiphoton absorption, the resulting molecular excited states undergo additional single-photon absorption directly into the ionization continuum. In collisions with molecular and ionic excited states, slow electrons efficiently extract energy: slow electrons "superelastically" scatter to become fast electrons; cross sections for this process diverge for low electron-impact velocities. Thus initiated, high-pressure ionization rapidly transforms the initially transparent gas into an optically thick plasma, in which most of the absorbing power is derived from electronic transitions originating on excited states of molecules and ions, and terminating on states consisting of additional free electrons and ions. Taken to its ultimate, a totally ionized plasma produced by laser radiation is now the object of laser fusion research.

Some researchers began to use ionization as a tool to investigate weak multiphoton absorption. Two groups almost simultaneously, Johnson *et al.* (1975) and Petty *et al.* (1975), devised a simple technique. A tunable laser was focused into a proportional-counter cell containing an inert gas and a trace amount of the molecule being studied (Fig. 1). For two-photon spectroscopy, when the energy of two photons was resonant with an allowed, two-photon transition, the energy of a third photon would be sufficient to ionize the resulting excited molecules, as represented in Fig. 2(a). Since ionization usually has a relatively unstructured absorption spectrum, and the power levels employed to produce two-photon absorption saturate the one-photon ionization step, the overall rate of ionization depends predominantly upon the rate of the initial two-photon step. Monitoring the amount of ionization produced in the proportional-counter cell as a function of wavelength generates a "two-photon" ionization spectrum. One of the first molecules investigated this

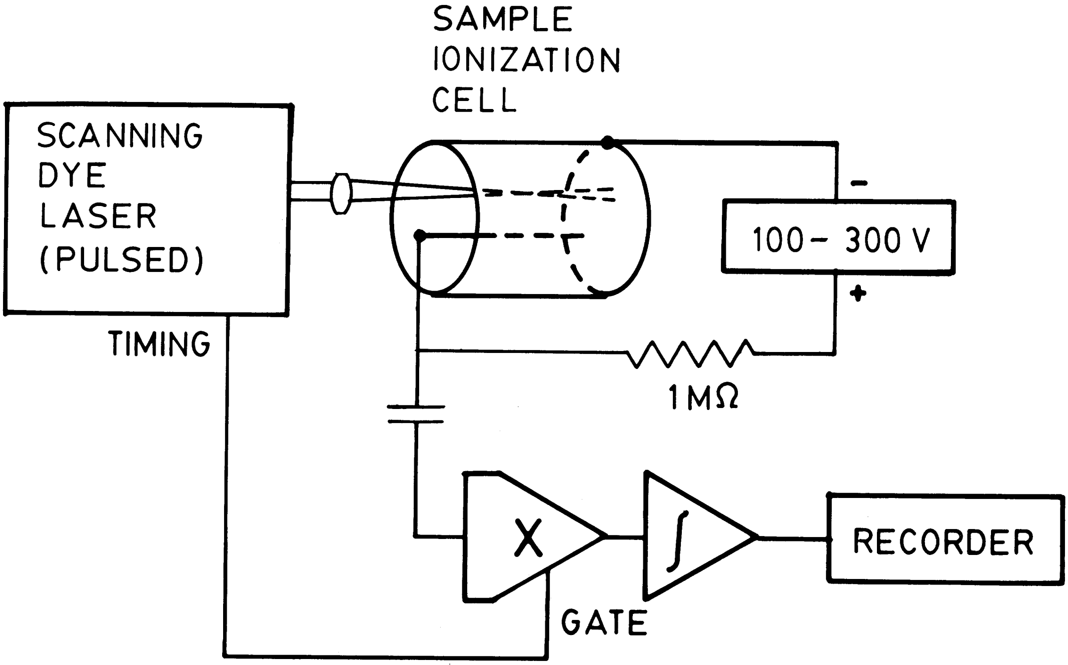

FIG. 1. Multiphoton ionization apparatus (schematic).

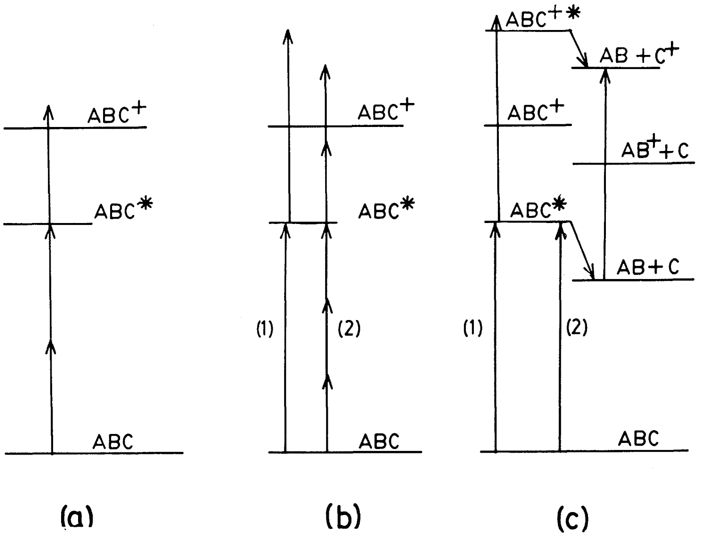

FIG. 2. Multiphoton ionization processes. (a) 2+1 multiphoton ionization occuring by two-photon absorption to a molecular excited state and subsequent one-photon ionization. (b) 1+1 and 3+2 multiphoton ionization processes. (c) Multiphoton ionization either (1) preceding dissociation of the ion, or (2) subsequent to dissociation of the neutral.

way was nitric oxide, NO; one of the first polyatomic molecules investigated was benzene, C_6H_6 (Johnson, 1975, 1976). Molecular states near the ionization limit (principally molecular Rydberg states) appear, states that are usually invisible because of the selection rules of one-photon spectroscopy.

In addition to this simple "2+1" process (two-photon absorption followed by one-photon ionization), numerous other *n*-photon combinations leading to absorption and ionization could, and did, occur, as exemplified in Fig. 2(b). Any of these processes are subsumed under the name "multiphoton ionization." Processes that depended upon resonant one-, two-, or many-photon intermediate processes were generally indicated by the additional term "resonant" or "selective."

2.1.3 Multiphoton Dissociation (MPD). With the recognition that intense visible or UV radiation rapidly excites molecules to high electronic states, culminating in ionization, a seductive argument can be made that saturated electronic absorption at high power densities would completely dominate "slower" processes involving nuclear displacements, such as molecular rearrangement and dissociation. Until the early 1980s, multiphoton dissociation was generally thought to compete ineffectively with multiphoton ionization; molecular fragmentation was thought to occur only after ionization of the parent molecule.

Studies of ions produced by multiphoton ionization of organic molecules suggested that rearrangement and dissociation could occur in the neutral molecule, before ionization, but poor understanding of the absorption spectra of the intermediate, neutral fragments did not allow definitive proof. Clear evidence that dissociation may precede one or more slow steps of absorption, and that it certainly precedes ionization, came from organometallic photochemistry. Multiphoton ionization of transition-metal compounds occurs by multiple molecular absorption events and rapid dissociation of the neutral molecule, followed by multiphoton ionization of naked, neutral transition-metal atoms (Gerrity *et al.*, 1980; Engelking, 1980; Leutwyler *et al.*, 1980).

In such cases, the MPI spectrum of a molecule actually expresses the atomic MPI spectrum of one or more of the molecule's constituent atoms, which have been ejected from the molecule by MPD. Subsequent work has shown the prevalence of MPD in the photochemistry of polyatomic organic molecules, such as benzene, where laser-induced fluorescence and resonance Raman spectroscopy show the presence of C_2, CH, and carbon atoms at high power levels.

Now we understand that the situation in a photochemical mechanism involving laser radiation is complicated by numerous competing pathways, and that photophysical and chemical steps can be intertwined, as represented in Fig. 2(c). In retrospect, the reason for this is clear: the electric fields within a molecule exceed those imposed by radiation, and any time an electron is displaced from the bonding regions between nuclei for any reason, nuclei are exposed to strong Coulomb repulsion. Two reviews in the same journal published within months of each other (Bernstein, 1982; Gedanken *et al.*, 1982) show the rapidity of this change of perspective.

2.2 Vibrational Multiphoton Absorption

2.2.1 Vibrational-State Ladders. Molecules couple to infrared (IR) radiation principally through the overall vibrational motion of molecular charge. Typically involving only a fraction of an electronic charge moving through only a fraction of a picometer, the resulting strength of a vibrational transition is commonly 10^{-4} of an electronic transition.

Low-energy vibrations of molecules usually take place in nearly harmonic potentials, containing "ladders" of nearly equally spaced vibrational energy levels. An IR laser frequency can almost coincide with a sequence of vibrational transitions corresponding to the intervals between levels of a particular normal mode, as shown in Fig. 3. At high laser powers, these nearly resonant intermediate states enhance multiphoton processes. Since vibrational spacing generally decreases with increasing mode energy, laser radiation that is resonant with molecular transitions at the bottom of a vibrational ladder becomes less resonant and couples less effectively with molecules already excited to higher energies, as shown in Fig. 3.

2.2.2 Isolated Molecules. The effectiveness of multiple resonances in assisting IR multiphoton transitions in isolated molecules depends to a large degree upon molecular size. For small molecules, such as diatomic molecules, with only one vibrational mode, anharmonicity quickly moves subsequent absorptions out of resonance. Except at extreme power densities, IR excitation of small molecules saturates lower transitions, but cannot give access to higher levels unless measures are taken to account for anharmonicity. In medium-sized molecules, it is easy to excite molecules rapidly to high vibrational levels, but difficult to drive the molecules to dissociation or rearrangement. In a process akin to hole burning, the energy ensemble of vibrating molecules acquires a bimodal, non-Boltzmann distribution: some low-energy molecules occupy vibrational and rotational states not effectively coupled to the radiation, while a high-energy group of molecules in a broader distribution of states interacts with the field. Bimodal population distributions are most often produced when molecular modes of vibration that occur at isolated frequencies are excited by IR laser radiation.

Large molecules, having a great number of vibrational modes, present many nearly coincident vibrations and overtones, even at moderate levels of excitation. Mixing of the numerous states reduces the interaction of any one state with the radiation field, giving rise to a dense cluster of states around each resonance. This is especially true at high energies. States that fill the gaps in a vibrational-state ladder in large molecules compensate for the anharmonicity that interrupts resonant multiphoton excitation to higher levels in small

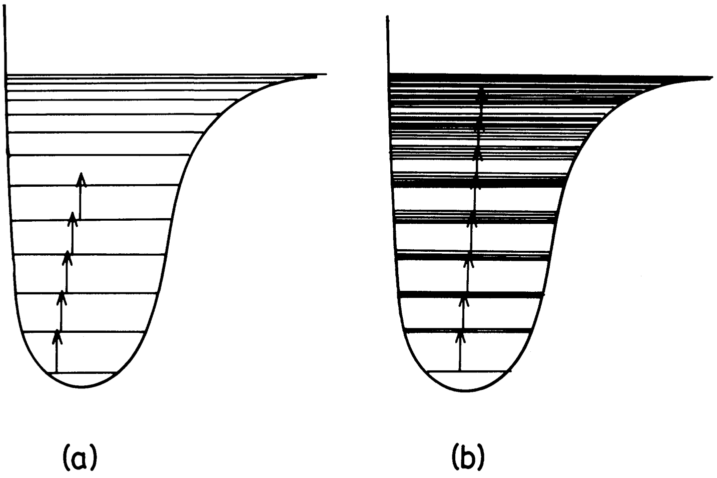

FIG. 3. IR multiphoton events with single-frequency radiation. (a) Resonant excitation drives small molecules up a ladder of nearly evenly spaced energy levels until anharmonicity moves states from further resonance. (b) Large molecules have high densities of states, providing near resonances all the way to dissociation.

molecules. With the increasing likelihood that each transition will be assisted by a resonance, excitation to dissociation becomes easier yet. Furthermore, with the dilution of resonances and the complication of the absorption spectrum, it is less likely that a narrow internal energy distribution will result, and the distribution of excitation in energy levels becomes more statistical, resembling a thermal Boltzmann distribution.

Vibrational transitions are weaker and more numerous than electronic transitions, making sequential resonant, or nearly resonant, transitions more important in the infrared and direct nonresonant multiphoton excitation less important in the infrared. Typically, one expects to need 10^{14} W m^{-2} or more to dissociate a diatomic molecule by near-resonant multiple transitions, and 10^{8}–10^{12} W m^{-2} for dissociation of a large molecule.

2.2.3 Effects of Collisions. If molecules are allowed to collide, the rates for IR ladder climbing increase. Colliding pairs of vibrationally excited molecules, which are no longer resonant with the radiation field, may "pool" energy into higher vibrational levels of one collision partner, leaving the other collision partner in lower vibrational levels. This brings the second molecule again in resonance with the exciting IR.

Collisional redistribution of vibrational energy is a statistical process: one expects to obtain a Boltzmann energy distribution. The persistence of a fraction of molecules in states that have transitions resonant with the radiation allows efficient heating. Power levels of 10^{4}–10^{7} W m^{-2} may lead to dissociation, rearrangement, or other thermally initiated chemistry.

IR heating of gases has proven to be effective in thermally initiating reactions for kinetic studies. This may be done either by directly coupling IR to the reactive molecules, or by indirectly heating the reactive molecules seeded in a bath of strongly absorbing molecules (Golden *et al.*, 1981).

3. ENERGY PARTITIONING

Chemists have, since the 1930s, known that certain bonds between atoms gave rise to characteristic frequencies in the IR, corresponding to bond stretches and bends. Thermal sources of radiation proved ineffective in breaking specific bonds, since energy could not be supplied fast enough to stretch a bond to breaking, in competition with intramolecular and intermolecular energy relaxation.

In recent years, the topic of mode-specific photochemistry has revived in the context of a better understanding of the energy redistribution that may occur inside molecules.

3.1 Randomization of Energy in Molecules

Energy flow in molecules falls between two extremes. In the "small-molecule" limit, radiation excites isolated states; the interaction with the radiation field is more important than the interaction between internal molecular states. In the "large-molecule" limit, radiation excites a dense band of internal states strongly mixed with the absorbing state; the interaction between numerous molecular states exceeds that with the radiation field. The difference is quite striking: small-molecule states typically fluoresce; large-molecule states typically retain the energy within the molecule.

The coupling between states within molecules is mediated by numerous mechanisms: vibrational mixing, Coriolis interactions, velocity and acceleration coupling of electronic and vibrational motion, and spin-orbit coupling.

The density of internal states is as important as the strength of interaction between them in determining the large-molecule limit. A single radiating molecular state interacting strongly with just a few molecular states produces simply a few, widely separated states. The large-molecule limit must be defined a bit more carefully by the two conditions

$$\Gamma \ll \gamma \tag{7}$$

and

$$\Delta E \ll \Gamma, \tag{8}$$

where Γ is the natural width of the radiative state, γ is the average strength of the interaction of the radiative state with other perturbing molecular states, and ΔE is the average spacing between perturbing states (the reciprocal of the density of states). The effect of various combinations of these parameters is outlined in Fig. 4.

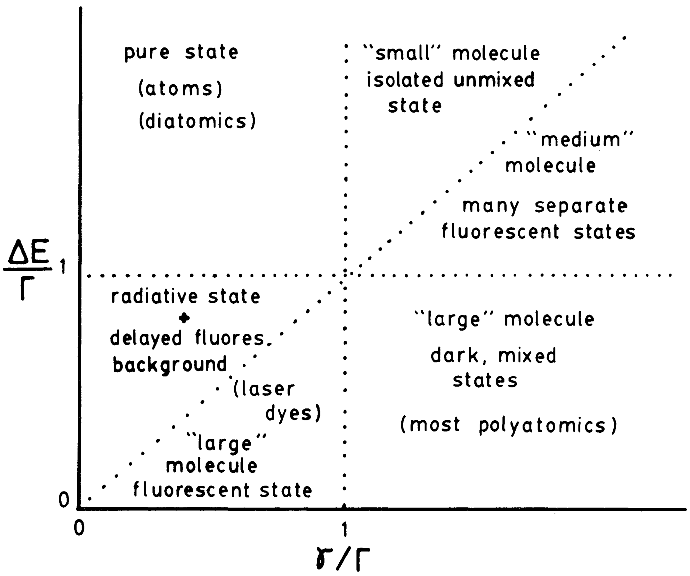

FIG. 4. Regimes of "large" and "small" molecule behavior. Here γ is the strength with which a radiative state interacts with other molecular nonradiative states; Γ is the strength of the radiative interaction; ΔE is the average spacing between mixing states.

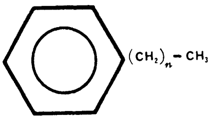
Under the large-molecule conditions, where both relationships hold, the high density of perturbing states provides the molecule with its own thermodynamic bath. If a single radiative state couples with a large number of nonradiative bath states, the mixture of perturbed states will rapidly dephase into a mixture of incoherently radiating states, each with a small fraction of the original transition strength. It appears that the energy absorbed by the initial state has dissipated into the bath states.

The phenomenon of a high density of internal molecular vibrations acting as an intramolecular thermodynamic bath has been carefully investigated in the case of alkyl benzenes in which the length *n* of the "floppy" carbon chain attached to the rigid benzene ring is systematically increased:



$(CH_2)_n-CH_3$

The electronic transition occurs primarily on the benzene ring, but couples with the molecular vibrations. As might be expected, the fluorescence quantum yields and the radiative lifetimes of molecules decrease as the chain length, and hence the density of vibrational states, increases (Smalley, 1982).

This ability of large molecules to transfer energy between electronic, vibrational, and spin-rotational manifolds of states has a profound effect upon the chemistry of molecules. In laser photochemistry, the rate at which this happens often competes with the rate at which subsequent photons are absorbed. In effect, the rate of intersystem crossing, internal conversion, and vibrational mixing defines the rate by which energy deposited in a given state, or mode, naturally "randomizes" within molecules, and it is against this rate that photoexcitation must compete.

In the condensed phase, vibrational relaxation typically occurs on the order of tens of femtoseconds to hundreds of picoseconds, as shown in laser pump-probe experiments (Elsaesser and Kaiser, 1991). One should be aware, however, that in simple liquids, such as liquid nitrogen or inert gases, vibrational relaxation times on the order of minutes have been found (Brueck and Osgood, 1976)!

3.2 Energy Localization

Recent work on molecules has shown the conditions for maintaining local concentrations of energy in spite of relatively high densities of vibrational states. In some molecules, at high levels of vibrational excitation the energy coupling between modes becomes weak. Under these conditions, it is possible to have vibrational energy localized primarily in one or more modes for many vibrational periods.

Examples of mode-specific chemistry include the work of Sinha *et al.* (1990) in which singly deuterated water was alternatively excited along the O—H bond or along the O—D bond. Upon reaction with hydrogen atoms,

$$H+HOD(4\nu_{OH})\rightarrow\begin{cases}OD+H_2, & (9)\\ OH+HD, & (10)\end{cases}$$

reaction (9) is enhanced, compared to (10), when the O—H bond is excited to the fourth overtone of the OH stretch. Bar *et al.* (1991) found that photodissociation of the same molecule at 193 nm depended upon the mode in which one quantum of vibration was placed. In this case, HOD excited to $\nu_3=1$ produced a different mix of photodissociation products from that normally produced by dissociation of HOD ground state, while there was no significant change in the product distribution when HOD was excited in the vibrational mode $\nu_1=1$.

Not all molecules are suitable for mode-specific photochemistry, as pointed out theoretically in the work of Kellman *et al.* (1991) on the HOD system. For example, Marquardt and Quack (1991), working on CHX_3 theoretical models, point out that the energy initially localized in a wave packet on the CH stretch mixes with CH bends in 80 fs, and is randomly distributed in hundreds of femtoseconds.

4. CHEMICAL CHANGES

4.1 Ionization and Detachment

One of the more striking effects of laser photochemistry is the frequent appearance of ions, even when working with photon energies less than the molecular ionization potential. This ionization usually results from the processes, shown in Fig. 2, of direct multiphoton absorption, resonant multiphoton ionization involving several intermediate states, or ionization of chemical products resulting from rearrangements or elimination of groups of atoms.

An analogous process for negative ions is the production of neutral species by multiphoton photodetachment. In fact, one of the first structured multiphoton spectra observed was that of photodetachment of C_2^- (Lineberger and Patterson, 1972). Detachment is reviewed (along with ion dissociation) by Miller (1981).

At high pressures, collisional mechanisms allow molecules to pool energy, and "chemi-ionization" may result. This is thought to be one possible mechanism to account for multiphoton ionization by IR absorption, similar to the production of ionization in flames (Avouris *et al.*, 1980).

4.2 Dissociation

The major photochemical pathway is that of dissociation. Lasers have been instrumental in exploring photodissociation by their ability to initiate and probe the sequence of events as molecules come apart. For example, it has been possible to excite, and observe, the emission by molecules while they are dissociating. Imre *et al.* (1984) reviewed the seminal experiments, along with the accompanying advances in theory that allow these experiments to be understood.

Lasers have also provided insight into the distribution of products, in terms of energy release, angular distributions of products, and the internal rotation and vibrational states of the fragments (Leone, 1985).

One study looked at the details of predissociation in formaldehyde by carefully comparing the rotational state distribution expected from an RRKM (Rice-Ramsperger-Kassels-Marcus) statistical theory with the state populations measured for CO (Bamford *et al.*, 1985). The RRKM model assumes an equipartitioning of energy between all molecular modes. Although there are only four atoms present, the excited electronic state efficiently couples to the vibrational manifold associated with the electronic ground state, which then decomposes by elimination of hydrogen:

$$H_2CO+h\nu\rightarrow H_2CO(S_1)\rightarrow H_2CO(S_0,\text{vib.})$$
$$\rightarrow H_2+CO(\text{rot.}).\quad(11)$$

In liquid solutions, photodissociation may be followed immediately by recombination of species trapped by a solvent cage. The effect of this cage has been the object of much study since it was first observed, and the prototypical system here is the photodissociation of I_2.

This system is still not fully understood, but the use of picosecond and faster lasers has allowed us a better understanding than in the past. A recent review is provided by Harris *et al.* (1988). As currently understood, dissociation happens on the subpicosecond time scale, followed by recombination on the order of several picoseconds. Vibrational relaxation occurs within several hundred picoseconds in polyatomic solvents. The most difficult step, which is not entirely understood, is the I-atom escape from the solvent cage, which can take place in anywhere from tens of picoseconds to tens of nanoseconds, depending upon the solvent in a way that is not yet understood.

One area of investigation that would be nearly impossible without lasers is photodissociation of isolated molecular ions in molecular beams or ion traps (Moseley, 1985). Examples of these studies include work on aromatic molecular ions of benzene (Freiser and Beauchamp, 1975),

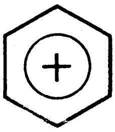
$$C_6H_6^+ + h\nu\ (2.5\ \text{eV}) \rightarrow C_6H_6^{+*},$$

$$C_6H_6^{+*} + h\nu\ (1.5\ \text{eV}) \rightarrow C_6H_5^+ + H, \qquad (12)$$

and toluene (Eyler, 1976),

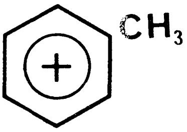
$$C_7H_8^+ + h\nu \rightarrow C_7H_7^+ + H. \qquad (13)$$

In the first case, the benzene cation

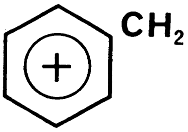


requires sequential electronic absorption of two photons in order to surmount the barrier to dissociation. This is one example of large-molecule photoabsorption, as discussed above, followed by dissociation. Interestingly, the intermediate formed by the absorption of one photon is very long-lived (seconds) and appears to be a vibrationally hot ion, but in its electronic ground state. Relaxation of the initially produced, electronically excited state into a mixture of vibrational levels of the ground electronic state prevents the excited molecular ion from radiating, and prepares the ion for absorption of an additional quantum of radiation. The combined energy of two photons now exceeds the threshold for dissociation of about 4 eV.

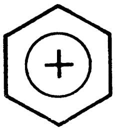
The toluene ion,



illuminated at almost the same energy, dissociates in a one-photon process. Direct elimination of a hydrogen from the methyl group to produce the benzyl cation



is energetically allowed when 2.3 eV is supplied by radiation. However, isomerization of the carbon atom backbone of the molecule, enlarging the ring to seven members,



in concert with the elimination of a hydrogen, would be energetically possible with the addition of only 1.7 eV of energy from radiation. The near coincidence of the photothreshold (2.3 eV) with the predicted thermodynamic threshold for the production of benzyl appears to indicate that direct dissociation occurs without (at least initially) isomerization of the molecular ion fragment.

Dissociation is also the usual step initiating radical chain reactions, such as polymerization. Commercially important are reactions involving azides,

$$RN_3 + h\nu \rightarrow RN{:} + N_2, \qquad (14)$$

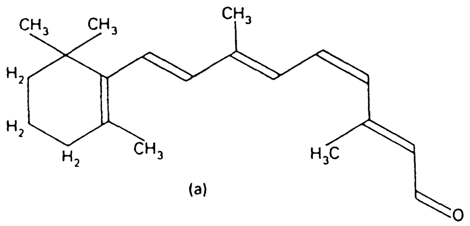
triazines, and electron-transfer initiators such as diaryliodonium and triarylsulfonium salts.

4.3 Isomerization

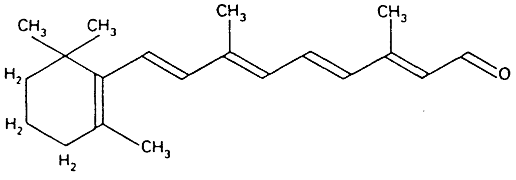
Isomerizations, the rearrangement of atoms within single molecules, are some of the cleanest photochemical transformations. Classical photochemistry has focussed intently on *cis-* to *trans-* isomerizations, and these are the object of laser photochemistry, too.

IR photochemistry of the isomers of 1,2-dichloroethene at 981 cm^{-1} results in a photostationary mixture in which the higher-energy *cis-* conformation dominates, in contrast to the result produced by simple heating (Ambartzumian *et al.*, 1976).

Photophysical and photochemical processes accompanying isomerizations of the visual pigment rhodopsin have been studied on time scales ranging from femtoseconds to seconds with lasers. The key transformation occurring there is the isomerization of the conjugated chain of retinal between conformations (a) and (b):



(a)



(b)

4.4 Condensation and Addition

A common photochemical process is the initiation of polymerization, the condensation of many monomer molecules into larger polymer molecules. While the usual mechanism is radical-initiated or radical-ion–initiated chain reaction, occasionally a direct addition of an excited reactant with another is causative.

One of the more striking effects observed upon passing laser light through an absorbing gas sample is that of photoinduced condensation, producing brilliant opalescence along the laser beam. Examples of this include alkali-metal vapors through which light from a dye laser is directed. In this configuration, a significant fraction of alkali-metal-atom excited states are produced, which then may act as nucleation centers for the formation of diatomic molecules and clusters. Several mechanisms appear to be operating; the most striking occurs when the radiation density is sufficient to cause ionization. Ion-atom potentials are always attractive, and they operate at long range, and this electrostatic force, in contrast to covalent bonding forces, does not saturate, allowing the growth of large clusters of molecules that otherwise might not even react.

5. APPLICATIONS

Their cost per mole makes laser photons an expensive reagent, economical in only high-value products. Uses that can be foreseen for laser photons include the production of drugs, the isolation of isotopes, processing of materials on or near surfaces, and the storage and retrieval of information.

5.1 Holography

Laser photochemistry proved important early in the field of holography (see HOLOGRAPHY, OPTICAL). Lasers provided the coherent light, and the interference patterns were recorded by the photochemistry of either silver halide photographic emulsions or organic photoresists. Holographic technology now provides nearly ghost-free commercial diffraction gratings (see MONOCHROMATORS).

5.2 Isotope Selection

High wavelength specificity of lasers, along with sufficient power to cause chemistry on the mole scale, led to interest in using lasers for isotope production. Some possible methods are reviewed by Letokhov (1983) and some of the concerns are raised by Krauss (1977). Numerous processes have become available for laser isotope separation (Cantrell *et al.*, 1979; Hartford, 1979; Jensen *et al.*, 1980; Letokhov, 1979; Letokhov and Moore, 1976, 1977; Zare, 1977). The application to the separation of uranium isotopes has been the focus of studies on both atomic U and its compounds (Dietz *et al.*, 1982).

5.3 Surface Modification

The most common industrial use of lasers in materials processing is for cutting or machining, applying the high energy densities of laser beams to burn or ablate materials. Secondary to this use, lasers have found their way into hardening of materials, thermal treatments, and exposure of photoresists.

5.3.1 Etching. One possibility for increasing the effectiveness of laser ablation techniques is in modification of a nonabsorptive material to make it absorptive. High–band-gap materials will develop color centers upon electron irradiation. At low power levels, lasers can be used to photobleach these color centers; at high power levels, these same color centers can be used to provide the initial absorption necessary to initiate ablation.

Lasers have been found to enhance greatly the rate at which a chemical process removes material from surfaces. Plasma etching and electrolytic etching are examples where lasers enhance the rate of reaction. One effect of lasers that is different from most other techniques is the ability to etch long channels in materials along the axis of light propagation with diameters narrower than the beam profile (Podlesnik and Gilgen, 1989).

5.3.2 Deposition. Laser decomposition of organometallic compounds over surfaces generates metal atoms and deposits metal layers at the adjacent surface (Osgood, 1983; Ehrlich and Tsao, 1983; Jones *et al.*, 1985). Direct dissociation of gaseous organometallic compounds occurs promptly, and the metal ions often possess significant translational energy, as observed in the Doppler profiles of optical transitions of these ions (Marinero and Jones, 1985). This would seriously complicate the ability to deposit patterns at surfaces, since metal atoms generated in the gas phase would tend to spread over the surface, away from the region of photodissociation. Dissociation has been found, however, to be enhanced at surfaces, which permits the writing of structures directly on the surface with dimensions on the order of 10^{-7} m (Wilson and Houle, 1985; Houle *et al.*, 1986).

The field of laser deposition writing is summarized in the book edited by Ibbs and Osgood (1989).

5.4 Information Storage

Many lasers in the information industry provide controlled light for exposure of optical recording media. Most photochemical processes are based upon photographic or photoresist technology, although currently information storage is dominated by photophysical techniques such as xerography (*q.v.*) or thermal melting, such as in the now familiar commercial CD and "laser" disks. Currently, the relative lack of cw uv lasers operating at wavelengths below 300 nm, compared to the ready availability of IR and visible lasers, limits the types of photochemical recording methods available to information technology.

5.5 Chemical Analysis

Lasers have been used to ablate surfaces, thereby generating gaseous ions, atoms, and molecular fragments from samples of surfaces and molecules at surfaces. One use to which multiphoton ionization has been applied is in the detection of molecules eluting from a gas chromatograph (Klimcak and Wessel, 1980) (see CHROMATOGRAPHY).

5.6 Biochemistry

Since a number of biological processes are photochemical, it has been natural to use light in the study of these. The photochemistry of rhodopsins, the pigments of the eye, has been extensively investigated with ever-shortening laser pulses. For a review, see Birge (1990). The major chemical mechanism of vision is isomerization of the long, conjugated-chain molecule (see Sec. 4.3), but numerous conformational changes occur in this molecule before and after this isomerization occurs.

One area of concern to molecular biologists is the rate at which proteins, especially enzymes, change configurations. Optical techniques have been used to study these changes. Miller (1991) reviews how transient optical gratings have provided information about the transformations occurring in hemoglobin with the addition and release of oxygen or CO, and the rate at which various conformations of the heme group relax.

GLOSSARY

Ablation: Removal of material from a surface caused by the impact of light, atoms, molecules, or ions. Generally, a thermal process involving local evaporation.

Bond-Specific Photochemistry: Photochemistry having products determined by a specific bond or combination of bonds set into vibrational motion.

Chemi-ionization: Ionization caused by a chemical reaction.

Conformation: The (possibly unstable) arrangement of atoms inside a molecule.

Conformers: Different, relatively stable, arrangements of atoms, each consisting of identical numbers and types of atoms. A dissociating or rearranging molecule may pass through different conformers. Conformers need not be capable of being physically or chemically isolated.

Hole Burning: Depletion of part of an inhomogeneous distribution of molecules, caused by the interaction of light with those molecules; selective photobleaching.

Internal Conversion: Mixing of the vibrational levels of an electronic state with the vibrational levels of another electronic state.

Intersystem Crossing: Mixing between states of different spin.

Isomers: Different molecular conformations, consisting of identical atoms, that are stable, or metastable long enough to be physically or chemically separated.

Lamb Dip: The reduction in absorption (hole burning) observed when two counterpropagating laser beams interact with the same atoms. Usually observed at the center of a Doppler-broadened transition.

"Large" Molecule: A molecule having a high density of states, forming numerous overlapping resonances that interact simultaneously with radiation of a single frequency.

Local Mode: Classically, relative motion of one atom, or a group of atoms, in a molecule. Quantum mechanically, an eigenfunction or superposition of degenerate, or nearly degenerate, eigenfunctions of the vibrational Hamiltonian with considerable amplitude on one or a few atoms.

Mechanism: Sequence of physical and chemical steps leading to a chemical change. Sometimes used to refer to the most unique or characteristic step of an overall mechanism.

Mode-Specific Photochemistry: Photochemistry having products determined by the vibrational mode set into motion.

Multiphoton Absorption: Direct multiphoton absorption occurs when two or more photons are absorbed at once, mediated by higher-order perturbation terms of the molecular Hamiltonian interaction with the radiation field. Sequential one-photon events are sometimes called by this name, but more properly may be called "multiple photon absorption."

Multiphoton Ionization (MPI): Ionization caused by multiphoton absorption, either directly into the ionization continuum, or by absorption to an intermediate resonant state, followed by photoionization. The latter is termed "resonant" or "selective."

Normal Mode: Classically, molecular vibration in which (nearly) all atoms move concertedly and periodically with the same frequency, but possibly not with the same phase. Quantum mechanically, eigenfunction of the vibrational Hamiltonian.

Organometallic: A compound containing organic carbon and metal atoms.

Photodetachment: Ejection of an electron from a negative ion by the effect of light.

Photodissociation: Fragmentation of a molecule into two or more pieces by the effect of light.

Photoresist: An organic resin that polymerizes under the influence of light.

Rabi Frequency: The rate at which a stimulated electronic transition would occur in response to a radiation field. A simple two-level system will alternately absorb and emit, toggling between excited and ground states at this frequency.

Rovibronic State: An individual state of an isolated molecule, including contributions from rotational, vibrational, and electronic motion.

RRKM: Rice-Ramsperger-Kassel-Marcus theory of unimolecular reactions, based upon the statistical flow of vibrational energy within a molecule. The rate at which fluctuations localize energy in critical, reactive bonds determines the rate of reaction.

"Small" Molecule: A molecule having a sparse density of states in which isolated resonances interact individually with a radiation field of a single frequency.

Spontaneous Raman Scattering: Inelastic scattering by matter of photons into a random final state.

Stimulated Raman Scattering: Inelastic scattering of photons stimulated by the radiation field interacting with matter.

Vibrational Relaxation: Loss of internal vibrational energy into other modes of motion.

18.1
Introduction

The uses of lasers in spectroscopy are extensive. The key characteristics of laser light – particularly the unparalleled combination of an essentially monochromatic output at high intensity levels – are extremely well suited to a wide variety of spectroscopic techniques. Often, high laser powers are exploited in the determination of weak or transient spectral features, or to produce optically nonlinear processes; equally, the narrow bandwidth of many laser sources is utilized for high-resolution studies. A wide variety of optical materials is employed in the lasers themselves, and the detailed nature of these materials determines the principal output characteristics such as wavelength and achievable power. Since the construction of the first laser based on ruby, widely ranging materials have been adopted as laser media. The range is still being extended to provide output at new wavelengths and, as can be seen from Table 18.1, the output available from commercial lasers now covers most of the electromagnetic spectrum.

By a variety of means, laser light can also be tailored to specific applications by frequency-conversion and pulse-generation techniques; the facility to modify these characteristics is again important for many spectroscopic investigations. This chapter reviews the basic mechanisms and principles of operation of the most important laser sources and beam management techniques, focusing on systems that are especially well suited to spectroscopic applications. Space does not permit a thorough description of the entire range of laser systems now available; the more limited scope of the following account is a discussion of representative laser instrumentation.

18.2
Optically Pumped Solid-State Lasers

The active medium in most solid-state lasers, capable of delivering 1 W or more power in the UV to near-IR range, is generally a transparent crystal or glass doped with a small amount of transition metal; transitions in the metal ions are responsible for the laser action. The two most common dopants are chromium (in the ruby and alexandrite lasers) and neodymium (Nd : YAG and Nd : glass lasers), with

the dopant concentration typically 1% or less. Such lasers are optically pumped by a broadband flash-lamp source, and can be pulsed to produce the high intensities.

18.2.1
Ruby Laser

The ruby laser has an important place in history as it was the first type ever constructed (in 1960). In construction, the modern ruby laser comprises a rod of commercial ruby (0.05% Cr_2O_3 in an Al_2O_3 lattice) of between 3 and 25 mm diameter and up to 20 cm length. The chromium ions are excited by the emission from a flash-lamp coiled around it, or placed alongside it within an elliptical reflector as shown in Figure 18.1.

From the energy level scheme shown in Figure 18.2, it is apparent that the ruby laser may be regarded as a *pseudo three-level system*, because in the course of excitation, decay, and emission, only three Cr^{3+} levels are involved; $^4A_2$, $^4T_1$ or $^4T_2$, and ^2E. These energy levels are quite different from those of a free chromium atom, due to crystal field splitting. The initial flash-lamp excitation takes the Cr^{3+} ions up from the ground state E_l ($^4A_2$) to one of the two E_3 (^4F) levels. Both of these levels have subnanosecond lifetimes, and rapidly decay into the E_2 level (^2E). The decay takes place by nonradiative processes that channel energy into lattice vibrations, heating the crystal. Because the E_2 level has a much longer decay time of around 4 ms, a population inversion is created between the E_2 and E_l states, leading to laser emission at a wavelength of 694.3 nm as the majority of Cr^{3+} ions cascade down to the ground state. The lasing process thus generates a single, intense pulse of light, typically between 0.3 and 3 ms duration; the delay between successive pulses usually lasts several seconds, and can be as long as a full minute. A very different kind of pulsing can be created by the technique known as *Q-switching*, discussed in Section 18.6.2

A problem with the ruby laser, common to all lasers of this type, is the damage caused by the repeated cycle of heating and cooling associated with the generation of each pulse, which

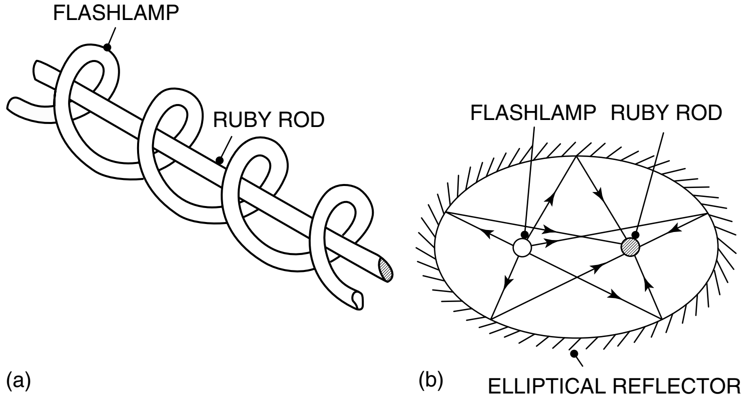

Fig. 18.1 Arrangement of flash-lamp tube and ruby rod in a ruby laser. (a) Helical flash-lamp option; (b) confocal flash-lamp and laser rod within an elliptical reflector.

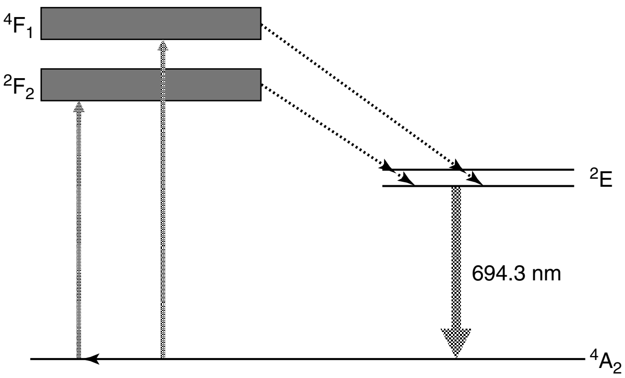

Fig. 18.2 Energetics of the three-level ruby laser. The vertical arrows upward on the left hand side refer to pumping transitions. The dashed lines refer to nonradiative relaxation from the pump bands into the upper lasing level. The broad vertical arrow downward corresponds to the laser line at 649.3 nm.

ultimately necessitates the replacement of the ruby rod. To improve performance, the rod usually needs to be cooled by circulation of water in a jacket around it. Despite its drawbacks, with pulse energies as high as 200 J, the ruby laser represents a powerful source of monochromatic light in the optical region. The emission bandwidth is typically about 0.5 nm, but this can be reduced by a factor of up to 10^4 by suitable optics. The beam diameter of a low-power ruby laser can be as little as 1 mm, with 0.25 mrad divergence; the most powerful lasers may have beams up to 25 mm in diameter and a divergence of several mrad.

18.2.2
Neodymium Lasers

Neodymium lasers are of two main types. In one, the host lattice for the neodymium ions is a crystal – usually yttrium aluminum garnet crystal ($Y_3Al_5O_{12}$) – and in the other, the host is an amorphous glass. These are referred to as *Nd : YAG* and *Nd : glass*, respectively. Although transitions in the neodymium ions are responsible for laser action in both cases, the emission characteristics differ because of the influence of the host lattice on the neodymium energy levels. Also, glass does not have the excellent thermal conductivity properties of YAG crystal, so that it is more suitable for pulsed than for continuous-wave (CW) operation. Like the ruby laser, both types of neodymium laser are normally pumped by a flash-lamp arranged confocally alongside a rod of the laser material in an elliptical reflector. The energy levels of neodymium ions involved in laser action are split by interaction with the crystal field, as illustrated in Figure 18.3. As a result, transitions between components of the $^4F_{3,2}$ and $^4I_{11/2}$ states, forbidden in the free state, are permitted and can give rise to laser emission. The $^4F_{3,2}$ levels are initially populated following nonradiative decay from higher energy levels excited by the flash-lamp, and because the terminal $^4I_{11/2}$ laser level lies above

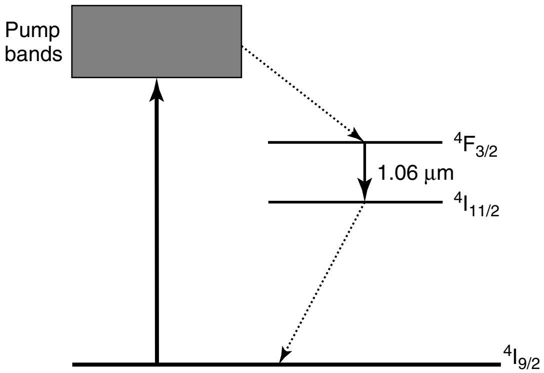

Fig. 18.3 Simplified energy levels of a four-level neodymium laser lasing at 1.06 μm.

the $^4I_{9/2}$ ground state, we thus have a pseudo- four-level system.

The principal emission wavelength for both types of neodymium laser is around 1.064 μm, in the near-IR (or 1.053 μm in the less common Nd : YLF lasers, where lithium replaces aluminum in the host lattice). Some commercial lasers can also operate on a different transition, producing 1.319 μm output. The YAG and glass host materials impose very different characteristics on the emission, however. Quite apart from the differences in thermal conductivity, which determine the question of continuous or pulsed operation, one of the main differences appears in the line width. Because glass has an amorphous structure, the crystal field splitting also varies from site to site. Hence, the line width is much broader than in the Nd : YAG laser, where the lattice is much more regular and the field splitting is more uniform. However, the concentration of neodymium dopant in glass may be as large as 6%, compared with 1.5% in a YAG host, so that a much higher energy output can be obtained. For both these reasons, the Nd : glass laser is ideally suited for the production of extremely high intensity ultrashort pulses by the technique of mode-locking (see Section 18.6.3). In fact, amongst all commercially available lasers, it is the neodymium lasers that deliver the highest available laser beam intensities.

The output power of a typical CW Nd : YAG laser is several watts, and can exceed 200 W. When operating in a pulsed mode, the energy per pulse varies according to the method of pulsing and the pulse repetition rate, but can be anywhere between a small fraction of a joule and 100 J for a single pulse. The majority of Nd : YAG research applications in spectroscopy make use not of the 1.064 μm radiation as such, but rather the high-intensity visible light that can be produced by frequency-conversion methods. Particularly important in this respect are the wavelengths of 532, 355, and 266 nm obtained by harmonic generation (see Section 18.7.1).

Diode-pumped solid-state lasers represent a very different laser technology. These miniature-scale devices, which can often fit comfortably into the hand, incorporate a semiconductor diode laser (Section 18.3) to directly pump a small Nd : YAG crystal. Cavity modifications enable line-widths of less than 5 kHz (2×10^{-7} cm^{-1}) to be attained in certain models. While CW output powers are generally low (milliwatt scale), the

1-W target is exceeded in some commercially available systems. Also important is the common inclusion of frequency-conversion crystals in these devices, so providing milliwatt emission in the visible region, especially a 532-nm line in the green. Such integrated solid-state lasers have the advantages of smaller size, higher efficiency, better stability, and lower noise levels than most gas discharge lasers.

18.2.3
Widely Tunable Lasers

Recently, other types of solid-state laser have been developed which, although again based on optical transitions in transition metal ions embedded in a host ionic crystal, produce *tunable* radiation. For a number of spectroscopic applications, such lasers represent an attractive alternative to tunable lasers based on organic dyes. Their chief advantages are an appreciably more rugged and compact construction and operation without use of toxic chemicals.

The recently developed titanium : sapphire laser, commonly pumped by a primary laser beam such as the all-lines output of an ion gas laser, is the best known example in this category, and is today one of the most widely used commercially available solid-state lasers. Crucially, the coupling of electronic levels with lattice vibrations here leads to a broad, continuous band of *vibronic* energy levels. On the basis of the Al_2O_3 crystal doped with approximately 0.1% Ti_2O_3, lasing occurs on vibronic $^2E \rightarrow {}^2T_2$ transitions in the Ti^{3+} ions, offering high-power tunable CW or pulsed emission over the exceptionally large wavelength range 650–1100 nm in the near-infrared, peaking near 800 nm. At that wavelength, over 5 W CW outputs can be achieved. The titanium : sapphire laser is finding an increasingly wide range of applications, particularly in spectroscopy. Other commercially available vibronic lasers offering pulsed output in the infrared are Co^{2+}-doped MgF_2 (the first tunable solid-state laser) tunable over the range 1.75–2.50 μm, and chromium-doped Mg_2SiO_4 (forsterite), in which the laser-active species is Cr^{4+} and the corresponding emission range 1.15–1.35 μm.

18.2.4
Color-Center Lasers

Another type of solid-state laser in which the active medium is a regular ionic crystal does not involve transition metal ions. This is the so-called *F-center* (or *color center*) laser that operates on optical transitions at defect sites in alkali halide crystals, as for example in KCl doped with thallium; the color centers are typically excited by a pump Nd : YAG or argon/krypton ion laser. Such lasers produce radiation that is tunable over a small range of wavelengths in the overall region 0.8–3.4 μm; different crystals are required for operation over different parts of this range. One disadvantage of this type of laser is that the crystals need to be held at cryogenic temperatures. Color center lasers have found limited applications, although they have proven use in the high-resolution spectroscopy of small molecules.

18.2.5
Fiber Lasers

As the name suggests, the gain medium of these devices are silica or fluoride glass fibers doped with active rare-earth ions

(King, 2004). Some of dopants used include Nd, Tm, or Yb. The fiber, which has an external cladding with an index of refraction which is lower than that of the core, confines the pump and laser light to the core. Mirrors that are attached at the ends of the fiber or Fresnel reflections at each end complete the cavity. The devices are usually end-pumped through one of the mirrors (longitudinal pumping), although side pumping is possible. The long interaction lengths and wave guiding nature of the cladded fibers translates into devices with high gain, low thresholds, high efficiencies, and compactness. Unlike other solid-state lasers, the beam quality in these devises is determined here mainly by the refractive index profile of the cladding materials. Gain broadening in the fiber allows for limited tunability. Coherent emission can be obtained between ≈0.3 and 4.0 μm using different ions and different fibers.

A particularly important dopant is erbium, Er^{3+}, which under laser-diode pumping at 0.81, 0.98, or 1.48 μm can produce coherent radiation between 1.52 and 1.62 μm. This output range overlaps $\lambda = 1.55$ μm, which corresponds to the wavelength of lowest transmission losses in fiber-optic systems. This makes Er^{3+}-doped fiber amplifiers a key component in optical communications systems. A schematic energy level diagram of Er^{3+} is shown in Figure 18.4. Overall, the behavior of the $^4I_{15/2}$ lower laser state is similar to that of a dye laser molecule (Section 18.5.5). The higher energy M_J components are sparsely populated at typical operating temperatures, which results in a population inversion with respect to the $^4I_{13/2}$ upper lasing state. The inversion is maintained by rapid lower-level nonradiative relaxation.

One parasitic effect that can reduce the infrared gain in a fiber laser is the process of upconversion where light is emitted at higher photon energies than that of the pump photon generating the excitation. However, at the same time, this has led to another class of solid-state fiber lasers, called *upconversion lasers*, that operate at different wavelengths in the visible, depending on the rare-earth ion dopant(s) involved (Auzel, 2004).

Several mechanisms can lead to upconversion. The first is sequential absorption of pump laser photons through metastable (relatively long lived) ion excited states. In this case, low dopant concentrations but high pump powers

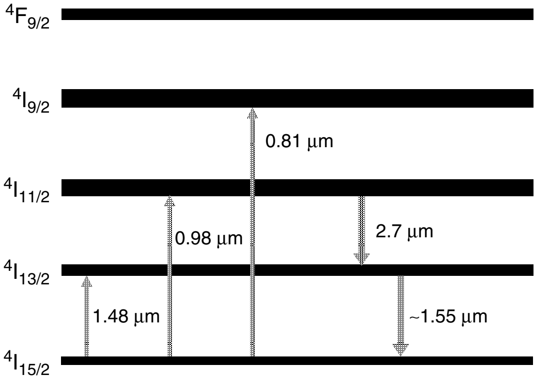

Fig. 18.4 Energy level diagram of Er^{3+} showing pumping transitions as vertical upward arrows and lasing transitions as vertical downward arrows. The thickness of the lines indicates unresolved fine structure.

are required. A second mechanism involves sequential energy transfers between different rare-earth ions. This could involve a simple radiative transfer where the emission of a donor ion is absorbed by an acceptor ion. Such an interaction has an R^{-2} interatomic distance dependence. Alternatively, the process could involve a nonradiative mechanism such as a Forster resonant energy transfer (FRET) or a Dexter transfer. Again, the emission of the donor ion must overlap the absorption profile of the acceptor species. However, the Forster mechanism is mediated by a dipole–dipole interaction between the donor and acceptor, and has a steep R^{-6} distance dependence. Dexter energy transfers are controlled by even higher order multipole interactions or very short-range exchange forces, and therefore are expected to more important in systems with forbidden transitions. In both cases, the donor and acceptor ion concentrations need to be relatively high and the energy transfer can be resonant or phonon assisted. A third mechanism involving cooperative upconversion is possible when the donor and acceptor ions are the same, and the dopant concentration has led to clustering. Here, a resonant dipole-dipole interaction between the two excited ions having an R^{-3} distance dependence cause one ion to be promoted to an even higher excited state, whereas the other is de-excited.

The choice of fiber is important for upconversion lasers. First, they must be transparent at the wavelengths used to pump the ions. Perhaps more importantly, they should have relatively large phonon energies to minimize phonon-assisted nonradiative relaxation of the metastable ions states involved in the upconversion process. Some of the more successful devices have been constructed using fibers made from the five component fluoride glass ZBLAN: (53 mol % ZrF_4; 10 mol % BaF_2; 4.5 mol % LaF_3, 3.5 mol % AlF_3, and 20 mol % NaF) (Jordan, Jha and Ryan, 1993). On the other hand, Si fibers can be problematic because they tend to absorb at wavelengths longer than around 2 μm.

18.3
Diode Lasers

In the solid-state lasers considered above, the energy levels are associated with low concentrations of dopant. Because, under these conditions, the dopant atoms are essentially isolated from each other, their energy levels remain discrete and the emission exhibits the same kind of line spectrum that we associate with isolated atoms or molecules. In the case of semiconductor diode lasers, however, it is energy bands, rather than discrete energy levels that are involved in the laser action.

Solid-state electronic devices generally make use of junctions between *p*-type and *n*-type semiconductors. The most familiar semiconductor materials are Class IV elements such as silicon and germanium; however, binary compounds between Class III and Class V elements, such as gallium arsenide (GaAs), exhibit similar behavior. In the latter cases, the lattice consists of two interpenetrating face-centered cubic lattices, the *p*- and *n*-type crystal reflecting a stoichiometry that departs from precisely 1 : 1. In *p*-type material, some arsenic atoms are replaced by gallium; in *n*-type crystal, the converse applies. On the basis of a junction between these materials, diode lasers operate in a broadly similar way to light-emitting diodes. When an electrical potential is applied across the very thin diode junction formed between *p*- and *n*-type semiconductor layers, the electrons crossing the semiconductor boundary recombine with holes and drop down from the conduction band to the valence band. In doing so, they emit radiation in the process as illustrated in Figure 18.5. The emission is most often in the infrared, and the optical properties of the crystal at such wavelengths make it possible for the crystal end faces to form the confines of the resonant cavity. One advantage of this kind of edge emitter is its extremely small size, usually about half a millimeter. However, the geometry of the gain region does result in very poor beam quality and collimation; divergences of 10° are by no means unusual. However, this does not preclude edge emitters from being used to pump fiber or other solid-state lasers to obtain better beam outputs, albeit, at the expense of overall efficiency.

There are two main types of semiconductor lasers: those operating at fixed wavelengths and others that are tunable. The three most common fixed-wavelength types are gallium arsenide, gallium aluminum arsenide, and indium gallium arsenide phosphide. Gallium arsenide lasers emit at a wavelength of around 0.904 μm; the wide range of flexibility in the stoichiometry of the other types makes it possible to produce a range of lasers operating at various fixed wavelengths in the region 0.8–1.3 μm. “Lead salt” diode lasers, which are derived from nonstoichiometric binary compounds of lead, cadmium, and tin with tellurium, selenium, and sulfur, emit in the range 2.8–30 μm (3500–330 cm^{-1}) depending on the exact composition. Although these lasers require a very low operating temperature, typically in the range 15–90 K, the operating wavelength is very temperature-dependent, and the wavelength can be tuned by varying the temperature. The tuning range for a lead

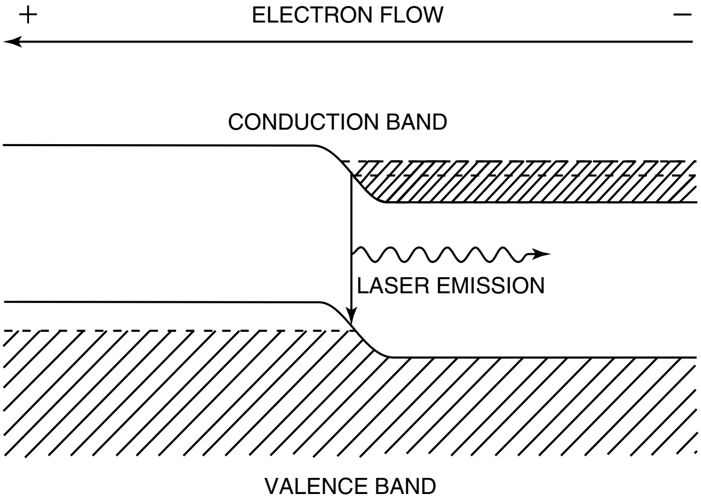

Fig. 18.5 Energetics of a diode laser; energy levels of *p*-type material on the left and *n*-type on the right.

salt diode laser of a particular composition is typically about 100 cm^{-1}.

Modes in a diode laser are typically separated by 1–2 cm^{-1}, and each individual mode generally has a very narrow line width, $10^{-3}\,\mathrm{cm}^{-1}$ or less. The output power of CW diode lasers is generally on the milliwatt scale, though some array devices are capable of emitting as much as 10 W. Diode lasers are very well suited to high-resolution IR spectroscopy, because the line width is sufficiently small to enable the rotational structure of vibrational transitions to be resolved for many small molecules. This method has proved particularly valuable in characterizing short-lived intermediates in chemical reactions. More diverse applications can be expected as the range of diode laser emission wavelengths encroaches further into the visible region – devices emitting at the blue end of the spectrum are now available, in some cases through frequency-doubling methods (Section 7.1).

18.3.1
Vertical Cavity Surface Emitter Lasers

Vertical cavity surface emitter lasers (VCSEL) are diode lasers where the axis of coherent beam propagation is perpendicular to the gain region at the p–n junction. In this geometry, the width of the active area exceeds the height, so that beam divergence due to diffraction is much reduced (Hecht, 2005). However, because the active volume is small, high-reflectivity mirrors must be attached to the ends of the cavity as part of the fabrication process. Alternatively, distributed-Bragg-reflection gratings can be used to deflect light oscillating in the horizontal plane of an edge emitter out through the surface. Grating-coupled surface emitters have also been designed where a second-order grating in the active layer diffracts the light through the surface. The coherent emission from this configuration is bright with good spatial quality.

18.3.2
Visible Laser Diodes

Doped III–V nitride-based semiconductors have a wide direct band gap for blue emission (Leinen *et al.*, 2000). For example, the band gap of AlGaInN can be varied between 2 and 6.2 eV at room temperature depending on its composition. Commercial edge and surface emitting lasers based on InGaN emit light by the recombination of injected electrons and holes in an active layer (Nakamura, 1998). The In allows a strong conduction band to valence band emission at room temperature which otherwise would be difficult to obtain using GaN alone. These devices are expected to have a large impact on the development of full color laser displays, which require at least three primary colors: red, green, and blue to produce any other visible wavelength. Blue-emitting diode lasers also provide an approximately three time enhancement in the capacity of digital versatile disks (DVDs) over those read using red diode lasers. Presently, ''Blu-ray'' discs and ''HD–DVDs'' are competing formats that both capitalize on the use of blue-emitting diode lasers for reading and writing, and for providing digital movies with a higher resolution than conventional DVDs.

18.3.3
Quantum Dot Lasers

Quantum dots are nanometer-sized semiconducting assemblies whose energy levels are fully discrete and atomic-like (Asada, Miyamoto and Suematsu, 1986). The energy level spacings depend on the radius of the dot. Whereas bulk semiconductors are three dimensional, quantum films are two dimensional, and quantum wires are one dimensional, quantum dots are often classified as zero dimensional. Considerable effort has been expended on fabricating arrays of uncapped (no organic surface terminators) InAs quantum dot lasers grown on GaAs that can lase at 1.3 μm (Mowbray, 2005; Fiore *et al.*, 2006). InAs self assembles on a GaAs substrate into a quantum dot array upon epitaxial growth because the two semiconductors have significantly different lattice constants. Although the individual dots have narrow spectral lines, size dispersion in an assembly of dots results in an inhomogeneous broadening of several tens of nanometers. The resultant quantum dot arrays have low gain for stimulated emission due to their lower density of states and large spectral widths. However, this problem can be overcome by stacking several layers of quantum dots within one assembly. On a positive note, these devices have minimal sensitivity to operating temperatures between 20 and 85 °C because their energy level spacings are larger than the Boltzmann energy, kT. They require ultra low threshold current densities for lasing, and the inhomogeneous broadening provides some degree of tunability.

18.3.4
Quantum Cascade Lasers

Quantum cascade laser emission is a result of electronic transitions between the discrete energy levels of a quantum well within the conduction band of a semiconductor. A quantum well is an ultrathin (typically nanometer scale) layer of one semiconductor sandwiched between two layers of a

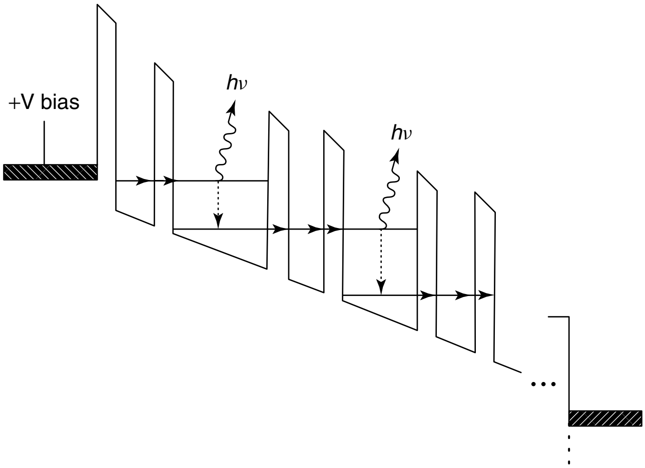

Fig. 18.6 Well structure of a quantum cascade laser.

second semiconductor with a wider band gap. This two-dimensional arrangement effectively confines injected electrons within the well. Because the discrete energy level spacing with the quantum well can be varied by changing its thickness, lasers based on this geometry are tuned between 4 and 24 μm in the mid- to far-infrared.

Although these devices require sophisticated molecular beam epitaxy to be fabricated, they are unique in that unlike other semiconductor devices the laser wavelength of the continuous output is not dependent on the chemical properties or the composition of the medium (Faist *et al.*, 1994). As shown in Figure 18.6, a typical device consists of a series of quantum well. Under an applied voltage, an electron injected into the first quantum well will emit a photon when it drops from higher to lower energy. Because the well is within the conduction band, the electron can tunnel into an identical adjacent well where it produces a second photon. This process is repeated for each well. The effect of multiple quantum wells is that one electron can produce many photons as it cascades down an energy "staircase" created by the applied voltage. This avalanche effect results in output lasers powers which are ~1000 X that of a diode laser.

18.3.5
Quantum Microcavity Lasers

Microcavities are resonators that are characterized by high quality factors, Q, and small volumes, V. Like all resonators, microcavities support discrete optical mode frequencies for photons propagating along its axis. The lowest frequency mode supported by the resonator is called the *fundamental resonator mode.* Because the resonator mode frequency spectrum is size-dependent, microcavities, by virtue of their small dimensions, have mode frequency distributions that are considerably sparser than those for larger cavities.

There are three common geometries associated with microcavities (Vahala, 2003). The first is a Fabry–Perot resonator with two coplanar mirrors separated by one of more multiples of $\lambda/2$ where λ is the emission wavelength. Here, the Q-factor, (which is related to the photon lifetime in the cavity) is determined primarily by the reflectivity of the mirrors and is typically of the order of 2×10^3. The typical volume of a Fabry–Perot microcavity of refractive index n, operating at wavelength λ is $V = 5(\lambda/n)^3$.

The second configuration consists of spherical or a disk–shaped dielectric structures that confine optical surface waves by continuous total internal reflection. In general, the resultant atomic-like optical modes can be classified by three indices: n, ℓ, and m (Righini *et al.*, 2005). The radial mode numbers, n, corresponds to the number of maxima in the radial component, while the angular momentum index, ℓ, is related to the number of wavelengths contained in the equatorial length. The combination $\ell - |m| + 1$ gives the number of maxima in the polar component. The smallest volume modes, called *whispering gallery modes,* are low order radial modes with $\ell \approx |m|$ that orbit in the equatorial ring. Typical Q-factors and volumes for these so-called whispering gallery resonators are 12×10^3 and $6(\lambda/n)^3$, respectively. The Q-factor is limited by losses due to surface roughness.

The third type of microcavity is based on photonic crystals. Photonic crystals are materials with an index of refraction periodicity on the order of λ. The photonic band gap which opens if the index contrast of the periodicity is sufficiently large corresponds to a frequency range where light with wavelengths ∼2λ will not propagate (Yablonovitch, 1987). This is the optical analog of the electronic band gap in semiconductors. However, microcavities can be formed by introducing a defect into the periodic structure (for example by drilling an additional hole or omitting a hole). These cavities can be very small ($V \sim 1.2(\lambda/n)^3$), and their Q-factors can very large ($\sim 13 \times 10^3$) provided there is an adequate spatial extent of the index periodicity. However, photonic crystals can be challenging to fabricate for operation in the visible region of the spectrum.

When an optically active medium is placed inside a microcavity, its spontaneous emission can be dramatically changed because the spontaneous emission rate depends on the optical mode density at the emission wavelength. For example, media in cavities having a fundamental mode frequency that is resonant with its emission frequency will exhibit an enhanced emission rate. This is the so-called Purcell effect. Conversely, a cavity can be designed to suppress spontaneous emission. Similarly, media can experience an enhanced or reduced absorption depending on whether or not the medium's absorption frequency is resonant with a mode of the cavity.

Microcavity physics has led to the development of several laser sources. Lasing has been observed in dye-filled water droplets, dye-doped silica and polystyrene spheres, semiconductor microdisks, vertical cavity micropillars containing a quantum dot, and doped photonic crystals. One unique property of lasers based on microcavities is their low thresholds relative to conventional devices. Indeed, it has been argued that an ideal microcavity laser, where spontaneous emission has been suppressed, is actually thresholdless (Rice and Carmichael, 1994).

18.4
Atomic and Ionic Gas Lasers

The class of lasers in which the active medium is a gas covers a wide variety of devices. Generally, the gas is monatomic, or else it is composed of very simple molecules. In both cases, because laser emission results from optical transitions in free atoms or molecules, usually at low pressures, the emission line width is small. The gas is often contained in a sealed tube, with the initial excitation provided by an electrical discharge, so that in many cases, the innermost part of the laser bears a superficial resemblance to a conventional fluorescent light. The tube can be constructed from various materials, and need not necessarily be transparent; silica is commonly employed – and also beryllium oxide, which has some advantages in its high thermal conductivity. It is quite a common feature to have the laser tube contain a mixture of two gases, one of which is involved in the pump step and the other in the laser emission. Such gas lasers are extremely reliable, and they are the most widely used type for routine purposes.

18.4.1
Helium–Neon Laser

The helium–neon laser was the first CW laser ever constructed, and it was also the first laser to be made available to a commercial market, in 1962. The active medium is a mixture of the two gases contained in a glass tube at low pressure; the partial pressure of helium is approximately 1 mbar, and that of neon 0.1 mbar. The initial excitation, provided by an electrical discharge, primarily serves to excite helium atoms by electron impact. The excited helium atoms subsequently undergo a process of collisional energy transfer to neon atoms; certain levels of helium and neon are very close in energy, so that this transfer takes place with a high degree of efficiency. Because the levels of neon that are so populated lie above the lowest excited states, a population inversion is created relative to these levels, enabling laser emission to occur as shown in Figure 18.7.

Three distinct wavelengths can be produced in the laser emission stage; one visible wavelength, typically of milliwatt power, appears in the red at 632.8 nm, and there are two IR wavelengths of somewhat lower power at 1.152 and 3.391 μm. Following emission, the lasing cycle is completed as the neon undergoes a two-step radiationless decay back down to its ground state. This involves transition to a metastable $2p^5 3s^1$ level, followed by collisional deactivation at the inner surface of the tube. The last step has to be rapid for the laser to operate efficiently; for this reason, the surface/volume ratio of the laser tube has to be kept as large as possible, which generally means keeping the tube diameter small. In practice, tubes are commonly only a few millimeters in diameter. Other very weak transitions are utilized in a 1-mW helium–neon laser emitting at various wavelengths including 543.5 nm in the green; its principal virtue is that it is substantially cheaper than any other green laser.

Helium–neon lasers operate continuously, and despite their low output power, they have the twin virtues of being

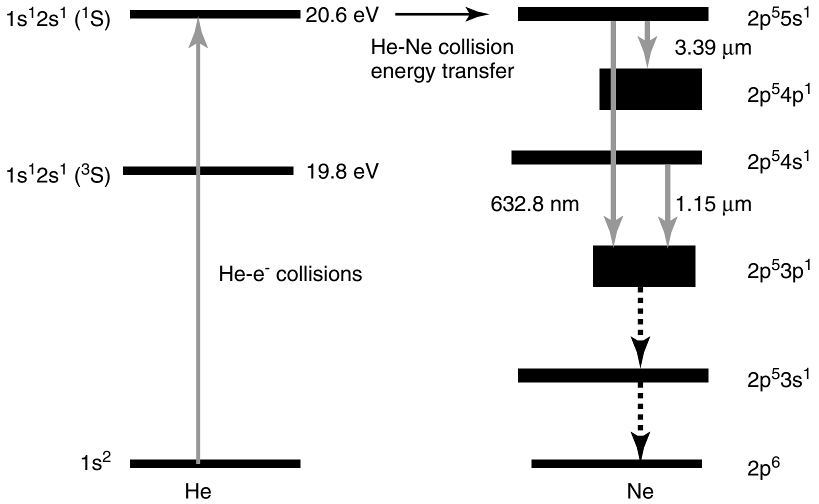

Fig. 18.7 Simplified energy levels involved in He–Ne lasing. The broadness of the levels is to indicate unresolved fine structure.

both small and relatively inexpensive. Consequently, they have more widely ranging applications than any other kind of laser. Their principal applications are those that hinge on the typically narrow laser beam width, where power is not very important. Another laser of similar type is the helium–cadmium laser, in which transitions of cadmium atoms result in milliwatt emission at 442 nm in the blue and 325 nm in the ultraviolet.

18.4.2
Argon and Krypton Lasers

The argon laser is the most common example of a family of ion lasers in which the active medium is a single-component inert gas. The gas, at a pressure of approximately 0.5 mbar, is contained in a plasma tube of 2–3 mm bore, and is excited by a continuous electrical discharge. Argon atoms are ionized and further excited by electron impact; the pumping process populates several ionic states. The population inversion between these states and others of lower energy results in emission at a series of discrete wavelengths over the range 350–530 nm (see Table 18.1), the two strongest lines appearing at 488.0 and 514.5 nm. These two wavelengths are emitted as the result of transitions from the singly ionized states with electron configuration $3s^2 3p^4 4p^1$ down to the $3s^2 3p^4 4s^1$ state. Further radiative decay to the multiplet associated with the ionic ground configuration $3s^2 3p^5$ then occurs, and the cycle is completed either by electron capture or by further impact excitation. Doubly ionized Ar^{2+} ions contribute to the near-ultraviolet laser emission.

Because several wavelengths are produced by this laser, dispersive optics are generally placed between the end mirrors to select one particular wavelength for amplification; the output can thus be varied. By selecting a single longitudinal mode, an output line width as small as 0.0001 cm^{-1} is obtainable. The pumping of ionic levels required for laser action requires a large and continuous input of energy, and the relatively low efficiency of the device means that a large amount of thermal energy has to be dissipated. Cooling is commonly achieved by the circulation of water in a jacket around the tube. The output power of a CW argon laser usually ranges from milliwatt emission up to about 25 W. Such lasers have found widespread research applications in spectroscopy, where they are often employed to pump dye lasers (see Section 18.5.5).

The other common member of the family of ion lasers is the krypton laser. In most respects, it is very similar to the argon laser, emitting wavelengths over the range 350–800 nm, although because of its lower efficiency the output takes place at somewhat lower power levels, up to around 5 W. The strongest emission is at a wavelength of 647.1 nm. In fact, the strong similarity in physical requirements and performance between the argon and krypton lasers makes it possible to construct a laser containing a mixture of the two gases, which provides a very good range of wavelengths across the whole of the visible spectrum – see Table 18.1. Such lasers emit different wavelengths useful for biomedical applications, the blue-green argon lines being especially useful in many biological applications.

Laser operation does not by itself automatically produce polarized light, although the output is commonly at least partially polarized as a result of

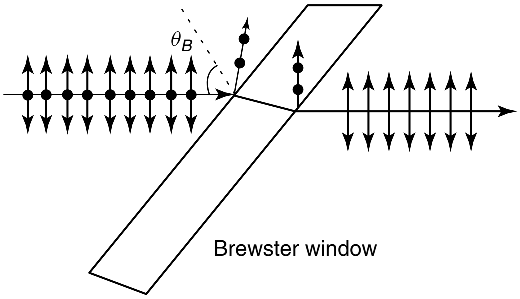

Fig. 18.8 Brewster angle laser window as used in a gas laser. Light polarized in the plane of the figure (double headed arrows) has a low reflection loss at the Brewster angle (θ_B) while light polarized perpendicular to the plane of the figure (indicated by dots) is highly reflected off both surfaces of the window. Only the polarization in the plane of the figure will be strongly amplified in the laser medium.

interactions with the numerous optical components. In these lasers (and others), it is desirable to obtain highly polarized emission, and it is usual to incorporate optics into the laser cavity to accomplish this. The standard method is to use a Brewster angle window. This is a parallel-sided piece of glass set at the Brewster angle, defined as $\theta_B = \tan^{-1} n$, where n is the refractive index of the glass for the appropriate wavelength. The Brewster angle is the angle at which reflected light is completely plane polarized. When such elements are used for the end windows of a gas laser tube, for example, one selected polarization experiences gain and is amplified within the cavity. Polarized emission thus ensues, as shown in Figure 18.8.

An alternative is to make use of an optically anisotropic or *birefringent* crystal such as calcite, in which orthogonal polarizations propagate in slightly different directions and can thus be separated. Calcite is a good example of such a material. Crystals of this type have a number of other important uses in controlling laser polarization; mostly, these stem from the fact that in such media, different polarizations propagate at slightly different velocities. By passing *polarized* light in a suitable direction through such a crystal, the birefringence effects a change in the polarization state, the extent of which depends on the distance the beam travels. With a slice of crystal of the correct thickness, plane polarized light thus emerges circularly polarized, or *vice versa,* and with a crystal of twice the thickness, plane polarized light emerges with a rotated plane of polarization, or circularly polarized light reverses its handedness. The two optical elements based on these principles are known as a *quarter-wave plate* and a *half-wave plate,* respectively. These optical elements can be used intracavity or external to the resonator.

18.5
Molecular Gas Lasers

18.5.1
Carbon Dioxide Laser

In the CO_2 laser, the energy levels involved in laser action are rotation–vibration levels, and emission therefore occurs at much longer wavelengths, well into the IR. The lasing medium consists of a mixture of CO_2, N_2, and He gas approximately in the ratio of partial pressures 1 : 4 : 5; the helium being added to improve the lasing efficiency. The sequence of excitation is illustrated in Figure 18.9. The first step is the excitation, by electron impact, of

various metastable rotational sublevels in the first vibrationally excited level of nitrogen. The rotational sublevels of one vibrationally excited state (001) of carbon dioxide (having one quantum of energy in the ν_3 vibration, the antisymmetric stretch) has almost the same energy as the vibrationally excited nitrogen. Consequently, collision between the two molecules results in very efficient transfer of energy to the CO$_2$. Laser emission then occurs by two routes, involving radiative decay to sublevels of the (100) and (020) states. The two laser transitions result in emission in bands centered on wavelengths at around 10.6 and 9.6 μm, respectively. Because various rotational sublevels can be involved in the emissive transitions, use of suitable optical elements enables the laser to be operated at various discrete frequencies within the 10.6 and 9.6 μm bands as listed in Table 18.2. Because the CO$_2$ energy level positions vary for different isotopic species, other wavelengths may be obtained by using isotopically substituted gas.

A small carbon dioxide laser, with a discharge tube about half a meter in length, may have an efficiency rating as high as 30%, and produce a continuous output of 20 W; even a battery-powered hand-held model can produce 10 W CW output. Much higher powers are available from longer tubes; although efficiency drops, outputs in the kilowatt range are obtainable from the largest devices. Apart from extending the cavity

length, another means used to increase the output power is to increase the pressure of carbon dioxide. Carbon dioxide lasers can be made to operate at or above atmospheric pressure. To produce sufficiently strong fields without using dangerously high voltages, it is necessary to apply a potential across, rather than along the tube; such a laser is referred to as a *transverse excitation atmospheric* (*TEA*) *laser*. In devices where the gas pressure is raised to around 15 atmospheres, pressure broadening results in the formation of a quasi-continuum of emission frequencies, enabling the laser output to be continuously tuned over a range of approximately 910–1100 cm^{-1}.

18.5.2
Nitrogen Laser

The nitrogen laser operates on electronic, rather than vibrational transitions. A high-voltage electrical discharge populates the $C^3\Pi_u$ triplet electronic excited state, and the laser transition is to the lower energy metastable $B^3\Pi_g$ state. The upper laser level has a very short lifetime of only 40 nanoseconds, and consequently population inversion cannot be sustained; essentially all the excited nitrogen molecules undergo radiative decay together over a very short period of time, effectively emptying the cavity of all its energy. This *super-radiant* emission is sufficiently powerful that a highly intense pulse is produced without the need for repeatedly passing the light back and forth between end mirrors. The laser automatically operates in a pulsed mode, producing pulses of about 10 nanoseconds or less duration at a wavelength of 337.1 nm. Bandwidth is approximately 0.1 nm, and pulse repetition frequency is 1–200 Hz. Pulses tend to have a relatively unstable temporal profile as a result of the low residence time of photons in the laser cavity. Because the laser can produce peak intensities in the 10^{10} Wm^{-2} range, the nitrogen laser is one of the most powerful commercial sources of ultraviolet radiation, and it is frequently used in photochemical studies. It has also been a popular choice as a pump for dye lasers, although here it is now often displaced by the more powerful wavelengths from excimer lasers or the second or third harmonics of the Nd : YAG laser.

18.5.3
Iodine Laser

Another laser operating on broadly similar principles is the iodine laser, more correctly termed as the *atomic iodine photodissociation laser*. Unusually, polyatomic chemistry is involved in its operation, but the crucial laser transition takes place in free atomic iodine, so that it is arguable whether or not it is truly designated as a molecular laser. The laser is activated by the photolysis of an iodohydrocarbon or iodofluorocarbon gas such as 1-iodoheptafluoropropane, C_3F_7I, by ultraviolet light from a flashlamp. The gas is introduced into a silica laser tube at a pressure of 30–300 mbar; the ensuing mechanisms are illustrated in Figure 18.10. Laser emission involves transition between an excited metastable $^2P_{1/2}$ state and the ground $^2P_{3/2}$ state of atomic iodine; this produces narrow line width output at a wavelength of 1.315 μm (7605 cm^{-1}), consisting of closely spaced hyperfine components encompassing a range of less than 1 cm^{-1}. In the absence of any other pulsing mechanism, the laser typically produces pulses of microsecond duration, and pulse energies of several joules; however the output is often modified by Q-switching or mode-locking (see Section 8) to produce pulse trains of nanosecond or subnanosecond duration.

An important advantage of the iodine laser is the fact that the active medium is comparatively cheap and available in large quantities. Moreover, its emission wavelength lies in a region offering excellent atmospheric transmission. One variation is a device known as the *chemical oxygen iodine laser*, in which collisional energy transfer occurs from electronically excited ($^1\Delta$) oxygen

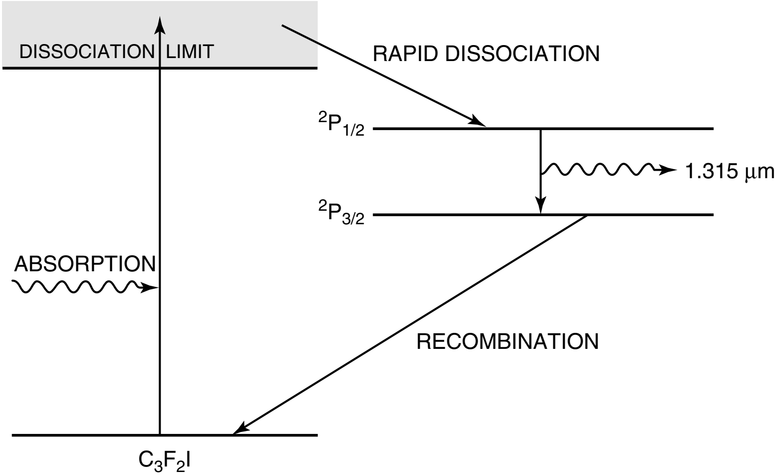

Fig. 18.10 Energetics of the atomic iodine photodissociation laser (not showing fine structure or side reactions).

molecules to atomic iodine, here formed by dissociation of molecular iodine, populates the $^2P_{1/2}$ state and so leads to the same 1.315 µm laser emission. By employing supersonically flowing gases, multikilowatt CW outputs can be achieved.

18.5.4
Excimer Lasers

In excimer lasers, the active medium is an *exciplex* or an excited complex. The crucial feature of an exciplex is that only when it is electronically excited, does it exist in a bound state with a well-defined potential energy minimum; the ground electronic state generally has no potential energy minimum, or else only a very shallow one. Most examples are found in the inert gas halides such as KrF. In principle, it is only homonuclear diatomics, such as Xe_2, that should be termed *excimers*, but in connection with lasers the designation is widely applied to heteronuclear systems. The exciplex is generally formed by chemical reaction between inert gas and halide ions produced by an electrical discharge. In the case of krypton fluoride, KrF, for example, the exciplex has a lifetime of about 2.5 nanoseconds. The decay transition can be stimulated to produce laser emission with a high efficiency, typically around 20%.

Excimer lasers are super-radiant, producing radiation with pulse durations of 10–20 nanoseconds and pulse repetition frequencies generally in the 1–500 Hz range. Pulse energies can be up to 1 J, with peak powers in the milliwatt region and average power between 20 and 100 W. The emission wavelengths of commercially available systems are: F_2 157 nm; ArF 193 nm; KrCl 222 nm; KrF 248 nm; XeCl 308 nm; XeF 351 and 353 nm. These short ultraviolet wavelengths lie in a region of the electromagnetic spectrum absorbed by a wide range of materials; photoabsorption often results in the rupture of chemical bonds and some degree of sample vaporization.

18.5.5
Dye Lasers

Dye lasers are essentially different from every other common category of laser. Major differences arise due to the unusual nature of the active medium, a solution of a chemically complex organic dye. A wide range of more than 200 dyes can be used for this purpose; the only general requirements are an absorption band in the visible and/or the ultraviolet, and a broad fluorescence spectrum. The kind of compounds that best satisfy these criteria consist of comparatively large polyatomic molecules with extensive electron delocalization. One of the most widely used systems is the dye known as *Rhodamine* 6G ($C_{28}H_{31}N_2O_3Cl$), whose broad absorption and fluorescence are shown in Figure 18.11.

Generally, the absorption of visible light first results in a transition from the ground singlet state S_0 to the energy continuum belonging to the first excited singlet state S_1. This is immediately followed by rapid radiationless decay to the lowest energy level within the S_1 continuum, as illustrated in Figure 18.12; in the case of Rhodamine 6G, this process is complete within 20 picoseconds of the initial excitation. Fluorescent emission then results in a downward transition to levels within the S_0 continuum, followed by further radiationless decay. It is the fluorescent emission process that has made the basis of laser action, provided a population inversion is set up between the upper and lower levels involved in the transition; this is essentially a four-level laser. Clearly, because the emitted photons have less energy, the fluorescence must always occur at longer wavelengths than the initial excitation.

One significant loss mechanism is quenching of the excited states through interaction with other molecules; triplet quenchers such as dimethylsulfoxide (DMSO) are often added to increase the output power by repopulating singlet

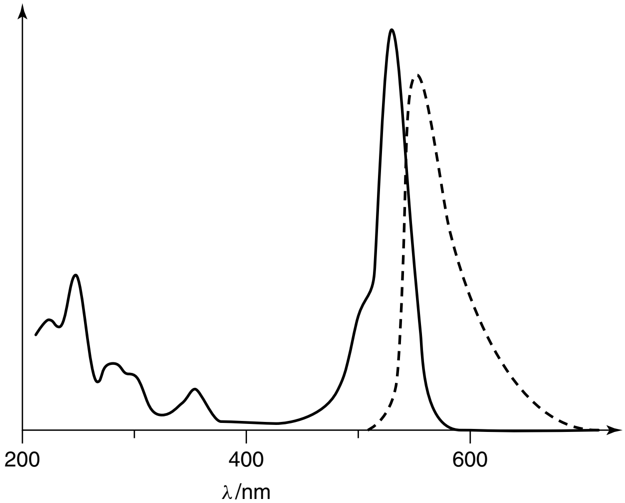

Fig. 18.11 Solution spectra of Rhodamine 6G in ethanol. The solid curve shows absorption and the dotted curve shows the fluorescence at longer wavelength.

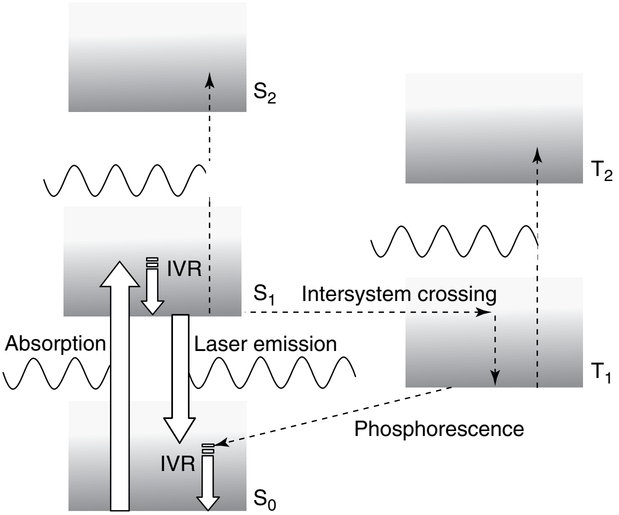

Fig. 18.12 Jablonski diagram for a laser dye. Solid vertical arrows show transitions involved in laser action; dotted arrows illustrate some competing transitions. IVR: intramolecular vibrational redistribution.

states. Another problem is the heat produced by the radiationless decay transitions, a necessary part of the laser cycle. This can rapidly degrade a dye, and therefore it is common practice to continuously circulate the dye solution, to facilitate cooling. A common setup is shown in Figure 18.13. The pump radiation from a flash-lamp, or primary laser source with emission in the visible or near-ultraviolet range, is focussed at a point traversed by a jet of dye solution, which typically has a concentration in the range 10^{-2}–10^{-4} mol 1^{-1}. The solvent is usually based on ethylene glycol, which provides the viscosity needed to maintain an optically flat jet stream.

Fluorescent emission from the dye jet is stimulated by the formation of an optical cavity, with two parallel end mirrors placed on either side of the jet. However, because the fluorescence occurs over a range of wavelengths, monochromatic laser emission can only be obtained by the use of additional dispersive optics within the cavity; rotation of this element can change the wavelength amplified within the dye laser, so that *tunable emission* is obtained. A dye laser based on a solution of Rhodamine 6G in methanol, for example, is continuously tunable over the range 570–660 nm. The full range of commercially available dye lasers provides complete coverage of the range 200 nm–1 μm: typical tuning curves for some of the more important dyes are shown in Figure 18.14.

The dye laser is often used as a means of providing continously tunable radiation Commonly, an inert gas or nitrogen laser is used as the pump, and the output is tunable over a range of wavelengths (determined by the choice of dye), all longer than the pump. The facility for tuning provides a very useful method of obtaining laser emission

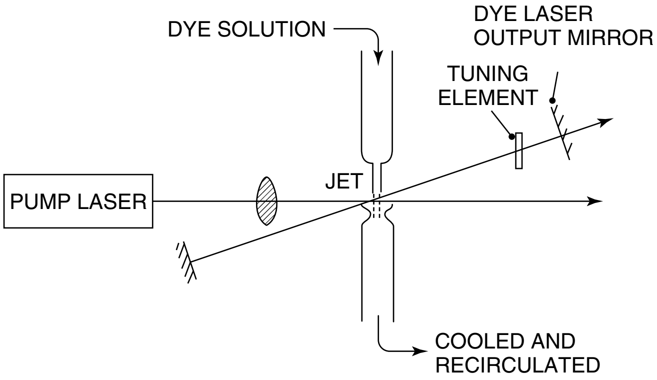

Fig. 18.13 Schematic diagram of a laser-pumped dye laser. (Adapted from Andrews (1997).)

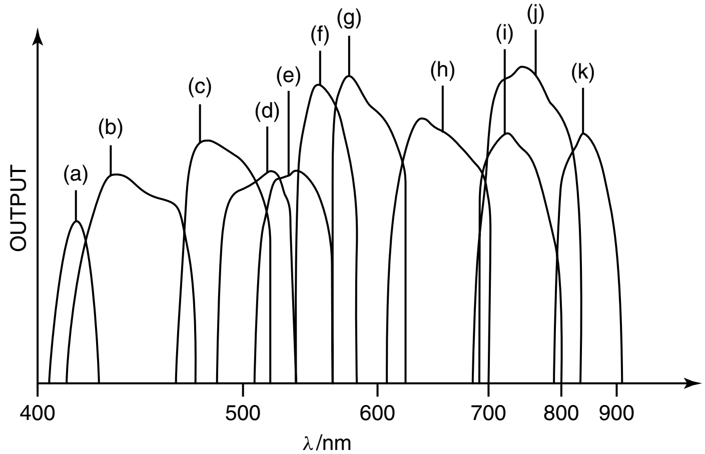

Fig. 18.14 Tuning curves for a dye laser pumped by lines from a krypton/argon laser. The dye and pump wavelength for each curve are given in Table 18.3. (Reproduced by kind permission of Coherent Radiation Ltd.)

at a chosen wavelength. Conversion efficiencies are generally somewhat low; 5–10% is common, although with certain dyes figures of 20% or more are possible. The highest powers are obtained by pumping with harmonics of a Nd laser. CW dye lasers produce emission with line width in the range 10–20 GHz (around 0.5 cm^{-1}), although with suitable optics this can be reduced to about 1 GHz. The combination of narrow line width, good frequency stability and tunability is particularly attractive for spectroscopic applications. One disadvantage of the dye laser is that it tends to have rather poorer amplitude stability than a gas laser, so that indirect spectroscopic methods such as fluorescence or the photoacoustic effect are often the most appropriate.

One important variation on the concept is the *ring dye laser*, in which the laser radiation travels around a cyclic route between a series of mirrors, rather than simply back and forth between two. When both clockwise and anticlockwise traveling waves are present, their frequencies are normally identical. However, any rotation of the laser itself results in a small difference between these two frequencies, and detection of this difference can be used as the basis for very accurate measurement of the rotation; this is the principle behind the ring laser gyroscope. Alternatively, an optical diode can be placed within the cavity to select one particular direction of propagation (clockwise or anticlockwise). In this case, the ring laser has an emission line width typically at least a factor of ten smaller than a conventional dye, but in state-of-the-art actively stabilized cases the line width may be as small as 10^{-15} cm^{-1}.

18.6
Pulsing Techniques

There are several reasons why it is common practice to make use of a pulsing device, either to convert a CW laser to pulsed output or to shorten the duration of the pulses emitted by a naturally pulsed laser. One objective is to obtain high peak intensities, to optimize multiphoton or other nonlinear optical processes. Another motive is to produce pulses of very short duration to make measurements of processes that occur on the same timescale. There are three widely used pulsing methods, reviewed below.

18.6.1
Cavity Dumping

Cavity dumping refers to a method of rapidly emptying a laser cavity of the energy stored within it. The simplest means of achieving this with a CW laser would be to have both of the end mirrors fully reflective, but with a third coupling mirror able to be switched into the beam to reflect light out of the cavity. This configuration would deliver a single pulse of light, terminating laser action until the coupling mirror was again switched out of the beam. In practice, an acousto-optic modulator is usually employed. This double-pass device is driven by a radio-frequency electric field, and generates an acoustic wave that produces off-axis diffraction of the laser beam. The cavity-dumped output of the laser in this case consists of an essentially sinusoidal temporal profile; the frequency of oscillation is twice the acoustic frequency of the cavity dumper, typically of the order of megahertz. This method of pulsing is often used in conjunction with mode locking (Section 18.6.3).

18.6.2
Q-Switching

The term *Q-switching* refers to a method that essentially involves first reducing, and then swiftly increasing the quality, or Q-factor of the laser, formally defined as $Q = 2\pi \times$ energy stored in cavity/energy loss per optical cycle (where the optical cycle length is the inverse of the resonant frequency). Q-switching thus represents the effect of suddenly reducing the rate of energy loss within the cavity. In practice, the pumping rate has to exceed the rate of spontaneous decay to build the required population inversion, and the time taken for Q-switching has to be sufficiently short to produce a single pulse. There are several commonly used methods. One of the most common is an electro-optical method based on a Pockels cell, which rapidly switches the cavity transmissivity of a selected polarization, effecting a shutter action when voltage is applied. A Pockels cell consists of a crystalline material such as potassium dihydrogen phosphate (KDP) that exhibits the Pockels effect, essentially a proportional change in refractive index on application of an electric field. A Pockels cell can be used to rotate the plane of polarization of light passing through it, or to reverse the handedness of circularly polarized light. However, its particular advantage is that, because the effect takes place only while the electric field is applied, modulation of the field at a suitable frequency results in the corresponding modulation of the beam polarization. The Q of the resonator can be *actively* switched from low to high when the Pockel cell is used in conjunction with a polarizer by applying a voltage to the Pockel cell. Pockel cells are also a particularly useful for increasing detection sensitivity in many techniques based on optical activity, such as polarimetry and circular differential Raman scattering.

Another common method for Q-switching involves the use of a *saturable absorber* dye such as cryptocyanine. With a cell containing a saturable absorber solution placed inside the laser cavity, the intensity of emission increases to a point where the dye is bleached only after a large population inversion has been achieved in the active medium; stimulated emission therefore results in the emission of a pulse of light. This last method of Q-switching is known as *passive*, because the switching time is not determined by external constraints. Q-switching generally produces pulses with a duration of the order of 10^{-9}–10^{-8} s.

18.6.3
Mode-Locking

The third, widely used method of producing laser pulses is known as *mode locking*. This produces pulses of much shorter duration than those produced by either cavity dumping or Q-switching, the output typically being measured on the picosecond or femtosecond scale and referred to as *ultrashort*. The technique has very important applications in chemistry in the study of ultrafast reactions, for example.

The mechanism of mode locking is as follows. Laser emission generally occurs over a small range of line frequencies within the emission line width of the active medium, separated $\Delta\nu = c/2L$, (the free spectral range, determined by the cavity length L), which is typically around 10^8 Hz. In the case of solid-state or dye lasers, where the fluorescence is broad, the number of longitudinal modes N sustained within the laser cavity may thus be as many as $10^3 - 10^4$ if frequency-selective elements are absent. Mode locking establishes a phase relationship that leads to constructive interference between all the modes at just one point, with destructive interference everywhere else. Consequently, a single pulse of travels back and forth between the end mirrors, giving a shot of output each time it encounters the output mirror. The pulse duration (the pulse-width at half power) is given by $\Delta t = 4\pi L/(2N+1)c$, and the interval between successive pulses is the cavity round-trip time. Hence, mode-locked pulses are typically separated by an interval of around 10 nanoseconds, and have a duration of $1 - 10$ picoseconds; the greater the number of modes, the shorter the pulse length, in accordance with Fourier principles. The temporal

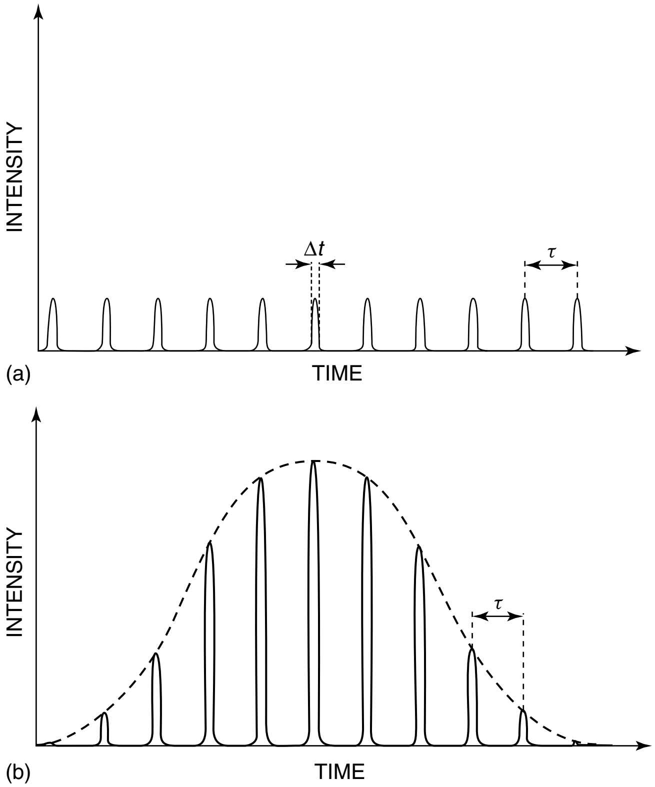

Fig. 18.15 Temporal profile of mode-locked emission from: (a) CW laser; (b) pulsed laser. In the second case, several pulses than illustrated would normally be found within the overall pulse envelope.

profile of the emission from mode-locked CW and pulsed lasers is as shown in Figure 18.15, and in each case consists of a pulse train. The instantaneous intensity of a mode-locked laser pulse can be readily computed on the assumption that the overall energy emitted within the duration of one laser round-trip is the same before and after mode-locking. Thus, with a pulse-length reduction from 10 nanoseconds to 1 picosecond, the pulse power can be increased by a factor of approximately 10^4, increasing the power of GW pulses up to the region of 10^{13} W.

As with Q-switching, there are several means of accomplishing mode-locking, both active and passive methods. The active methods generally involve modulating the gain of the laser cavity using an electro-optic or acousto-optic switch driven at the frequency $c/2L$. Passive mode-locking is generally accomplished with a saturable absorber cell – although, in the exceptional case of the titanium : sapphire laser, automatic mode-locking can be observed without the inclusion of any such element.

Another mode-locking technique principally employed with tunable dye lasers is *synchronous pumping*. Here, a mode-locked primary laser pumps a dye laser whose optical cavity length is adjusted to be equal to that of the pump, so that the round-trip time of the dye laser matches the interval between pump pulses. In this way, frequency-converted pulses propagating within the dye laser cavity arrive at the dye jet at the same rate as the pump pulses. The period over which amplification is effective in the dye laser is thus very short, and once again picosecond pulses emerge. In practice, the dye laser cavity length needs to be kept constant to within a few microns, so that special mounting and temperature control are necessary. Finally, there are various means by which pulse lengths can be reduced, as for example in *colliding-pulse* ring dye lasers.

18.6.4
Ultrafast Pulse Compression

Mode-locking commercially available lasers in conjunction with pulse compression techniques can now provide pulses of a few picoseconds duration in the infrared, and ultrashort pulses measured on the femtosecond (10^{-15}s) timescale in the UV/visible range. A common approach in generating ultrashort pulses is to first pass a longer pulse (on the order of 1–100 picoseconds) through an optical fiber to impose a chirp on the pulse carrier, and then compress the output using a dispersive delay line often made from two gratings (Figure 18.16).

A chirped pulse is one in which the wavelength of the carrier changes continuously throughout the pulse. A chirp

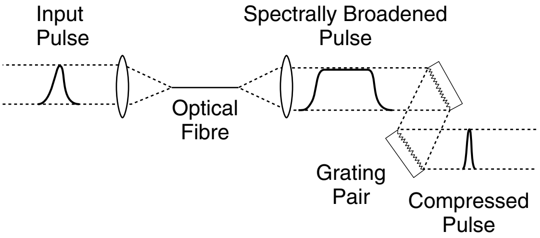

Fig. 18.16 Experimental arrangement used for pulse compression.

can occur in an optical fiber due to the nonlinear process of self-phase modulation, where the index of refraction of the fiber is instantaneously modified in the presence of an intense light pulse through the nonlinear optical Kerr effect (Monerie, 1989). This variation in the index of refraction produces a shift in the instantaneous phase of the pulse. The effect is that as the pulse passes through the fiber, its leading edge experiences a shift to lower frequencies, while its trailing edge experiences a shift to higher frequencies. In a normally dispersive medium, the front of the pulse will move faster than the back of the pulse, resulting in both a spectral and temporal broadening. The effect of the grating pair after the fiber is to produce a phase shift that is opposite to the chirp (Treacy, 1969). This compresses the output of the fiber. Geometrically, the phase shift is a result of time delays that arise because the optical path length due to Bragg diffraction off the gratings increases with increasing wavelength.

Early work using a fiber/grating pair combination yielded 30-femtosecond pulses at 619 nm, corresponding to 14 optical cycles (Shank *et al.*, 1982). More sophisticated arrangements involving prisms and diffraction gratings have led to pulses as short as 6 femtoseconds at 620 nm (Fork *et al.*, 1987). Recently, chirped mirrors have been developed, which have the same function as a grating pair (Steinmeyer, 2006). These are dielectric mirrors multilayered with low and high index coatings whose thicknesses increase monotonically from the surface to the substrate. The reflectivity of such a structure takes place at a depth within the mirror stack that depends on wavelength. This imposes a negative group delay on the pulse that compensates for any material dispersion in the laser system leading to ultrashort pulse generation.

18.6.5
Continuum Generation

It is a notable feature of ultrashort (picosecond) laser pulses that, on passage through certain media, a broad continuum of light is generated, typically covering a range of about 10 000 cm^{-1} of the laser frequency. The facility to produce such a broad continuum of light with such short duration has a number of distinctive uses, as for example in the flash photolysis study of ultrafast reactions. The light produced by this method, which results from a mechanism known as *self-phase modulation,* is referred to as an *ultrafast supercontinuum laser source* or as *picosecond continuum.* A typical spectral profile is shown in Figure 18.17. Such a source is an invaluable component of the instrumentation for ultrafast pump-probe spectroscopy.

18.7
Short Wavelength Coherent Radiation

18.7.1
Frequency Conversion

In tailoring the wavelength of laser output for different applications, a variety of methods can be utilized. One method involves the use of dye lasers, as discussed above. Another is Raman shifting, in which the stimulated Raman effect is employed for conversion to either shorter or longer wavelength. The latter process is

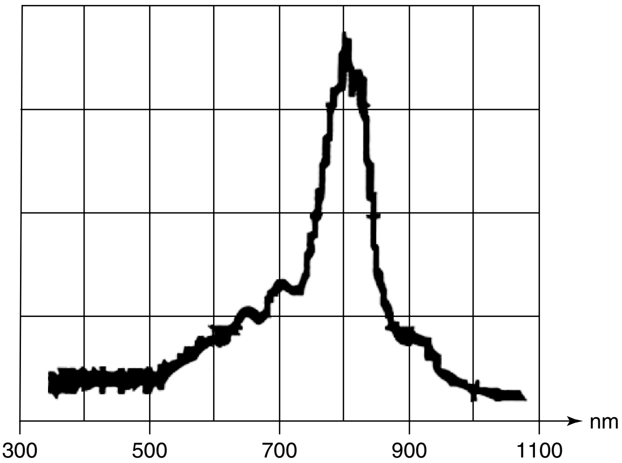

Fig. 18.17 Typical spectrum of the supercontinuum generated by a titanium : sapphire laser, drawn on a logarithmic vertical scale. (Redrawn from an original, courtesy of Coherent Laser Group.)

usually accomplished by the passage of the laser light through a suitable crystal or a stainless steel cell containing gas at a pressure of several atmospheres. Conversion efficiency for the principal Stokes shift to longer wavelength can be as high as 35%. The nature of the crystal or gas determines the frequency increment; $Ba(NO_3)_2$ gives a shift of 1047 cm^{-1}, while the most commonly used gases H_2, D_2, and CH_4 produce shifts of 4155, 2987, and 2917 cm^{-1} respectively. However, by far the most widely adopted method of frequency conversion involves frequency doubling.

18.7.2
Frequency Doubling

Frequency doubling is the best known example of a *nonlinear optical* process. The latter term refers to a wide range of frequency-conversion effects that are nonlinearly dependent on laser intensity, such that their conversion efficiencies are generally improved when laser power is increased. The energetics of frequency doubling (second harmonic generation) are illustrated in Figure 18.18.

Two photons of laser light with frequency ν are assumed to be absorbed by a substance in its ground state, and a single photon of frequency ν' is emitted through a return transition to the ground state. However, this process is parametric. The high intensity of electric field of the incident laser forces the electrons to oscillate in the ground state at the harmonic frequency. This induced nonlinear polarization is a source of *coherent* emission at the doubled frequency. As frequency doubling is a concerted process; there is no intermediate excited state with a measurable lifetime; hence, the energy-time uncertainty principle allows the process to take place regardless of whether there are energy levels of the substance at energies $h\nu$ or 2 $h\nu$ above the ground state. Indeed, it is usually better if there are not, because the presence of such levels can lead to competing absorption processes. Symmetry

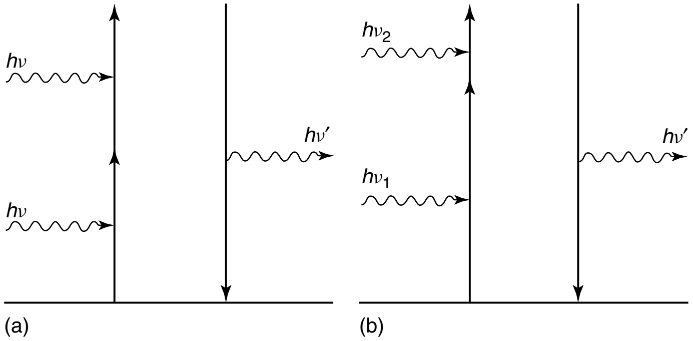

Fig. 18.18 Energetics of (a) frequency doubling, where the emitted photon has frequency $\nu' = 2\nu$, and (b) frequency mixing, where the emitted photon has frequency $\nu' = \nu_1 + \nu_2$.

considerations reveal that the frequency-doubling process can take place only in media that lack a center of symmetry – generally a noncentrosymmetric crystal is employed. Although liquids can very weakly generate second harmonics where their bulk symmetry is broken, a feature that can incidentally prove useful for the characterization of liquid surfaces, they are ineffective for efficient frequency conversion.

One singular advantage of harmonic generation is that it is a *coherent* process, so that with laser input the emission also has typically laserlike characteristics even though no population inversion was created in the material. To sustain coherence, however, it is necessary for the conversion process to conserve photon momentum. For harmonic emission in the forward direction, momentum is conserved only if the harmonic photons have wave vector $\mathbf{k}' = 2\mathbf{k}$, where $\mathbf{k}$ is the wave vector of the laser photons; this leads to a requirement for the refractive indices of the pump beam and the harmonic to be equal. Fulfillment of this wave-vector matching condition can only be accomplished in birefringent solids where refractive index is a function of the polarization and direction of propagation. Here, it is often possible to obtain index matching by careful orientation of the crystal. Refractive indices are often very heat sensitive, and fine control of the temperature is normally required; the crystal is accordingly mounted inside a temperature-controlled heating cell. Either the crystal orientation or its temperature can be varied for any particular incident wavelength, to achieve maximum efficiency. Conversion efficiencies may be as high as 20–30%, and under optimum conditions, it is still higher. Frequency doubling is particularly useful for generating powerful visible (532 nm) radiation using an infrared Nd laser pump. Two of the most widely used crystals are KDP (KH_2PO_4) and lithium niobate (Li_3NbO). The better choice for tunable UV generation is β-barium borate, with a transparency range of 190–3500 nm.

The generally high conversion efficiency of frequency doubling makes it possible to use a series of crystals to produce $4\times, 8\times, 16\times, \ldots$, the pump frequency, and so to obtain coherent radiation at very short wavelengths. Similarly, third harmonic generation (which can take place in either centrosymmetric or noncentrosymmetric media) can be used to generate 355 nm radiation from Nd : YAG sources. More commonly, however, suitable crystals can be used to generate odd harmonics (3×, 5×, 7×, etc.) by two-colour mixing (see below). Indeed 355 nm is usually generated in Nd: YAG systems by mixing 532 nm +1.06 micron light. For some spectroscopic applications, it is also significant, that, a doubling crystal coupled with a dye laser provides tunable emission over a range of wavelengths, below the operating wavelength of the pump.

18.7.3
Optical Parametric Oscillators

In frequency mixing, a variation of the frequency-doubling process permits a coupling between two beams of laser radiation with different frequencies to produce output at the sum frequency, as illustrated in Figure 18.18(b). Because wavelength is inversely proportional to frequency, the emitted wavelength is given by $1/\lambda' = 1/\lambda_1 + 1/\lambda_2$, hence shorter than either of the input wavelengths. A closely related application of nonlinear optics concerns the *optical parametric oscillator*, essentially a difference-frequency technique. Often the third harmonic at 355 nm from a Nd : YAG laser pumps the nonlinear crystal, placed along with suitable frequency-selective elements in a secondary cavity (as in a dye laser). The result is that two new frequencies (the signal and idler frequency) are formed whose sum equals that of the pump. Wide tunability and high conversion efficiencies can be obtained in the IR by this method because phase matching for a specific wavelength can be achieved by rotating the nonlinear crystal to specific angles with respect to the optic axis. The same principles can be applied in the visible and UV by the adoption of a different pump, such as one of the other harmonics of a Nd : YAG laser. For example, pumping beta-barium borate crystal, with fourth-harmonic 266 nm radiation, can produce tunable output covering the range 300 nm to 2.5 μm.

18.7.4
Frequency Tripling and Four-Wave Mixing

Higher order frequency mixing can be employed as means of generating shorter wavelength radiation. Two methods, which exploit third-order nonlinearities in centrosymmetric media (media where second order effects are absent), are nonresonant third harmonic generation, THG, and two-photon resonance enhanced four-wave mixing (Lipson, Shi and Lacey, 2002). The energy level schemes for these processes are shown in Figure 18.19. Radiation in the vacuum ultraviolet (VUV, $100\,\text{nm} \leq \lambda \leq 200\,\text{nm}$) or the extreme ultraviolet (XUV, $\lambda < 100\,\text{nm}$) can be obtained by using visible and UV fundamentals. Although technically the radiation produced by THG or four-wave mixing is not the result of a population inversion, the radiation has all the characteristics of a laser; namely, it is coherent, directional, monochromatic, and, even more significant for molecular spectroscopy, is widely tunable. There are no other "real" VUV or XUV laser sources that are competitive in this regard.

Nonresonant THG arises when intense lasers pulses at a frequency ν induce a nonlinear polarization in an atomic medium that acts as a source of radiation at 3ν. Solids and liquids

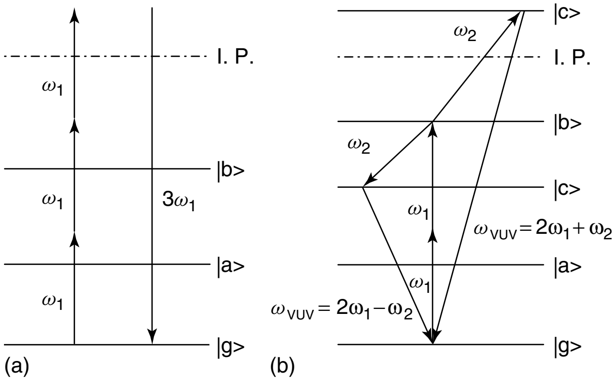

Fig. 18.19 Energetics of (a) frequency tripling, where the emitted photon has frequency $\omega' = 3\omega_1$, and (b) two-photon resonance-enhanced four-wave mixing, where the emitted photon has frequency $\omega' = 2\omega_1 \pm \omega_2$.

are usually never used as they become strongly absorbing below 200 nm. In almost all cases, pulsed lasers are used to generate the third harmonic radiation because its intensity is proportional to the cube of the input fundamental laser power, $P_\omega{}^3$. The medium must also be negatively dispersive; that is, the wave vector mismatch between the light at 3ν and the light at ν must be <0. This limits the tunability of the generated light to the red of allowed Rydberg ← ground state transitions in the medium. Still as shown in Figure 18.20, significant portions of the VUV and XUV can be covered using rare gases and Hg as nonlinear media. Typical conversion efficiencies range from 10^{-6} to 10^{-3}%, which while low, still translate into intense coherent VUV and XUV outputs given that commercially available dye lasers for example can readily provide fundamental beams with high peak powers (1–10 MW; ~10-nanosecond pulse durations). One particularly simple and popular source is VUV light at ~118 nm radiation generated by tripling the third harmonic of a Nd : YAG laser at 355 nm. Such a source can have wide applications in the soft-ionization of organic molecules, that is, ionization without fragmentation.

Two-photon resonantly enhanced four-wave mixing is a two-color third-order nonlinear process where one laser at frequency ν_1 is tuned to be in resonance with a two-photon allowed transition in a nonlinear medium. A second laser operating at ν_2 can be tuned to generate coherent radiation at the sum and difference frequencies $2\nu_1 \pm \nu_2$. The expression four-wave mixing indicates that three input waves generate a fourth output signal. The nonlinear output wavelengths lie in the VUV and XUV when using visible and UV fundamentals.

The coherent output radiation is widely tunable because there is no inherent restriction on the frequency ν_2. Phase matching for sum-frequency mixing requires the medium to be negatively dispersive. However, the medium can be either positively or negatively dispersive for four-wave difference mixing. Most atomic media that have been used for four-wave mixing

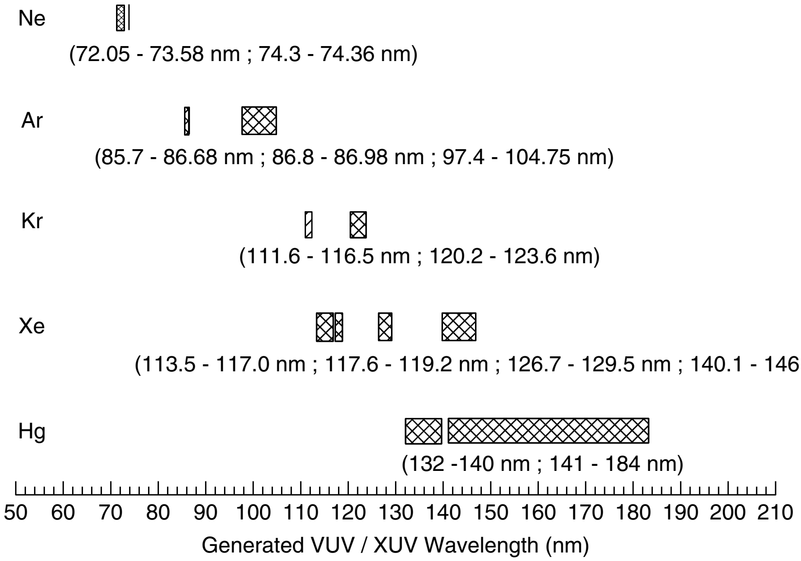

Fig. 18.20 VUV and XUV spectral tuning regions for nonresonant THG in Ne, Ar, Kr, Xe, and Hg.

are intrinsically negatively dispersive because the generated light lies higher in energy than the energy of the main resonance line of the medium, whereas the fundamental energies lie below.

Pulsed fundamental laser beams are almost always used since both sum- and difference-mixing scale as $P_1{}^2P_2$. The advantage of two-photon resonance enhanced four-wave mixing over nonresonant THG however, is that the third-order nonlinear susceptibility of the process can be enhanced many orders of magnitude by tuning one of the fundamental laser frequencies to be in resonance with a two-photon allowed transition in the nonlinear medium. In this way, intense VUV and XUV radiation can be generated with only moderate incident laser powers.

The tuning ranges available using Kr gas, Xe gas, Hg vapor and Mg vapor are shown in Figure 18.21. Metal vapors need to be generated at high temperatures, usually in heat pipes, while rare gas are easily handled in a gas cell. Rare gases have the additional advantage that they can also be expanded as supersonic expansions in a vacuum system. These gas jets are spatially localized and therefore can be supported in a windowless arrangement, provided the vacuum system has adequate differential gas pumping capacity. The elimination of windows is ideal for XUV generation as there are no broadly transmitting materials in these spectral regions.

18.7.5
Higher Order Harmonic Generation

The high intensities ($10^{13}-10^{16}$ W cm^{-2}) associated with femtosecond sources such as Ti : sapphire lasers can be used to extend the generation of short wavelength light into the soft X-ray region by

high-order harmonic generation. When the intensity of the input laser pulses is sufficiently high, electrons from a gas-phase atomic medium are ionized and begin to move away from the resultant ions at relativistic velocities. However, because the distance they travel is small within one or more laser periods, they still respond to the electric field by undergoing ponderomotive free space oscillation. Those electrons that recombine with the ions within a fraction of one optical cycle give up their energy as high order multiples of the input laser frequency. However, a plateau exists on the frequency of harmonic light that can be generated, which is determined by the ionization potential of the atom being ionized and the maximum kinetic energy of the recombining electron (Corkum, 1993). Remarkably, the pulse duration of the light generated by this strong field interaction is on the attosecond (10^{-18} s) timescale that provides new opportunities to probe complex electron dynamics in molecules and materials (Kapteyn *et al.,* 2007). The output efficiency scales with the gas density, and phase matching is approximately independent of the order of the process. Wavelengths as short as 2.7 nm have been generated in He using 26-femtosecond 800-nm pulses from a Ti : sapphire laser (Chang *et al.*, 1997). Coherent harmonic generation up to order 221 and shorter continuum range of wavelengths up to order 297 were resolved. The shortest wavelength lies within the "water window" region of X-ray transmission, making these sources useful for the study of biological samples.

18.7.6
Free-Electron Laser

The free-electron laser has a highly accelerated electron beam as its active medium. One of the most common experimental arrangements, illustrated in Figure 18.22, involves passing a beam of very high energy (10^7–10^8 MeV) relativistic electrons from the accelerator of a synchrotron ring between the poles of a series of regularly spaced magnets of alternating polarity called an *undulator*. The electrons are repeatedly accelerated and decelerated in a direction perpendicular to their direction of travel, resulting in an oscillatory path, as shown. The effect of this process is to produce emission of coherent *bremsstrahlung* radiation along the axis of the laser at a wavelength that depends on the periodicity of the undulator and the energy of the electrons. The radiation is then trapped between parallel mirrors and stimulates further emission.

High-energy electrons travel at an appreciable fraction of the speed of light, and can be characterized by a parameter f, denoting the ratio of their relativistic total energy to their rest-mass energy. If the magnet separation is d, then the laser emission wavelength is given by the simple formula $\lambda = d/2f^2$. Because the energy of the electrons emerging from the accelerator can be continuously varied, the result is again a laser with tuning capability. There is, in principle, no limit to the range of tuning right across the infrared, visible, and ultraviolet regions of the electromagnetic spectrum. Moreover, this kind of laser has been shown to produce high average powers and to be capable of a reasonable efficiency. For example, a setup in the Naval Research Laboratory in the USA. can produce 75 MW pulses of 4 mm radiation with an efficiency of about 6%. The efficiency in the visible and ultraviolet is generally lower. The downside of these devices is that they are expensive and require access to a large synchrotron facility.

Plans have been made to develop free-electron lasers that can operate in the soft and hard X-ray regions. For example, a second generation free-electron laser has been proposed for the BESSY beamline in Germany where a seed laser pulse copropagates with the electron bunch through the undulator to allow other laser sources to be synchronized for pump-probe experiments (Follath, 2007). The seed laser pulses at 51–1.24 nm are generated by higher harmonic generation of a tunable laser operating between 230 and 460 nm. Nonlinear interactions generate higher harmonics of the seed laser, and therefore additional insertion

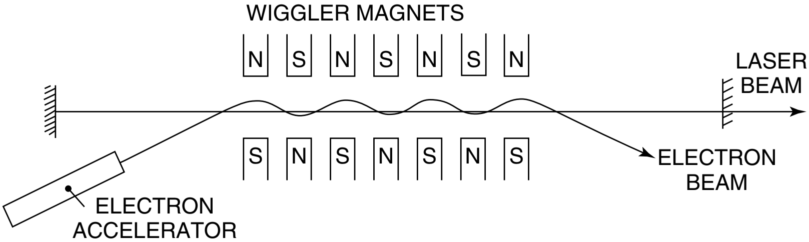

Fig. 18.22 Configuration of a free-electron laser.

devices are required to extract our one particular wavelength. Proof of principle of this approach has been realized by researchers at Brookhaven National Laboratory who demonstrated a high-gain harmonic-generation free-electron laser operating in the ultraviolet at 266 nm (Yu *et al.,* 2003).

18.7.7
Tabletop X-ray Lasers

Despite the obstacles inherent in generating a population inversion that can lead to gain in the X-ray region, there have been many notable successes (Rocca, 1999). While the field is too broad to cover in this article, it is worth noting that Rocca and coworkers have developed fixed-wavelength soft X-ray lasers that use fast pulsed discharge excitation of capillary channels to create plasmas that exhibit gain by collisional recombination. For example, this scheme was used to generate coherent radiation on the 46.9 nm 3p-3s ($J = 0-1$) line of Ne-like Ar (Rocca *et al.*, 1994). These lasers are attractive because of their small size, earning them the moniker "tabletop" devices.

INTRODUCTION

Laser technology deals with operation of lasers and the characterization and the use of their output beams. Although lasers are used in various kinds of systems that are important in various practical applications, only basic techniques are presented here. For more detailed descriptions on various kinds of lasers and application systems, the reader is advised to consult appropriate other articles of this Encyclopedia and the references listed at the end of the present article.

1. MEASUREMENT OF BASIC CHARACTERISTICS OF LASERS

1.1 Mode of Oscillation and Beam Divergence

Normally a laser is designed to operate in its fundamental TEM_{00} transverse mode so that an output beam having Gaussian intensity distribution is generated, although sometimes a higher-mode or mixed-mode output may be sought for some very specialized applications. In practice some amount of higher modes is mixed with the fundamental mode, and the beam pattern shows some deviation from the pure Gaussian distribution. Precise measurement of the beam pattern can be made by observing the intensity distribution of the cross section of the laser beam with a charge-coupled-device (CCD) camera and analyzing the two-dimensional pattern with a computer.

The Gaussian beam behaves just like a part of a spherical wave at a long distance from the beam waist, which is the point where the spot size of the beam has its minimum value. A beam waist corresponds to the focal point in geometrical optics and has a nonzero size because of diffraction of the light wave. The spot size of a Gaussian beam can be defined as

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

the radius of the contour of the spot where the intensity is $1/e^2$ of the peak value. When the beam is focused by a lens of focal length f, the minimum spot size, which shall be designated as d, is given by the relationship $d = f\theta$, where θ is the half-angle beam divergence in radians. For a Gaussian beam, θ is given by the equation

$$\theta = [(\lambda/\pi w_1)^2 + w_1^2/R_1^2]^{1/2}, \qquad (1)$$

where λ, w_1, and R_1 are the wavelength, the beam spot size, and the radius of curvature of the laser beam at the input face of the lens, respectively. In practice, it is convenient to make the second term negligibly small by making the input laser beam nearly parallel using a beam expander, which is an inverted Galilean telescope. In a practical laser beam the measured beam divergence is always larger than that given by (1) because of the presence of the higher modes.

In above discussion, we assumed axial symmetry of the laser beam. However, in some kinds of lasers, the active part of the laser medium strongly deviates from axial symmetry. The output beam of such lasers may not be axially symmetric. The typical example of such is the semiconductor diode laser: the active part of it is very thin in the direction perpendicular to the *pn* junction layer. The output of a diode laser reflects such a peculiar structure, showing an asymmetric diffraction pattern. The typical beam divergence of a diffraction-limited, single-mode diode laser is 10° in the direction parallel to the junction layer, and 30°–40° in the perpendicular direction. Because even such a large angular spread is due to diffraction, a single-mode diode laser output can be converted into a parallel axially symmetric beam by the use of properly designed optics.

1.2 Output Power

The absolute value of the average output power is normally obtained by a calorimeter. Let the laser beam or a well-defined part of it be absorbed by a body, the heat capacity of which is well known, for a known duration of time. The average power is determined by measuring the temperature rise of the body due to the absorbed laser energy. A more conventional method is to use a commercially available calibrated bolometer. In carrying out the measurement, care must be taken that the effective area of the detector is large enough to collect all the input beam, the absorption rate of the detector is well known, and the intensity of the laser-beam is not strong enough to burn the detector surface or to cause any nonlinear optical effect (which scatters part of the energy of the laser beam out of the detector as photons of a different wavelength).

In a pulsed laser, the output energy per pulse can also be measured by the same technique by knowing how many pulses are incident on the detector. The average output, which is directly measured by the bolometer, is also a very important quantity for many kinds of applications.

We assumed that only a coherent output beam is coming out of a laser in the above discussion. However, this is not true in most practical cases, and a typical laser output includes an incoherent part of amplified spontaneous emission in addition to the coherent output. In order to remove the incoherent part of the output beam, which is spread wide over the coherent beam, the use of a spatial filter is strongly recommended. This is a device with two focusing lenses aligned on the axis of the laser beam at a distance where the two lenses share a common focal point, at which a pinhole is placed so that only the focusable component of the laser beam is passed through.

It is important in designing a laser to eliminate the incoherent part of the output. In a high-gain laser such as rare-gas halide lasers it is especially important, and sometimes the incoherent portion exceeds the coherent portion in integrated energy. However, in lasers designed for some special applications in which uniform illumination of a surface is essentially important, the lasers are designed so as to make the output incoherent while still keeping the beam divergence small.

1.3 Temporal Brightness

The temporal brightness, which is defined as the output power per unit solid angle, is a very important physical quantity that specifies the output characteristics of lasers. The higher the brightness, the higher the intensity of the focused laser beam. When the output power of a laser is rapidly changing, simultaneous measurements of the instantaneous output power, which is expressed as $f(t)$, the integrated output power W, and the beam divergence θ for a given time interval t give the brightness of the beam $B(t)$ as follows:

$$B(t)=Cf(t)/\pi\theta^2, \tag{2}$$

where

$$C=W\Big/\int_0^t f(t)dt^{-1},$$

assuming that only the relative value of $f(t)$ is known. In the case where a time resolution of the order of 1 ns is sufficient, the instantaneous output power can be measured by detecting the relative value of the instantaneous intensity by a photodiode and displaying it on an oscilloscope. A high-speed streak camera provides a high time resolution up to the order of 1 ps. Those interested in subpicosecond resolution phenomena and their measurements should refer to the article ULTRAFAST PULSE PHENOMENA.

1.4 Spectral Brightness

Suppose that the output of a laser is stationary for the sake of simplicity. Although a laser beam is generally regarded as monochromatic light, the output energy of a laser is more or less spread in the frequency domain. By expressing the output power of a laser in a frequency domain $[\nu, \nu+d\nu]$ as

$$dI=I_0S(\nu)d\nu\,, \tag{3}$$

where I_0 is a constant, $S(\nu)$ is defined as the normalized spectroscopic brightness. The following techniques are the most standard ones to measure the spectroscopic brightness.

1.4.1 Grating Spectrometer and Fabry–Pérot Interferometer. For the measurement of a light source having rather broad spectral width and where a resolution of only 0.01 nm (12 GHz) or lower is needed, a conventional grating spectrometer is the most suitable measuring device. A Fabry–Pérot étalon (see INTERFEROMETERS AND INTERFEROMETRY) is appropriate to measure a spectral width of 30–1 GHz. It should be noted here that both of the above instruments are made for incoherent light sources, and one should remove the spatial coherence of the beam before using them. Because a rather long time interval is normally needed in measurements with the above two instruments, inserting a ground glass or a sheet of tissue paper in front of the monochromator slit or the Fabry–Pérot étalon is sufficient.

1.4.2 Scanning Confocal Fabry–Pérot Optical Spectrum Analyzers. Units having finesse of higher than 200 are commercially available, providing a versatile way to measure the power spectrum of coherent sources having spectral widths of a few megahertz to a few gigahertz.

1.4.3 Homodyne Detector and Electronic Spectrum Analyzer. When a resolution of better than a few MHz is needed, homodyne detection by the use of a photodiode as a mixer is convenient. The key to obtaining a good signal-to-noise ratio in mixing two coherent optical beams is to align the wave fronts of the two beams with high accuracy.

1.4.4 Autocorrelation Measurements. According to the Wiener–Khinchin theorem, the Fourier transform of the autocorrelation function of a signal gives its power spectrum, and the spectral brightness of a laser beam can be obtained by measuring its autocorrelation. That is, if we describe the normalized temporal evolution of a laser output by $f(t)$, the autocorrelation function, represented by $A(\tau)$, is defined by

$$A(\tau)=\int_{-\infty}^{+\infty} f(t+\tau)f^*(t)dt. \tag{4}$$

In principle, the spectral brightness is obtained by obtaining the experimental value of $A(\tau)$ by varying the delay time τ and then carrying out numerical Fourier transformation by a computer.

2. WAVELENGTH MEASUREMENTS

As the length standard is connected to the frequency standard by the speed of light, which is defined as $2.997\,924\,58\times10^8$ m/s, a laser wavelength measurement is equivalent to a laser frequency measurement. The wavelength of a laser relative to another is directly measured by comparing the interference fringes by the use of various types of interferometer arrangements.

2.1 Moving Michelson-Type Wavelength Meter

This most popular method essentially counts the number of fringes when one arm of a Michelson interferometer travels a known distance. The distance is normally measured by counting fringes made by another laser beam, the wavelength of which is established as a secondary standard (Hall and Lee, 1976).

A basic setup is schematically shown in Fig. 1. If the length of the fixed arm is l_1 and the movable one l_2, the difference in the optical path length for a round trip of the two arms is given by $2l_1-2l_2$, and interference of the two beams shows maxima when the following relationship holds:

$$2l_1-2l_2=n\lambda/2\ . \tag{5}$$

Therefore if two laser beams having respective wavelengths λ_1 and λ_2 are introduced to the interferometer at the same time separately and fringe counts of n_1 and n_2, respectively, are obtained for the same value of $2l_1-2l_2$, then we have

$$n_1\lambda_1/2=n_2\lambda_2/2\ . \tag{6}$$

If the wavelength of the one of the laser beams, for example, λ_1, is known, the other is given by

$$\lambda_2=(n_1/n_2)\lambda_1. \tag{7}$$

The technical difficulty in such a measurement is to move the end reflector M_2 smoothly without changing the direction of the reflected beam. The effect of an inevitable mechanical fluctuation of the moving reflector may be avoided by the use of a retroreflector such as a corner cube. Several wavelength standards are established on laser lines as listed in Table 1 by comparing their frequency with that of the cesium clock with a frequency chain method described below. The accuracy attained by this method ranges from a few parts in 10^7 to 10^8 for commercially available systems to a few parts in 10^{10} for the most elaborate laboratory systems.

2.2 Direct Frequency Comparison with Microwave Frequency Standard

This is not a conventional method to be applied in a routine measurement, but an elaborate way to establish secondary fre-

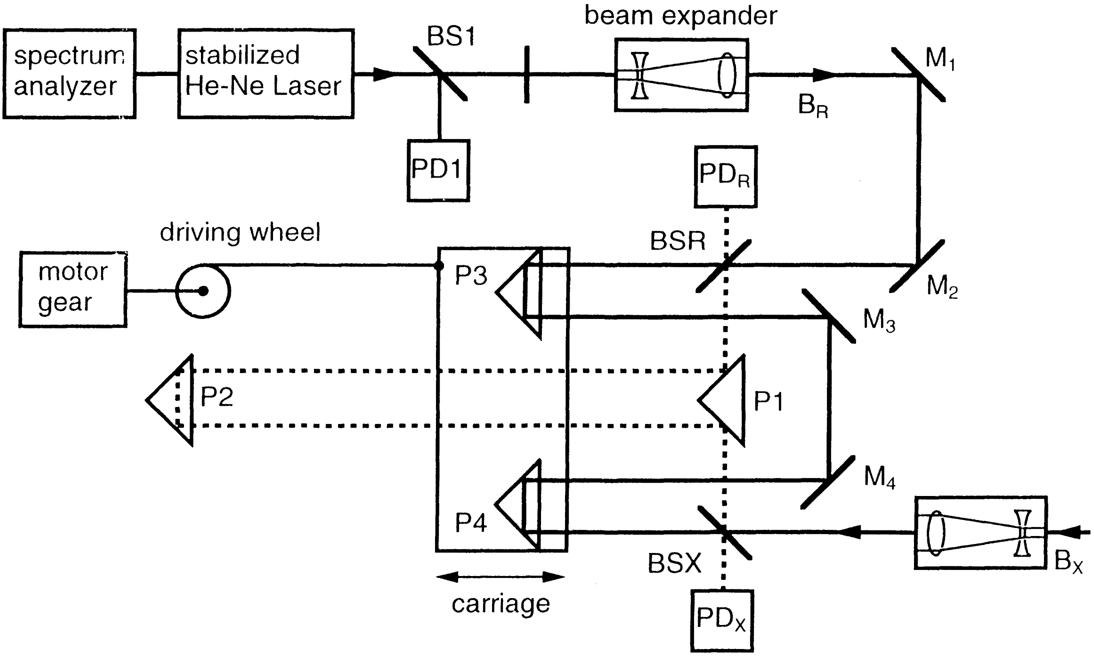

FIG. 1. A variation of the moving Michelson interferometer (Kowalski, *et al.*, 1977). The interference fringes of the reference and the sample beams are detected with PD_R and PD_X, respectively, as the carriage moves back and forth in the horizontal direction.

Table 1. Laser frequencies measured by direct comparison with calibrated microwave frequencies.

Atom or molecule	Frequency (THz)
HCN	0.890 760 550
H_2O	10.718 068 6
$^{12}C^{16}O_2$ *R*[20]	30.950 409
$^{12}C^{16}O_2$ *R*[22]	32.373 156
^{20}Ne (CH_4 *P*[7])	88.376 181 627[a]
^{20}Ne	196.780 372
^{20}Ne	260.103 264
$^{127}I_2$ [17–1 *P*(62)]	520.206 528[b]

[a] Frequency of the laser locked to the *P*[7] line of CH_4.

[b] Frequency of 17–1 *P*(62) transition of $^{127}I_2$ measured by the second harmonic of the 260-THz line of ^{20}Ne.

quency standards in optical region. Although the principle is to compare the higher harmonics of the microwave frequency standard with a laser frequency, direct comparison is impossible in the present state of art, and the frequency comparison chain must include several intermediate-frequency lasers ranging from far infrared to infrared. The frequencies of those lasers that have been determined by such a frequency comparison chain are tabulated in Table 1.

2.3 Fizeau Wavelength Meter

This is a method that can be used to determine the wavelength of a laser with pulsed output, in contrast to the two methods described above. As shown in Fig. 2, the principle is simply to compare the fringe separation observed by a Fizeau interferometer with that formed by a wavelength standard laser. The fringes can be counted by a photodiode array and the result is processed by a small computer. This is a versatile method to be used in the visible to near-infrared region, giving an accuracy of up to a few parts in 10^8.

3. MEASUREMENT OF THE CHARACTERISTIC PARAMETERS OF LASER MEDIA

The phenomenological characteristics of a laser medium are generally described by three parameters: small-signal gain, absorption coefficient, and saturation intensity, which will

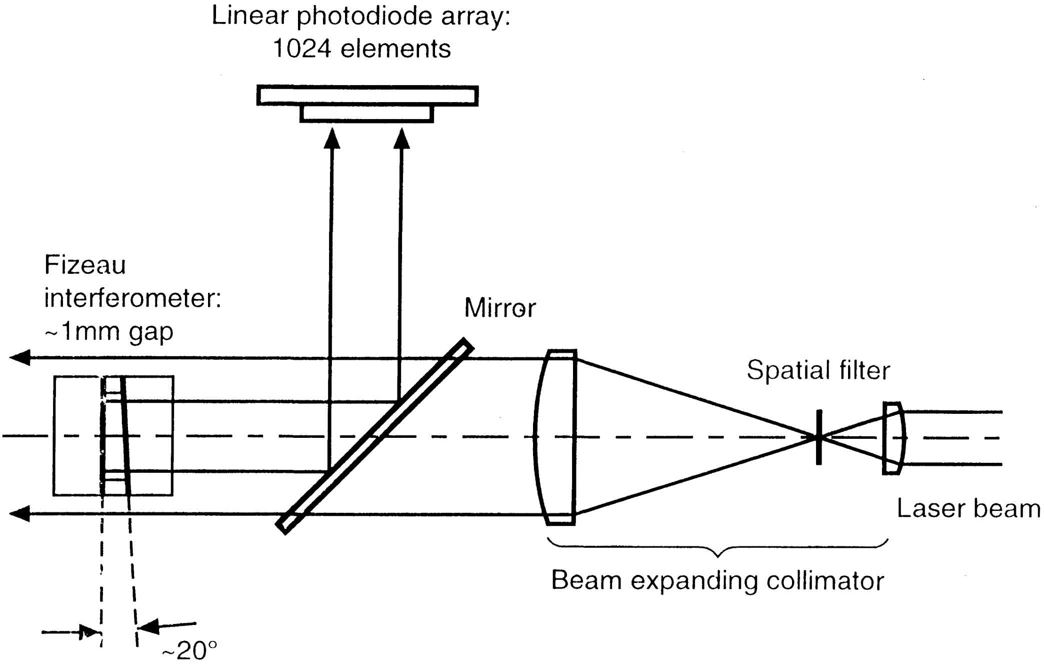

FIG. 2. Schematic diagram of the Fizeau-type wavelength meter (Snyder, *et al.*, 1977).

be designated by g_0, a, and I_S, respectively. The gain coefficient of the laser medium in operation with a laser radiation intensity of I is given by

$$g=\frac{g_0}{1+I/I_S} . \tag{8}$$

The effective gain coefficient, which is represented by g_e, is defined as

$$g_e=g-a . \tag{9}$$

Since the field intensity in the laser medium is dependent on the quality factor of the optical resonator, it is possible to determine the three constants by fitting the experimental values of the output obtained for various values of quality factor by replacing a set of reflectors that compose the resonator. However, the accuracy obtained by such measurements is rather poor, and they are not recommended if the following measurement is possible.

The most accurate determination of the above three amplifier constants can be made by realizing conditions under which the effective gain is expected to be constant in the medium. Such a condition is generally satisfied in the following three cases:

1. small-signal condition, that is, the input power is so small that saturation is negligible even after the laser beam has made a single excursion of the laser medium;
2. zero-gain condition, where the input power happens to make the saturated gain equal to the absorption coefficient, making the effective gain exactly zero; and
3. perfectly saturated gain condition, where the input gain is so large that the saturated gain is negligibly smaller than the absorption coefficient.

Figure 3 shows the output of an amplifier for a wide range of input intensity.

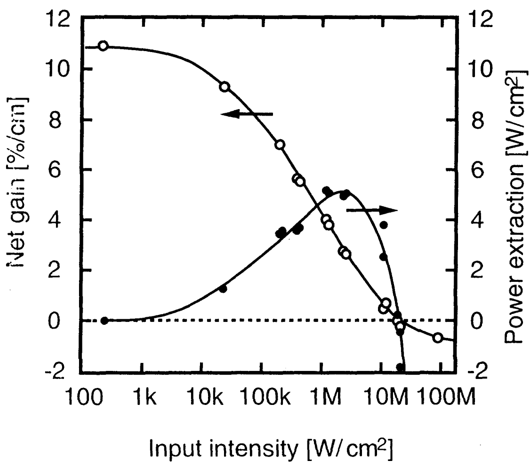

FIG. 3. An example of the output of a laser amplifier for a broad range of input intensity (Ueda and Takuma, 1987).

The small-signal condition may be checked easily by confirming the proportionality of the output and the input by making the input power level as low as possible, and g_0 is simply determined as the ratio of the output to the input power. The third condition is also defined accurately by confirming that the laser medium shows linear absorption by applying an extremely intense input power: the experimentally measured absorption coefficient under such a condition gives us the value of a with good accuracy. A good number of experimental runs with various input intensities may be needed, but in principle it is certainly possible to find the input power at which the saturated gain is exactly equal to the linear absorption and the zero effective gain condition is realized. Let us define such an intensity as I_n. Then we expect the following relationship to hold:

$$I_S=I_n/(g_0-a) , \tag{10}$$

which gives us the saturation intensity I_S from the values of g_0 and a obtained above. Thus the three key parameters can all be determined with a good accuracy.

Although the above method gives complete knowledge of the three characteristic parameters of an amplifier, it is not guaranteed that it can be applied to any laser medium. The measurement of gain under small-signal condition imposes the difficulty of obtaining a good signal-to-noise ratio in measuring the intensity of a laser beam at a very low power level. For some kinds of laser media, such a high intensity of input is needed to realize the third condition, and sometimes even the second condition, that the laser media are damaged by the laser beam, making accurate measurements impossible.

A typical example in which such measurements gave excellent results is the excimer lasers, especially the KrF laser, having high small-signal gain and rather low saturation intensity.

4. STABILIZATION OF THE LASER OUTPUT

Stabilization of the laser output is needed quite often when it is used in high-accuracy measurements. For some applications, stabilization of the output power of the laser source is needed. In many cases frequency stabilization of the laser output is needed.

4.1 Amplitude Stabilization

Amplitude stabilization can be accomplished by the use of a continuously variable attenuator and installation of a feedback loop to adjust the attenuation rate to make the output power of the attenuator constant. In practice, it can be accomplished easily when the laser beam is linearly polarized by a system as illustrated schematically in Fig. 4. The beam is passed through a Pockels cell that rotates the polarization plane of the beam in proportion to the increase of the output power. A polarizer placed behind the cell selects only the component having the same polarization as the original one. A small fraction of the output power is detected by a photodiode and the amplified detected signal is used to control the voltage applied to the Pockels cell.

The above method is the conventional way to obtain an amplitude-stabilized laser beam. However, one can expect to generate an amplitude-stabilized output directly from lasers or nonlinear devices by suppressing the amplitude noise. For example, a diode laser driven by a current-stabilized dc source shows amplitude squeezing at a pumping level much higher than the threshold value. This will be discussed in Sec. 5.3.

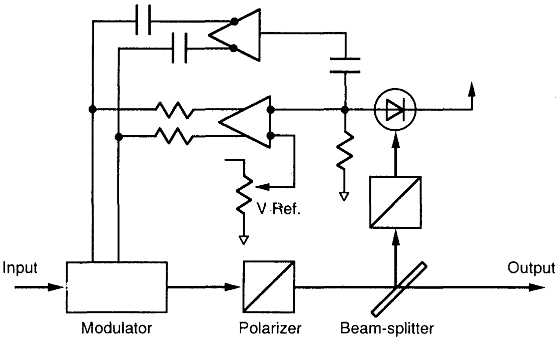

FIG. 4. Schematic diagram of an intensity stabilizer.

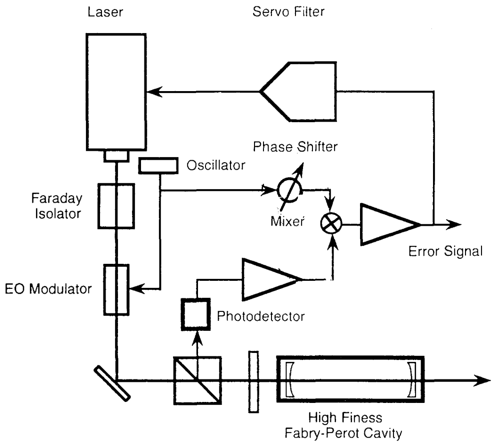

FIG. 5. Schematic diagram of a typical frequency-stabilized laser.

4.2 Frequency Stabilization

The general principle of laser frequency stabilization is to pass the laser beam through a frequency discriminator having a peak transmission or peak attenuation at a given frequency, and to control the laser frequency so that it always stays at the frequency defined by the frequency discriminator as schematically shown in Fig. 5. A Fabry–Pérot type optical resonator is widely used as the frequency discriminator, although it cannot be an absolute frequency standard unless it is calibrated with respect to some kind of absolute standard such as atomic or molecular spectral lines.

Recent progress in optical coating technology makes it possible to obtain low-loss, high-reflectivity reflectors, for example, 99.99% reflectivity and a few ppm loss, the use of which allows us to make a Fabry–Pérot resonator having a finesse of several hundred thousands by keeping a fairly high transmission rate for the beam of resonant frequency. The use of such an optical resonator gives us the possibility of controlling a laser frequency to be stabilized at a given frequency with subhertz accuracy. As a matter of fact, He-Ne lasers and laser-diode-pumped Nd:YAG lasers have been stabilized to a level of relative stability on the order of mHz, exceeding the theoretical limit of a free-running laser given by Schawlow and Townes. On the other hand, stabilization of absolute frequency involves several unknowns, such as the effect of heating of the mirror surface by the resonant radiation, the intensity of which is enhanced to an extremely high level in high-finesse resonator.

Stabilization of frequency-tunable lasers such as dye lasers, Ti sapphire lasers, or diode lasers poses difficult extra problems, such as keeping single-mode oscillation for a wide range of tuning. However, frequency stabilization up to the level of 1 MHz to 100 kHz can be realized rather easily even for those lasers.

5. SQUEEZING

According to the quantum mechanics of optical fields, uncertainties in the amplitude and phase are governed by the uncertainty relationships. That is, representing the root mean square deviations of the photon density and the phase as Δn and $\Delta\phi$, respectively, we have the relationship

$$\Delta n \, \Delta\phi \geqslant \tfrac{1}{2} \,. \tag{11}$$

This means that photon-density noise in the laser resonator can be suppressed by allowing the phase noise to increase. A normal laser oscillator generates coherent photons, which show equal uncertainty in the photon density and the phase. The process that generates photons having less uncertainty in the photon density is called *amplitude squeezing*, and that which generates less phase noise, *phase squeezing*.

Normal laser oscillation, which is built up from spontaneous emission, generates shot-noise–limited light. However, it is possible to generate squeezed-state photons by suppressing the fluctuations. The most commonly observed example is a semiconductor diode laser driven by a current-stabilized power source at a pump level much higher than its threshold. The general scheme to generate squeezed states is to use photon generation by nonlinear effects such as degenerate optical parametric oscillation, four-photon mixing, second-harmonic generation, or the stimulated Raman effect. An experimental setup for squeezed-state generation by a degenerate parametric oscillator is shown in Fig. 6. In this mechanism, the generated photons have a strong correlation with the pumping waves, and this is the key to generation of the squeezed state. Therefore quantum noise included in the pumping wave such as spontaneous emission tends to destroy the squeezed state. This makes experimental generation of the squeezed states difficult.

The common method to detect the squeezed state is a balanced homodyne detector as shown schematically in Fig. 7. The detected signal changes periodically with the phase of the local oscillator, and squeezing appears as the minimum detected noise being much less than the noise of the coherent photons.

The use of squeezed-state photons gives us the possibility of obtaining high sensitivity or accuracy in optical measurements. In practice, a squeezed state is easily destroyed by introducing loss or spontaneous emission, and so high precaution is needed. Even so, improvement in signal-to-noise ratio has been reported in a spectroscopic measurement.

6. MANIPULATION OF LASER BEAMS

6.1 *Q* Switching

In many laser applications, only a short pulse with high peak power is needed. In such cases, *Q* switching provides a convenient way of generating a pulse of a few to a few tens of nanosecond duration by extracting a large portion of the stored energy of the laser medium. A normal laser pumped by a pulsed source exhibits pulsed oscillation, generating pulses of the laser beam reflecting the temporal behavior of the pumping source. In such an oscillation, the population inversion is limited by the induced emission. However, if the laser oscillation is suppressed by inserting a loss in the laser cavity, an inverted population much higher than the threshold value can be built up. Then the cavity loss is suddenly

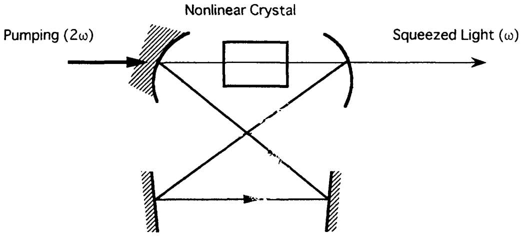

FIG. 6. Schematic diagram of a degenerate optical parametric oscillator that generates a squeezed output.

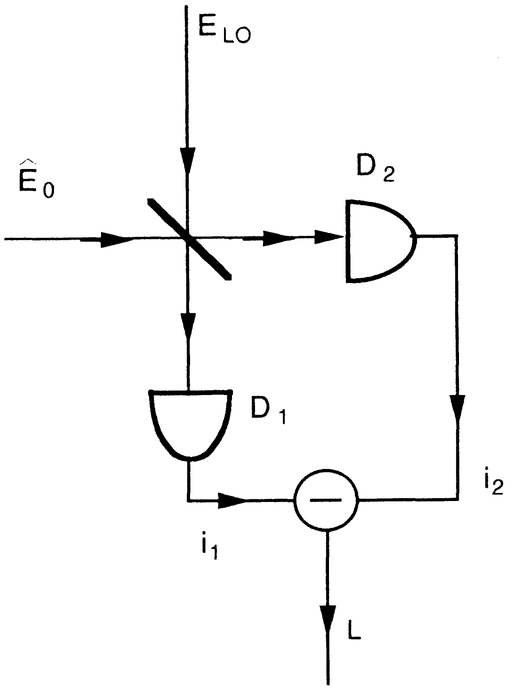

FIG. 7. Optical homodyne detector for detection of squeezed light. E_0 and E_{LO} stand for the sample beam and the reference beam, respectively. L stands for the local frequency output. D_1, D_2: detectors.

removed, and the energy stored in the medium as the inverted population can be extracted in a short time by building up the laser radiation. Such devices are often called *Q*-switched lasers and are widely used when a concentration of laser energy in a short time interval is needed.

As a *Q*-switching device, that is, a very fast shutter installed in a laser cavity, the Pockels cell is most frequently used in solid-state lasers. The laser is constructed in a way so that only linearly polarized light can be built up in the cavity by inserting a polarizer in the laser cavity, for example, and the Pockels cell rotates the direction of polarization 90° for the laser photon, making a round trip. Thus the oscillation of the laser is stopped until the population inversion reaches its maximum value by pulsed pumping and then the voltage applied on the Pockels cell is suddenly turned off. The laser radiation is built up rapidly by intense stimulated emission due to a large density of population inversion.

6.2 Modulation and Switching of Laser Beams

Many methods for laser applications require modulation or turning off and on the laser beams. There are two methods of frequency or phase modulation of laser beams. One is the acousto-optical modulator, which shows high modulation efficiency for frequencies lower than 100 MHz. However, only the electro-optical modulator is suitable for high-frequency modulation, although it is difficult to obtain high modulation efficiency.

An acousto-optical modulator consists of a transducer attached to a low-loss optical material having a high acousto-optical coefficient such as $PbMoO_4$, which is transparent to visible and near-infrared radiation. A supersonic wave is generated and propagates through the acousto-optical material in the direction perpendicular to the laser beam, and the latter is diffracted by a density grating made by the acoustic wave. The diffracted beam of the first order is frequency shifted by an amount equal to the frequency of the acoustic waves. The diffraction efficiency is approximately proportional to the power of the acoustic waves and can be higher than 50%.

For a frequency higher than 100 MHz, electro-optical modulation is the only method applicable at present. Electro-optical materials such as $LiNbO_3$ and $LiTaO_3$ have relatively high electro-optical coefficients and are most frequently used for such purpose. The electro-optical materials change their refractive indices when an electric field is applied. In most cases the electric field is applied in the direction perpendicular to the propagation direction of the laser beam and therefore the phase of the laser beam is shifted by an amount proportional to the applied electric field. The electro-optical modulator can be used as a fast intensity modulator and switching device having a high extinction rate. For more details, refer to OPTOELECTRONIC DEVICES and MODULATORS AND DEMODULATORS.

6.3 Optical Harmonic Generation

Second or higher-order harmonics of a laser beam can be generated in nonlinear optical materials. Second-harmonic generation is possible only in a medium that does not have point symmetry. Therefore piezoelectric crystals are good candidate nonlinear materials for second-harmonic generation. The intense electric field of the laser induces dipoles that oscillate at second or higher harmonics of the original frequency. The conversion efficiency is proportional to the nonlinear polarizability.

The second order nonlinear polarization, which we shall designate as $\mathbf{P}_2$, can be represented as follows when a plane wave of angular frequency ω is propagating in the z direction:

$$\mathbf{P}_2=\chi^{(2)}(\mathbf{E}_0e^{i\omega t-ikz})^2=\chi^{(2)}\mathbf{E}_0^2e^{2i\omega t-2ikz}, \quad (12)$$

where $\chi^{(2)}$ is the second-order nonlinear susceptibility of the medium. The above equation shows that the polarization wave of angular frequency 2ω propagates in the medium in the same direction as the fundamental laser beam with wave number $2k$. On the other hand, the wave number of the electromagnetic wave of angular frequency 2ω in the medium, which shall be represented by $k_{2\omega}$, is not equal to $2k$ because of dispersion of the medium. Thus special care must be taken in order to obtain phase matching between the polarization wave and the electromagnetic wave of the second-harmonic frequency.

The phase-matching condition can be established by the use of birefringence of anisotropic crystals. That is, in a negative uniaxial crystal, for example, one may be able to find an angle θ in refractive index space for which

$$n_e^{2\omega}(\theta)=n_o^{\omega}, \quad (13)$$

where the left-hand side represents the index of refraction of the extraordinary ray at angular frequency 2ω in the direction at an angle θ with the optical axis, and the right-hand side the index of refraction of the ordinary ray at ω. In a positive uniaxial crystal, the roles of extraordinary ray and ordinary ray should be exchanged.

The angle θ changes as a function of temperature of the crystal and the frequency of the laser beam, and it is sometimes possible to find a temperature at which the above condition is satisfied for $\theta=2\pi$. Such a case is sometimes called temperature phase matching, and is preferentially applied in the case where the phase matching is obtained at a temperature that the crystal can be easily kept at.

By choosing an appropriate nonlinear crystal, the efficiency of the second-harmonic generation can be made higher than 75% for a pulsed laser beam having high temporal spectroscopic brightness. For a continuously oscillating laser, high-efficiency generation of the second harmonic is rather difficult. The efficiency can be improved significantly in such a case by placing the nonlinear crystal in an optical cavity that is resonant at the laser frequency.

Generation of harmonics higher than the second can normally be done only with low efficiency. The efficiency can be improved greatly, but is still much lower than that of the second harmonic, by selecting a medium in which some resonance effect can be expected. In spite of the low efficiency that one expects in the high-order harmonic generation, it is useful for generating coherent radiation at extremely short wavelengths.

INTRODUCTION

The atoms that comprise a crystal are constantly executing small vibrations about equilibrium positions that form a structure periodic in each of three mutually perpendicular directions. At nonzero temperatures these atomic vibrations are due to thermal fluctuations in the crystal, while at the absolute zero of temperature they are due to the zero-point motion of the atoms that is associated with the quantum-mechanical uncertainty principle.

The vibrations of the atoms in a crystal play a significant role in many physical properties of the crystal. In insulating crystals, the thermodynamic, optical, elastic, and transport properties are determined by these atomic vibrations. Even in metallic and semiconducting crystals, in which the conduction electrons contribute to each of these properties, the contribution from the atomic vibrations is a significant part of the total.

The discussion of the vibrational properties of a crystal is based on the assumption that the potential energy of the crystal is a function of the instantaneous positions of the atoms in it. Because the displacements of the atoms from their equilibrium positions, as they oscillate about them, are small compared with the distance between nearest-neighbor equilibrium positions, the potential energy can be expanded in powers of these small displacements. The linear terms in this expansion are absent, since the expansion is about an equilibrium configuration. If the expansion is terminated at the terms quadratic in the atomic displacements, we have what is called the *harmonic approximation* to the potential energy. The higher-order terms in the expansion of the potential energy in powers of the atomic displacements, of third, fourth, ... order, constitute the *anharmonic* terms in the potential energy. In many cases these anharmonic terms contribute quantitative and qualitative corrections to physical properties of a crystal that are already calculated with good accuracy in the harmonic approximation, such as the thermodynamic functions. These corrections are usually small enough that they can be obtained by perturbation theory. However, as in the case of thermal expansion, they can also give rise to effects that have no counterpart in the harmonic approximation. Nevertheless, the harmonic approximation is generally a very good first approximation to the calculation of a vibrational property of a crystal, and serves as the starting point for perturbative calculations of anharmonic effects. (The exceptions to these statements are quantum crystals, e.g., solid helium, which we will not consider here.) Consequently, in what follows most of our discussion will be based on this approximation, and the effects of the anharmonic terms in the potential energy of a crystal will be discussed only briefly.

Although in principle the vibrational contribution to a physical property of a crystal can be calculated by considering the motions of the individual atoms in it, it turns out to be simpler, and physically more transparent, to exploit the special nature of the harmonic approximation—viz., that the potential energy is a positive-definite quadratic form in the

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

atomic displacements—to reformulate the calculation in such a way that the given physical property is expressed as the sum of contributions from collective motions of *all* the atoms in a crystal. Each of these collective motions, called a *normal vibration mode* of the crystal, is a phased linear superposition of the vibrations of the individual atoms, each with the same frequency, and is independent of all the other normal modes of the crystal. The number of these normal modes is equal to the number of degrees of freedom in the crystal. The statistical properties of the normal modes are central to the way in which they contribute to a given physical property of the crystal. In this article we describe these statistical properties, and their consequences, in particular for the thermodynamic and transport properties of a crystal.

1. DYNAMICS OF A CRYSTAL LATTICE

Let us consider an infinite crystal that is periodic in three mutually perpendicular directions. The equilibrium position of the κth atom in the lth primitive unit cell is given by the vector

$$\mathbf{x}(l\kappa)=\mathbf{x}(l)+\mathbf{x}(\kappa). \tag{1}$$

In this equation the vector $\mathbf{x}(l)$ is

$$\mathbf{x}(l)=l_1\mathbf{a}_1+l_2\mathbf{a}_2+l_3\mathbf{a}_3, \tag{2}$$

where l_i $(i=1,2,3)$ is an integer, and $\mathbf{a}_i$ $(i=1,2,3)$ are the primitive translation vectors of the crystal. $\mathbf{x}(l)$ defines the equilibrium position of the lth unit cell with respect to the origin of coordinates, chosen to coincide with one of the lattice sites. The vector $\mathbf{x}(\kappa)$ $(\kappa=1,2,\ldots,r)$ gives the positions of the r atoms in the unit cell relative to the equilibrium position of the latter. The volume of a primitive unit cell is given by $v_0=\mathbf{a}_1\cdot(\mathbf{a}_2\times\mathbf{a}_3)$.

The thermal motion of the atoms of the crystal consists of small displacements of all the atoms from their equilibrium positions, and we denote the displacement of the atom $(l\kappa)$ by $\mathbf{u}(l\kappa)$. The momentum of this atom will be denoted by $\mathbf{p}(l\kappa)$.

The total kinetic energy of the crystal can be expressed in the form

$$T=\sum_{l\kappa\alpha}\frac{p_\alpha^2(l\kappa)}{2M_\kappa}, \tag{3}$$

where M_κ is the mass of the atom of type κ, and $\alpha=x,y,z$. The total potential energy Φ of the crystal is a function of the instantaneous positions of all the atoms. It can be expanded in a series of powers of the displacements $\mathbf{u}(l\kappa)$ of the atoms from their equilibrium positions,

$$\Phi=\Phi_0+\sum_{l\kappa\alpha}\Phi_\alpha(l\kappa)u_\alpha(l\kappa)+\frac{1}{2}\sum_{l\kappa\alpha}\sum_{l'\kappa'\beta}\Phi_{\alpha\beta}(l\kappa;l'\kappa')u_\alpha(l\kappa)u_\beta(l'\kappa')+\cdots \tag{4}$$

where

$$\Phi_\alpha(l\kappa)=\left(\frac{\partial\Phi}{\partial u_\alpha(l\kappa)}\right)_0,$$

$$\Phi_{\alpha\beta}(l\kappa;l'\kappa')=\left(\frac{\partial^2\Phi}{\partial u_\alpha(l\kappa)\partial u_\beta(l'\kappa')}\right)_0,\quad \text{etc.} \tag{5}$$

The approximation in which the expansion (4) contains only terms through second order in $\mathbf{u}(l\kappa)$ is called the *harmonic approximation.* The terms neglected, of higher order in $\mathbf{u}(l\kappa)$, are called *anharmonic.* They are neglected because of their smallness.

From the definition (5) for $\Phi_\alpha(l\kappa)$ we see that it has the physical meaning of the negative of the force acting in the direction α on the atom $(l\kappa)$ when all the atoms of the crystal are at their equilibrium positions. Since in equilibrium no net force can be exerted on any atom, we must have

$$\Phi_\alpha(l\kappa)\equiv 0. \tag{6}$$

The Hamiltonian of the crystal $H=T+\Phi$ in the harmonic approximation therefore has the form

$$H=\Phi_0+\sum_{l\kappa\alpha}\frac{p_\alpha^2(l\kappa)}{2M_\kappa}+\frac{1}{2}\sum_{l\kappa\alpha}\sum_{l'\kappa'\beta}\Phi_{\alpha\beta}(l\kappa;l'\kappa')u_\alpha(l\kappa)u_\beta(l'\kappa'). \tag{7}$$

The coefficients $\{\Phi_{\alpha\beta}(l\kappa;l'\kappa')\}$ are called *atomic force constants.*

From their definition, Eq. (5), the atomic force constants possess the symmetry property

$$\Phi_{\alpha\beta}(l\kappa;l'\kappa')=\Phi_{\beta\alpha}(l'\kappa';l\kappa). \tag{8}$$

In addition, they are subject to restrictions that are imposed by the invariance of the potential energy against rigid-body translations and rotations of the crystal, which are expressed by (Maradudin *et al.*, 1971, pp. 8–10)

$$\sum_{l'\kappa'} \Phi_{\alpha\beta}(l\kappa;l'\kappa')=0, \tag{9}$$

$$\sum_{l'\kappa'} \Phi_{\alpha\beta}(l\kappa;l'\kappa')x_{\gamma}(l'\kappa') = \sum_{l'\kappa'} \Phi_{\alpha\gamma}(l\kappa;l'\kappa')x_{\beta}(l'\kappa'), \tag{10}$$

respectively. Finally, the symmetry and structure of a crystal impose further restrictions on the atomic force constants. The most important of these for our purposes in this article is a consequence of the periodicity of the equilibrium crystal structure. The potential energy (4) cannot change under a displacement of this structure through any of the vectors $\mathbf{x}(l)$ given by Eq. (2). This has the consequence that the atomic force constants $\{\Phi_{\alpha\beta}(l\kappa;l'\kappa')\}$ depend on the cell indices l and l' only through their difference,

$$\Phi_{\alpha\beta}(l\kappa;l'\kappa')=\Phi_{\alpha\beta}(l-l',\kappa;0\kappa') \tag{11a}$$

$$=\Phi_{\alpha\beta}(0\kappa;l'-l,\kappa'). \tag{11b}$$

Additional restrictions on the atomic force constants due to the symmetry of a crystal are discussed on pp. 10–14 of Maradudin *et al.* (1971).

From Hamilton's equations of motion that follow from Eq. (7),

$$\dot{u}_{\alpha}(l\kappa)=\partial H/\partial p_{\alpha}(l\kappa) \tag{12a}$$

$$\dot{p}_{\alpha}(l\kappa)=-\partial H/\partial u_{\alpha}(l\kappa), \tag{12b}$$

we immediately obtain the classical equations of motion of the atoms of the crystal,

$$M_{\kappa}\ddot{u}_{\alpha}(l\kappa)=-\sum_{l'\kappa'\beta} \Phi_{\alpha\beta}(l\kappa;l'\kappa')u_{\beta}(l'\kappa). \tag{13}$$

The solution of the system of equations (13) can be simplified if we exploit the periodicity of the equilibrium crystal structure expressed through Eqs. (11). Since the infinite crystal is periodic, it is natural to seek a solution of the system (13) in the form of a traveling wave,

$$u_{\alpha}(l\kappa)=\frac{u_{\alpha}(\kappa)}{\sqrt{M_{\kappa}}}\exp[i\mathbf{k}\cdot\mathbf{x}(l)-i\omega t], \tag{14}$$

where $\mathbf{k}$ is its wave vector, ω is its frequency, and the amplitude $u_{\alpha}(\kappa)$ is independent of l. On substituting Eq. (14) into Eqs. (13) we obtain as the equation for the $\{u_{\alpha}(\kappa)\}$

$$\omega^2 u_{\alpha}(\kappa)=\sum_{\kappa'\beta} D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})u_{\beta}(\kappa'), \tag{15}$$

where the matrix $D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})$ does not depend on the index l, and is equal to

$$D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})=\frac{1}{\sqrt{M_{\kappa}M_{\kappa'}}}\sum_{l'} \Phi_{\alpha\beta}(l-l',\kappa;0\kappa') \times\exp\{-i\mathbf{k}\cdot[\mathbf{x}(l)-\mathbf{x}(l')]\}. \tag{16}$$

In contrast with the system of equations (13), which is a system of an infinite number of equations in an infinite number of unknowns, the system (15) consists of $3r$ equations for each value of the wave vector $\mathbf{k}$. This result is due to the fact that the force constants $\{\Phi_{\alpha\beta}(l\kappa;l'\kappa')\}$ depend on l and l' only through their difference.

The solvability condition for the system of equations (15) is the vanishing of its determinant:

$$|D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})-\omega^2\delta_{\alpha\beta}\delta_{\kappa\kappa'}|=0. \tag{17}$$

Equation (17) is an equation of degree $3r$ in ω^2. We will denote the $3r$ solutions for each value of $\mathbf{k}$ by $\omega_j^2(\mathbf{k})$, where $j=1,2,...,3r$. From its definition (16) the matrix $D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})$ can be shown to be Hermitian. From this it follows that all of its eigenvalues $\omega_j^2(\mathbf{k})$ are real, while the frequencies $\omega_j(\mathbf{k})$ themselves can be either purely real or purely imaginary. The stability of the crystal translates into the requirement that all the frequencies $\omega_j(\mathbf{k})$ be real. The $3r$ functions $\omega_j^2(\mathbf{k})$ for each value of $\mathbf{k}$ can be regarded as the branches of a multivalued function $\omega^2(\mathbf{k})$. Equation (15) can therefore be rewritten in a form that makes the dependence of the frequency ω and of the corresponding eigenvector $\mathbf{u}(\kappa)$ on the wave vector $\mathbf{k}$ and branch index j explicit,

$$\omega_j^2(\mathbf{k})u_{\alpha}(\kappa|\mathbf{k}j)=\sum_{\kappa'\beta} D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})u_{\beta}(\kappa'|\mathbf{k}j). \tag{18}$$

The relation

$$\omega=\omega_j(\mathbf{k}) \tag{19}$$

is called the *dispersion law* for the vibrations of the crystal. Of the $3r$ solutions of Eq. (18) for each value of $\mathbf{k}$, three go to zero as $\mathbf{k}$ goes to zero. This can be seen as follows. On setting $\mathbf{k}=0$ in Eqs. (16) and (18), and dividing the latter by $\sqrt{M_\kappa}$, we obtain

$$\omega_j^2(\mathbf{0})\,\frac{u_\alpha(\kappa|\mathbf{0}j)}{\sqrt{M_\kappa}}=\frac{1}{M_\kappa}\sum_{l'\kappa'\beta}\Phi_{\alpha\beta}(l\kappa;l'\kappa')\times\frac{u_\beta(\kappa'|\mathbf{0}j)}{\sqrt{M_{\kappa'}}}. \tag{20}$$

If for each of the three values β can assume, viz., x, y, and z, $u_\beta(\kappa'|\mathbf{0}j)/\sqrt{M_{\kappa'}}$ is independent of κ', then in view of Eq. (9) we find that the right-hand side of Eq. (20) vanishes, implying the vanishing of $\omega_j^2(\mathbf{0})$. Thus we have three solutions for $\omega_j^2(\mathbf{k})$, one for each of the coordinate axes, that vanish with vanishing $\mathbf{k}$. From the form of Eq. (14) at $\mathbf{k}=0$ we see that the condition that $u_\alpha(\kappa|\mathbf{0}j)/\sqrt{M_\kappa}$ be independent of κ means that all r atoms in a primitive unit cell move in parallel and with equal amplitudes, which corresponds to a rigid-body displacement of the entire crystal. The three branches of $\omega^2(\mathbf{k})$ that vanish as $\mathbf{k}\to\mathbf{0}$ are termed *acoustic modes,* because the same property is shared by the frequencies of a continuous elastic medium. The remaining $3r-3$ solutions, which do not go to zero as $\mathbf{k}$ goes to zero, are called the frequencies of *optical modes.* The latter name is due to the fact that an electromagnetic wave incident on the crystal can interact only with the $\mathbf{k}=0$ modes whose frequencies are nonzero, and are generally in the far-infrared region of the optical spectrum.

The frequencies $\{\omega_j(\mathbf{k})\}$ belonging to the $3r$ branches of the vibrational spectrum possess the important property that they are even functions of $\mathbf{k}$,

$$\omega_j(-\mathbf{k})=\omega_j(\mathbf{k}). \tag{21}$$

For we see from Eq. (16) that

$$D_{\alpha\beta}(\kappa\kappa'|-\mathbf{k})=D^*_{\alpha\beta}(\kappa\kappa'|\mathbf{k}). \tag{22}$$

Consequently, if we replace $\mathbf{k}$ by $-\mathbf{k}$ in Eq. (18), and take the complex conjugate of the resulting equation, we obtain

$$\omega_j^2(-\mathbf{k})u^*_\alpha(\kappa|-\mathbf{k}j)=\sum_{\kappa'\beta}D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})\times u^*_\beta(\kappa'|-\mathbf{k}j), \tag{23}$$

where we have used the fact that $\omega_j^2(\mathbf{k})$ is real because $D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})$ is a Hermitian matrix. Thus $\omega_j^2(-\mathbf{k})$ and $\omega_j^2(\mathbf{k})$ are eigenvalues of the same matrix. With no loss of generality we can equate $\omega_j^2(-\mathbf{k})$ and $\omega_j^2(\mathbf{k})$, even for values of $\mathbf{k}$ at which degenerate eigenvalues occur, which leads to Eq. (21).

To each of the $3r$ values of $\omega_j(\mathbf{k})$ corresponds a vector $u_\alpha(\kappa|\mathbf{k}j)$ whose components are the solutions of Eq. (18). The homogeneous equations (18) define $u_\alpha(\kappa|\mathbf{k}j)$ to within an arbitrary constant factor. This factor can be chosen in such a way that $u_\alpha(\kappa|\mathbf{k}j)$ satisfies the orthonormality and closure conditions

$$\sum_{\kappa,\alpha}u^*_\alpha(\kappa|\mathbf{k}j)u_\alpha(\kappa|\mathbf{k}j')=\delta_{jj'}, \tag{24a}$$

$$\sum_{j}u^*_\alpha(\kappa|\mathbf{k}j)u_\beta(\kappa'|\mathbf{k}j)=\delta_{\alpha\beta}\delta_{\kappa\kappa'}. \tag{24b}$$

We have not yet specified the values that the wave vector $\mathbf{k}$ introduced in Eq. (14) can assume. They are clearly determined by the boundary conditions imposed on the atomic displacements $\{\mathbf{u}(l\kappa)\}$. The most convenient boundary conditions, which preserve the simplicity of the theory developed so far, are obtained if we subdivide the infinite crystal into "macrocrystals," parallelepipeds whose edges are defined by the vectors $L\mathbf{a}_1, L\mathbf{a}_2, L\mathbf{a}_3$, where L is a large number, of the order of 10^8, and which thus contain $L^3=N$ primitive unit cells. Any one of these macrocrystals can be regarded as the physical crystal whose properties we are studying. We then postulate that the atomic displacements are periodic with the periodicity of the macrocrystals. These conditions on the displacements are called the *cyclic boundary conditions* (Born and Huang, 1954, pp. 45–46). An equivalent set of boundary conditions require that in a finite crystal the atoms at corresponding points on opposite faces of the crystal move in exactly the same way. These conditions are called *periodic boundary conditions,* and are due to Born and von Kármán (1912, 1913).

Applied to the displacements given by Eq. (14), the cyclic boundary conditions require that

$$\exp(i\mathbf{k}\cdot L\mathbf{a}_1)=\exp(i\mathbf{k}\cdot L\mathbf{a}_2)=\exp(i\mathbf{k}\cdot L\mathbf{a}_3)=1. \tag{25}$$

To satisfy these conditions we introduce the translation vectors of the lattice reciprocal to the direct lattice defined by the vectors $\{\mathbf{x}(l)\}$:

$$\mathbf{G}(h)=h_1\mathbf{b}_1+h_2\mathbf{b}_2+h_3\mathbf{b}_3, \tag{26}$$

where h_i $(i=1,2,3)$ is an integer, and the primitive translation vectors of this *reciprocal lattice* $\mathbf{b}_i$ $(i=1,2,3)$ are defined by the set of equations

$$\mathbf{a}_i\cdot\mathbf{b}_j=2\pi\delta_{ij}. \tag{27}$$

Then from the result which follows from Eqs. (2), (26), and (27) that

$$\mathbf{x}(l)\cdot\mathbf{G}(h)=2\pi(l_1h_1+l_2h_2+l_3h_3)=2\pi(\text{integer}), \tag{28}$$

we see that we can write the vector $\mathbf{k}$ that satisfies Eqs. (25) as

$$\mathbf{k}=\frac{1}{L}\mathbf{G}(h)=\frac{h_1}{L}\mathbf{b}_1+\frac{h_2}{L}\mathbf{b}_2+\frac{h_3}{L}\mathbf{b}_3. \tag{29}$$

The values of the integers $\{h_i\}$ are no longer unrestricted, however. From Eqs. (14) and (28) we see that adding to $\mathbf{k}$ any translation vector $\mathbf{G}(h)$ of the reciprocal lattice leaves the value of $\mathbf{u}(l\kappa)$ unchanged. This means that all the distinct solutions to Eq. (18) are obtained if we restrict $\mathbf{k}$ to lie in one unit cell of the reciprocal lattice:

$$\mathbf{k}=\frac{h_1}{L}\mathbf{b}_2+\frac{h_2}{L}\mathbf{b}_2+\frac{h_3}{L}\mathbf{b}_3,$$

$$h_1,h_2,h_3=0,1,2,\ldots,L-1. \tag{30}$$

Thus, there are $L^3=N$ values of $\mathbf{k}$ allowed by the cyclic boundary conditions. Since there are $3r$ solutions of Eq. (18) for each value of $\mathbf{k}$, we see that the macrocrystal has as many vibration frequencies $\{\omega_j(\mathbf{k})\}$ as it has degrees of freedom.

A related consequence of Eq. (28) is that the dynamical matrix $D_{\alpha\beta}(\kappa\kappa'|\mathbf{k})$ defined by Eq. (16) is unchanged if we add to the wave vector $\mathbf{k}$ any reciprocal-lattice vector $\mathbf{G}(h)$. It follows that the normal-mode frequency $\omega_j(\mathbf{k})$ possesses the same property: $\omega_j(\mathbf{k})=\omega_j(\mathbf{k}+\mathbf{G}(h))$. Thus, all the distinct normal-mode frequencies are obtained by restricting $\mathbf{k}$ to one unit cell of the reciprocal lattice.

In practice, it is more convenient to restrict the allowed values of the wave vector $\mathbf{k}$ to the *first Brillouin zone* of the lattice defined by the vectors $\mathbf{a}_1$, $\mathbf{a}_2$, $\mathbf{a}_3$, rather than to a unit cell of the reciprocal lattice. The first Brillouin zone is obtained by drawing vectors from the origin of the reciprocal lattice to all the points of that lattice and constructing the planes that are the perpendicular bisectors of these vectors. The smallest volume containing the origin that is enclosed by these planes is the first Brillouin zone. It has the same volume as a primitive unit cell of the reciprocal lattice, and so contains the same number N of allowed values of $\mathbf{k}$ as the latter does, and it is invariant under the operations of the crystal class to which the crystal belongs. In what follows, therefore, sums over the wave vector $\mathbf{k}$ will be understood to be over those N values allowed by the cyclic boundary conditions that are contained in the first Brillouin zone.

In most calculations the precise values that $\mathbf{k}$ is allowed to have are not important. What is important is that they are distributed uniformly and densely throughout the Brillouin zone with a density equal to $V/(2\pi)^3$, where $V=Nv_0$ is the volume of the crystal. Thus, in sums over $\mathbf{k}$ we can treat $\mathbf{k}$ as a continuous variable and replace summation by integration according to

$$\sum_k f(\mathbf{k})=\frac{V}{(2\pi)^3}\int d^3k f(\mathbf{k}), \tag{31}$$

where the integration is over the volume of the first Brillouin zone.

Since the rather artificial cyclic boundary conditions on the atomic displacements have been adopted primarily for reasons of mathematical convenience, it has to be shown that the calculation of extensive vibrational properties of the crystal is insensitive to the imposition of these or any other boundary conditions. If this were not so, it would be virtually impossible to develop a theory of crystalline vibrations that possesses any degree of generality. Such a demonstration was given by Ledermann (1944), who showed that in the limit of large N the distribution of vibration frequencies of a crystal is affected negligibly by the assumption of any particular boundary conditions in the case that the range of the interatomic forces is finite. Subsequently, Hardy (1962) provided a justification for the use of the cyclic boundary conditions in calculations of extensive properties of ionic or polar crystals, in which the constituent atoms or ions interact through long-range Coulomb forces.

2. QUANTIZATION OF CRYSTAL VIBRATIONS

The vibrational Hamiltonian of a crystal,

$$H=\sum_{l\kappa\alpha}\frac{p_\alpha^2(l\kappa)}{2M_\kappa}+\tfrac{1}{2}\sum_{l\kappa\alpha}\sum_{l'\kappa'\beta}\Phi_{\alpha\beta}(l\kappa;l'\kappa')\times u_\alpha(l\kappa)u_\beta(l'\kappa'), \qquad (32)$$

is the sum of quadratic forms in the displacement components $\{u_\alpha(l\kappa)\}$ and in the conjugate momenta $\{p_\alpha(l\kappa)\}$. It can be diagonalized if we introduce the following expansions of $u_\alpha(l\kappa)$ and $p_\alpha(l\kappa)$ in traveling plane waves:

$$u_\alpha(l\kappa)=\frac{1}{\sqrt{NM_\kappa}}\sum_{\mathbf{k}j}u_\alpha(\kappa|\mathbf{k}j)\left\{\frac{1}{2}\,[q(\mathbf{k}j)+q(-\mathbf{k}j)]+\frac{1}{2}\left[\frac{i}{\omega_j(\mathbf{k})}\,\{\mathbf{p}(\mathbf{k}j)-p(-\mathbf{k}j)\}\right]\right\}e^{i\mathbf{k}\cdot\mathbf{x}(l)}, \qquad (33a)$$

$$p_\alpha(l\kappa)=\frac{1}{\sqrt{NM_\kappa}}\sum_{\mathbf{k}j}u_\alpha(\kappa|\mathbf{k}j)\left\{\frac{1}{2}\,[p(\mathbf{k}j)+p(-\mathbf{k}j)]+\frac{1}{2}\left[\frac{i}{\omega_j(\mathbf{k})}\,\{q(\mathbf{k}j)-q(-\mathbf{k}j)\}\right]\right\}e^{i\mathbf{k}\cdot\mathbf{x}(l)}. \qquad (33b)$$

In these expansions the quantities in square brackets are real displacements and momenta, corresponding to waves propagating with the wave vector **k**. In the new variables $p(\mathbf{k}j)$ and $q(\mathbf{k}j)$ the diagonalized Hamiltonian becomes the sum of the energies of independent harmonic oscillations,

$$H=\frac{1}{2}\sum_{\mathbf{k}j}[p^2(\mathbf{k}j)+\omega_j^2(\mathbf{k})q^2(\mathbf{k}j)]. \qquad (34)$$

In going from Eq. (32) to Eq. (34) we have used the result that

$$\sum_l e^{i\mathbf{k}\cdot\mathbf{x}(l)}=N\Delta(\mathbf{k}), \qquad (35)$$

where

$$\Delta(\mathbf{k})=\begin{cases}1 & \text{if } \mathbf{k}=\mathbf{G}(h),\\ 0 & \text{otherwise.}\end{cases} \qquad (36)$$

The vibrations described by the Hamiltonian (34) are called *normal modes,* and the corresponding coordinates $q(\mathbf{k}j)$ and momenta $p(\mathbf{k}j)$ are called *normal coordinates.* They are related by $p(\mathbf{k}j)=\dot{q}(\mathbf{k}j)$.

The Hamiltonian (34) is written in a form that permits a straightforward transition to a quantum-mechanical description of the vibrations of the crystal. For this we must regard $q(\mathbf{k}j)$ and $p(\mathbf{k}j)$ as quantum-mechanical operators obeying commutation relations that contain Planck's constant,

$$[q(\mathbf{k}j),p(\mathbf{k}j)]=i\hbar\Delta(\mathbf{k}-\mathbf{k}')\delta_{jj'}. \qquad (37)$$

It follows from Eq. (37) that

$$p(\mathbf{k}j)=-i\hbar\,\partial/\partial q(\mathbf{k}j). \qquad (38)$$

On substituting Eq. (38) into Eq. (34) we obtain the quantum-mechanical Hamiltonian operator of the crystalline vibrations,

$$\hat{H}=\frac{1}{2}\sum_{\mathbf{k}j}\left[-\hbar^2\frac{\partial^2}{\partial q^2(\mathbf{k}j)}+\omega_j^2(\mathbf{k})q^2(\mathbf{k}j)\right]. \qquad (39)$$

The corresponding Schrödinger equation has the form

$$\sum_{\mathbf{k}j}\left[-\frac{\hbar^2}{2}\frac{\partial^2}{\partial q^2(\mathbf{k}j)}+\tfrac{1}{2}\omega_j^2(\mathbf{k})q^2(\mathbf{k}j)\right]\Psi=E\Psi. \qquad (40)$$

Here E and Ψ are the energy and wave function of the vibrations, respectively. Since the Hamiltonian in Eq. (39) has the form of a sum of independent harmonic-oscillator Hamiltonians, one for each of the normal modes, the wave function Ψ can be represented as the product of the wave functions of the individual oscillators,

$$\Psi=\prod_{\mathbf{k}j}\psi_{n_j(\mathbf{k})}(q(\mathbf{k}j)), \qquad (41)$$

while the energy E is the sum of the energies of the individual oscillators,

$$E = \sum_{\mathbf{k}j} E_{n_j(\mathbf{k})}. \tag{42}$$

In Eqs. (41) and (42) $n_j(\mathbf{k})$ is a quantum number that labels the energy level of the oscillator ($\mathbf{k}j$). By substituting Eqs. (41) and (42) into Eq. (40) we find that the Schrödinger equation for an individual normal mode has the form

$$\left[-\frac{\hbar^2}{2} \frac{\partial^2}{\partial q^2(\mathbf{k}j)} + \frac{1}{2}\omega_j^2(\mathbf{k}) q^2(\mathbf{k}j) \right] \psi_{n_j(\mathbf{k})}(q(\mathbf{k}j)) = E_{n_j(\mathbf{k})} \psi_{n_j(\mathbf{k})}(q(\mathbf{k}j)). \tag{43}$$

The solution of this equation is well known from quantum mechanics (Schiff, 1949, p. 64):

$$E_{n_j(\mathbf{k})} = [n_j(\mathbf{k}) + \tfrac{1}{2}]\hbar\omega_j(\mathbf{k}) \tag{44}$$

and

$$\psi_n(q) = \left(\frac{\alpha}{\pi^{1/2} 2^n n!} \right)^{1/2} \exp(-\tfrac{1}{2}\alpha^2 q^2) H_n(\alpha q), \tag{45}$$

where $\alpha_j^2(\mathbf{k}) = \omega_j(k)/\hbar$, and $H_n(\alpha q)$ is the Hermite polynomial of nth degree, where $n = 0,1,2,\ldots$. The total vibrational energy of the crystal for the state characterized by the quantum numbers $\{n_j(\mathbf{k})\}$ is then given by

$$E_{\{n_j(\mathbf{k})\}} = \sum_{\mathbf{k}j} [n_j(\mathbf{k}) + \tfrac{1}{2}]\hbar\omega_j(\mathbf{k}). \tag{46}$$

The integer $n_j(\mathbf{k})$ is the number of quanta of vibrational energy $\hbar\omega_j(\mathbf{k})$ in the normal mode ($\mathbf{k}j$). This is often expressed by the statement that there are $n_j(\mathbf{k})$ *phonons* in the mode ($\mathbf{k}j$). The average number of phonons in this mode, $\bar{n}(\omega_j(\mathbf{k}))$, is temperature-dependent, and is simply obtained. Since the contribution to the total vibrational energy of the crystal is the sum of the energies of each of the vibrational modes, from the general principles of statistical physics we have that

$$\bar{n}(\omega_j(\mathbf{k})) = \frac{\sum_{n_j(\mathbf{k})=0}^{\infty} n_j(\mathbf{k}) e^{-[n_j(\mathbf{k}) + \frac{1}{2}]\hbar\omega_j(\mathbf{k})/T}}{\sum_{n_j(\mathbf{k})=0}^{\infty} e^{-[n_j(\mathbf{k}) + \frac{1}{2}]\hbar\omega_j(\mathbf{k})/T}}, \tag{47}$$

where T is the absolute temperature in energy units, i.e., Boltzmann's constant $k_B \equiv 1$. The sums are readily evaluated, and we obtain the result

$$\bar{n}(\omega_j(\mathbf{k})) = 1/(e^{\hbar\omega_j(\mathbf{k})/T} - 1). \tag{48}$$

Thus we find that the equilibrium distribution of phonons in the normal mode ($\mathbf{k}j$) is described by the Bose-Einstein distribution function, in which the chemical potential μ is set equal to zero,

$$\mu = 0. \tag{49}$$

The fact that the chemical potential of phonons is zero indicates that the creation and destruction of a phonon are accomplished without the expenditure of any energy.

The distribution function (48) is called the Planck distribution function. It has the following limiting forms:

$$\bar{n}(\omega_j(\mathbf{k})) = \begin{cases} \exp[-\hbar\omega_j(\mathbf{k})/T] \text{ as } T \to 0, & \text{(50a)} \\ T/\hbar\omega_j(\mathbf{k}) \text{ as } T \to \infty. & \text{(50b)} \end{cases}$$

Thus, in the limit of low temperatures, $T \ll \hbar\omega_j(\mathbf{k})$, very few phonons are present in the mode ($\mathbf{k}j$). However, in the high-temperature limit, $T \gg \hbar\omega_j(\mathbf{k})$, the mean number of phonons in this mode is proportional to the absolute temperature T.

The thermodynamic properties of the crystal can be completely described with the aid of the partition function, which in the present case has the form

$$Z = \sum_{\{n_j(\mathbf{k})\}} \exp(-E_{\{n_j(\mathbf{k})\}}/T). \tag{51}$$

If we substitute into this expression the sum (46), we obtain

$$Z = \prod_{\mathbf{k}j} \frac{\exp[-\hbar\omega_j(\mathbf{k})/T]}{1 - \exp[-\hbar\omega_j(\mathbf{k})/T]}. \tag{52}$$

The Helmholtz free energy of the crystalline vibrations can be obtained from the partition function

$$F = -T \ln Z = T \sum_{\mathbf{k}j} \ln\left[2 \sinh \frac{\hbar\omega_j(\mathbf{k})}{2T} \right], \tag{53}$$

as can the internal energy

$$E=F-T\left(\frac{\partial F}{\partial T}\right)_v$$

$$=\sum_{\mathbf{k}j}\left\{\frac{\hbar\omega_j(\mathbf{k})}{2}+\frac{\hbar\omega_j(\mathbf{k})}{\exp[\hbar\omega_j(\mathbf{k})/T]-1}\right\}, \quad (54)$$

the specific heat at constant volume

$$C_v=\left(\frac{\partial E}{\partial T}\right)_v=\sum_{\mathbf{k}j}\frac{[\hbar\omega_j(\mathbf{k})/2T]^2}{\sinh^2[\hbar\omega_j(\mathbf{k})/2T]}, \quad (55)$$

and the entropy

$$S=-\left(\frac{\partial F}{\partial T}\right)_v$$

$$=\sum_{\mathbf{k}j}\left\{\frac{\hbar\omega_j(\mathbf{k})}{2T}\coth\frac{\hbar\omega_j(\mathbf{k})}{2T}-\ln\left[2\sinh\frac{\hbar\omega_j(\mathbf{k})}{2T}\right]\right\}. \quad (56)$$

If the vibrational spectrum of the crystal $\omega_j(\mathbf{k})$ for $j=1,2,\ldots,3r$ is known, then Eqs. (53)–(56) in principle allow all four thermodynamic functions F, E, C_v, S to be calculated.

However, the number of atoms in a crystal is enormous, and the vibrational frequencies are very densely distributed in the spectrum. Therefore, it is more convenient in the calculation of these functions to use the frequency distribution function $g(\omega)$, which can be introduced in the following fashion. Let us consider an arbitrary additive function of the normal-mode frequencies,

$$S=\sum_{\mathbf{k}j}F(\omega_j(\mathbf{k})). \quad (57)$$

It can be transformed in the following way:

$$S=\int d\omega\sum_{\mathbf{k}j}\delta(\omega-\omega_j(\mathbf{k}))F(\omega)$$

$$=\int d\omega g(\omega)F(\omega), \quad (58)$$

where $\delta(\omega)$ is the Dirac delta function. The frequency distribution function $g(\omega)$ is therefore given by

$$g(\omega)=\sum_{\mathbf{k}j}\delta(\omega-\omega_j(\mathbf{k})). \quad (59)$$

The function $g(\omega)$ has the meaning of the density of vibrational states, where $g(\omega)d\omega$ is the number of normal modes with frequencies in the infinitesimally narrow interval between ω and $\omega+d\omega$. The frequency distribution function $g(\omega)$ therefore satisfies the normalization condition

$$\int_0^{\omega_{\max}} d\omega\, g(\omega)=3rN, \quad (60)$$

which indicates that the total number of normal modes of the crystal is $3rN$. In Eq. (60) $\omega_{\max}$ is the largest frequency of the vibrational spectrum.

The expressions for the free energy, the internal energy, the specific heat, and the entropy can also be expressed in terms of $g(\omega)$, and have the forms of averages over the frequency distribution function:

$$F=T\int_0^{\omega_{\max}} d\omega\, g(\omega)\ln\left[2\sinh\frac{\hbar\omega}{2T}\right], \quad (61)$$

$$E=\int_0^{\omega_{\max}} d\omega\, g(\omega)\hbar\omega\left[\frac{1}{2}+\frac{1}{\exp(\hbar\omega/T)-1}\right], \quad (62)$$

$$C_v=\int_0^{\omega_{\max}} d\omega\, g(\omega)\left(\frac{\hbar\omega}{2T}\right)^2\frac{1}{\sinh^2(\hbar\omega/2T)}, \quad (63)$$

$$S=\int_0^{\omega_{\max}} d\omega\, g(\omega)\left[\frac{\hbar\omega}{2T}\coth\frac{\hbar\omega}{2T}-\ln\left(2\sinh\frac{\hbar\omega}{2T}\right)\right]. \quad (64)$$

3. THE DEBYE SPECIFIC HEAT

According to classical theory the specific heat of a solid at constant volume is determined solely by the number of degrees of freedom of the system, with each of which is associated an energy T. The resulting specific heat $C_v=\partial E/\partial T=3rN$ has a constant value, independent of temperature. This constant value was observed experimentally at elevated temperatures, and the constancy of the specific heat at such temperatures became known as the law of Dulong and Petit. At lower temperatures, however, it turned out that the specific heat is strongly temperature dependent, specifically that it decreases with decreasing temperature.

In 1893, to give a theoretical basis for the law of Dulong and Petit, Richarz (1893, 1899) was led to characterize a crystal as an assembly of atoms each of which is executing a simple harmonic motion about its mean position in the crystal. Several years later Einstein (1907), in attempting to explain the optical properties of diamond, adopted the same model of a crystalline solid, and assigned the characteristic frequency ω_0 to the motion of each atom. In this way he was led to his well known theory of lattice specific heats. The frequency distribution function $g(\omega)$ in this case can be represented by a suitably normalized delta function,

$$g(\omega)=3rN\delta(\omega-\omega_0). \tag{65}$$

On substituting Eq. (65) into Eq. (63) we obtain an exponential dependence of the specific heat on temperature of the form

$$C_v\sim\exp(-\hbar\omega_0/T), \tag{66}$$

in the low-temperature limit. However, more detailed experimental investigations of the temperature dependence of the specific heat did not confirm this strong, exponential, temperature dependence.

This discrepancy prompted several investigations of the dynamical properties of crystals, which culminated with the publication, in 1912, of fundamental papers by Debye (1912) and by Born and von Kármán (1912, 1913), which laid the basis for the modern theory of lattice dynamics. The theories of Debye and of Born and von Kármán differed from that of Einstein in their recognition that the atoms of a crystal do not all vibrate with the same frequency, but that there is a distribution of frequencies available to the atomic motions. [Even before the work of Debye and of Born and von Kármán, Einstein (1911) had suggested that this is the case to explain the disagreement between the predictions of his theory and experiment.] Debye regarded a crystal as a continuous elastic medium, whose motion was described by the equations of elasticity theory in calculating the distribution of vibrational frequencies of a crystal. It is known that the theory of elasticity describes the long-wavelength, low-frequency vibration modes of a crystal correctly [see, e.g., Maradudin *et al.* (1971), pp. 21–31]. Debye made the additional, simplifying assumption that the elastic medium is elastically isotropic. In contrast, Born and von Kármán took explicit account of the discrete and periodic nature of a real crystal. It is essentially the latter theory that has been outlined in the preceding two sections of this article. Although the theory of Born and von Kármán was more comprehensive than that of Debye, the simplicity of the latter in comparison to the former had the consequence that Debye's theory eclipsed that of Born and von Kármán for more than 20 years, and even today finds widespread application in the study of the dynamical properties of solids. Therefore, we devote the remainder of this section to a discussion of Debye's approach.

If we denote by $\mathbf{u}(\mathbf{x},t)$ the displacement of an arbitrary point $\mathbf{x}$ of an isotropic elastic medium at time t, the classical equations of motion of such a medium have the form

$$\rho\,\frac{\partial^2\mathbf{u}}{\partial t^2}=\mu\nabla^2\mathbf{u}+(\lambda+\mu)\nabla(\nabla\cdot\mathbf{u}). \tag{67}$$

Here $\rho=v_0^{-1}\,\Sigma_\kappa\,M_\kappa$ is the mass density of the medium, where v_0 is the volume of a primitive unit cell. The quantities μ and λ are called the Lamé elastic coefficients. They describe the shear and hydrostatic deformations existing in a moving isotropic continuum. The right-hand side of Eq. (67) is the force acting on an infinitesimally small volume element of the elastic medium; the left-hand side is the inertial force.

A traveling elastic wave propagating in the medium can be described by a displacement vector of the form

$$\mathbf{u}(\mathbf{x};t)=\mathbf{u}_0\,\exp(i\mathbf{k}\cdot\mathbf{x}-i\omega t). \tag{68}$$

On substituting this expression into Eq. (67) we obtain

$$\omega^2\rho\mathbf{u}_0=\mu k^2\mathbf{u}_0+(\lambda+\mu)\mathbf{k}(\mathbf{k}\cdot\mathbf{u}_0). \tag{69}$$

If the amplitude of the wave is parallel to the wave vector $\mathbf{k}$, $\mathbf{u}_{0l}\|\ \mathbf{k}$, we speak of a longitudinal wave. In this case Eq. (69) takes the form

$$[\omega_l^2\rho-(\lambda+2\mu)k^2]\mathbf{u}_{0l}=0. \tag{70}$$

The frequency of a longitudinal wave is therefore equal to

$$\omega_l(\mathbf{k})=[(\lambda+2\mu)/\rho]^{1/2}k. \tag{71}$$

For two transverse waves the amplitude is perpendicular to the wave vector $\mathbf{k}$, $\mathbf{u}_{0t}\perp\ \mathbf{k}$. In this case the second term on the right-hand side of Eq. (69) vanishes. The frequency of the two degenerate transverse waves is therefore obtained from the equation

$$(\omega_t^2\rho-\mu k^2)\mathbf{u}_{0t}=0, \tag{72}$$

and equals

$$\omega_t(\mathbf{k})=(\mu/\rho)^{1/2}k. \tag{73}$$

The quantities

$$c_l=[(\lambda+2\mu)/\rho]^{1/2} \quad \text{and} \quad c_t=(\mu/\rho)^{1/2} \tag{74}$$

are the speeds of one longitudinal and two transverse elastic waves, respectively.

We can now obtain the frequency distribution function $g(\omega)$ for Debye's model of a crystal. The general definition of $g(\omega)$ is given in Eq. (59). In Debye's model there is one longitudinal and two transverse modes, so that the frequency distribution function assumes the form

$$g(\omega)=\sum_{\mathbf{k}}\delta(\omega-c_lk)+2\sum_{\mathbf{k}}\delta(\omega-c_tk). \tag{75}$$

By going over from summation over $\mathbf{k}$ to integration, with the use of Eq. (31), we obtain

$$g(\omega)=\frac{V}{(2\pi)^3}\int d^3k\,\delta(\omega-c_lk)+\frac{2V}{(2\pi)^3}\int d^3k\,\delta(\omega-c_tk). \tag{76}$$

On carrying out the integrations we find

$$g(\omega)=\frac{V}{(2\pi)^3}4\pi\left(\frac{1}{c_l^3}+\frac{2}{c_t^3}\right)\omega^2. \tag{77}$$

From this result we see that $g(\omega)$ increases without limit with increasing ω. However, a real crystal possesses only $3rN$ normal mode frequencies, among which, of course, is a maximum frequency. Therefore, to impart a greater physical sense to the Debye model it was necessary to impose a normalization condition on the frequency distribution function obtained through its use, viz.,

$$\int_0^{\omega_D}\frac{V}{(2\pi)^3}4\pi\left(\frac{1}{c_l^3}+\frac{2}{c_t^3}\right)\omega^2d\omega=3Nr, \tag{78}$$

where the maximum frequency of the Debye model, ω_D, is defined by this condition. On evaluating the integral on the left-hand side of this equation we find that

$$\omega_D=2\pi\left(\frac{9Nr}{4\pi V}\right)^{1/3}\left(\frac{1}{c_l^3}+\frac{2}{c_t^3}\right)^{-1/3}. \tag{79}$$

It is convenient to rewrite $g(\omega)$ given by Eq. (77) in terms of ω_D, when it becomes

$$g(\omega)=\begin{cases}3rN(3\omega^2/\omega_D^3) & 0\leqslant\omega\leqslant\omega_D\\ 0 & \omega>\omega_D.\end{cases} \tag{80}$$

It is useful to note that ω_D is an artificial limiting frequency that is introduced into the Debye model so that we can take into account correctly the total number of degrees of freedom in the system. It may not coincide with the true maximum frequency of the vibrational spectrum of the crystal.

The frequency distribution function (80) can be used to calculate the specific heat. The result obtained describes well the temperature dependence of the low-temperature specific heat, since only the low-frequency part of the frequency distribution function is significant for the determination of the latter. On substituting Eq. (80) into Eq. (63) we obtain for the specific heat

$$C_v(T)=3rN\left(\frac{T}{\Theta_D}\right)^3\int_0^{\Theta_D/T}dx\,\frac{x^4e^x}{(e^x-1)^2}, \tag{81}$$

where we have introduced the Debye characteristic temperature

$$\Theta_D=\hbar\omega_D. \tag{82}$$

In the limiting case of low temperatures, $T\ll\Theta_D$, the upper limit on the integral in Eq. (81) can be replaced by infinity. In this case the integral can be evaluated exactly, and we obtain the following dependence of the specific heat on temperature:

$$C_v(T)=3rN\frac{4\pi^4}{5}\left(\frac{T}{\Theta_D}\right)^3. \tag{83}$$

This T^3 dependence of the low-temperature specific heat was in agreement with experimental results.

From Eq. (81) we see that in the Debye theory the specific heat is characterized by the single, dimensionless parameter T/Θ_D. This means that the dependence of C_v on T given by Eq. (81) is universal. This means in turn that all experimental curves of the temperature dependence of the specific heat will coincide if the appropriate value of Θ_D is assigned to each solid.

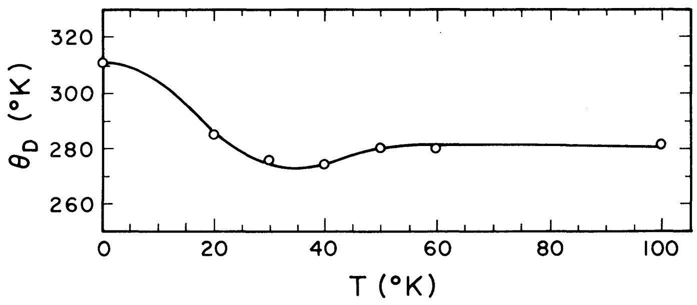

FIG. 1. The temperature dependence of the Debye characteristic temperature Θ_D for NaCl (Kellermann, 1941).

It turned out, however, that in order to obtain agreement between the Debye specific heat and an experimentally measured specific heat it was necessary to use different values of Θ_D at different temperatures. It was shown by Blackman (1934a, 1934b, 1936, 1937a, 1937b) that this temperature dependence of Θ_D can be obtained by equating the specific heat calculated numerically from the Born–von Kármán theory of lattice dynamics for a particular solid to the Debye expression for the specific heat (81). If the equation obtained in this way is regarded as an equation for Θ_D, one can establish the theoretical dependence of Θ_D on temperature. The comparison of this theoretical temperature dependence of Θ_D with that obtained from experimental data can serve as a sensitive criterion for the quality of the force-constant models used in the calculation of vibrational frequency distribution functions of crystals.

In Fig. 1 we show the temperature dependence of Θ_D for NaCl calculated by Kellermann (1941) by the method described above. From the figure we see that in the low-temperature limit Θ_D is a constant independent of temperature only at the very lowest temperatures, up to 5–7 K. Consequently, it is only at these low temperatures that the Debye T^3 law (83) is valid. The Debye temperature Θ_D is also constant over a broad temperature range at elevated temperatures. The reason for this will be discussed below.

If we compare the frequency distribution function used by Kellermann with the Debye frequency distribution function (Fig. 2), we see that they coincide only for frequencies up to the order of $\hbar\omega \sim 0.1\Theta_D$. At first glance it would seem, therefore, that the Debye expression for the specific heat, Eq. (81), should describe the temperature dependence of the specific heat in the temperature range $0 \leqslant T \leqslant 0.1\Theta_D$ ($T \lesssim 20$–50 K), in which only those normal modes of the crystal are excited that are well described by the Debye theory. As is seen from Fig. 1, the experimental data establish a different, smaller, upper limit for the applicability of the Debye theory ($T \lesssim 5$–7 K). This circumstance is related to the form of the integrand in the Debye expression (81), which is $x^4e^x/(e^x-1)^2$. For small values of x this function increases as x^2, while for large x it decreases as x^4e^{-x}. The maximum of this function occurs at $x \cong 3.922$. Consequently, the departure of the Debye frequency distribution function from the exact frequency distribution function will manifest itself in the temperature dependence of the specific heat at temperatures $T \gtrsim \frac{1}{4}(\hbar\omega/2)$. Thus, if the exact frequency distribution function coincides with the Debye frequency distribution function up to frequencies $\hbar\omega \lesssim 0.1\Theta_D$, then the Debye expression for the specific heat will describe the temperature dependence of the specific heat exactly only up to temperatures $T \lesssim 0.1\Theta_D/8 \cong 0.01\Theta_D$.

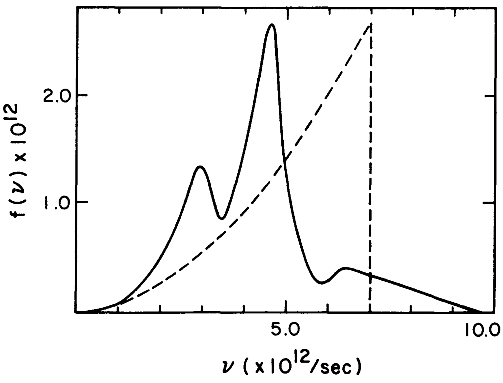

FIG. 2. The frequency distribution function $g(\omega)/3rN$ of NaCl (solid curve) compared with the corresponding Debye approximation to it (Born and Huang, 1954, p. 78).

In the high-temperature limit, $T > \hbar\omega_{\max}$, the specific heat of an arbitrary crystal, in the harmonic approximation, can be obtained by expanding the integrand in Eq. (63) in powers of T^{-1} and integrating the result term by term. The result can be expressed in the form

$$C_v = 3rN\left[1 - \sum_{n=1}^{\infty} (-1)^{n+1} \frac{2n-1}{(2n)!} \times B_{2n} u_{2n} \left(\frac{\hbar\omega_{\max}}{T}\right)^{2n}\right]. \tag{84}$$

In this expression, known as *Thirring's expansion* (Thirring, 1913, 1914a, 1914b), the B_{2n} are the Bernoulli numbers (Adams, 1957),

$$B_2 = \tfrac{1}{6},\quad B_4 = \tfrac{1}{30},\quad B_6 = \tfrac{1}{42},\quad B_8 = \tfrac{1}{30},$$
$$B_{10} = \tfrac{5}{66},\quad B_{12} = \tfrac{691}{2730},\quad B_{14} = \tfrac{7}{6},\ \ldots, \tag{85}$$

while u_{2n} is the dimensionless $2n$th moment of the frequency distribution function $g(\omega)$,

$$u_{2n} = \frac{1}{3rN\omega_{\max}^{2n}} \int_0^{\omega_{\max}} d\omega\, g(\omega)\omega^{2n} g(\omega). \tag{86}$$

The attractiveness of the expansion (84) is that the moments $\{u_{2n}\}$ can be calculated without an explicit knowledge of $g(\omega)$ from the result that

$$u_{2n} = \frac{1}{3rN\omega_{\omega_{\max}}^{2n}} \sum_{\mathbf{k}j} \omega_j^{2n}(\mathbf{k}) = \frac{1}{3rN\omega_{\omega_{\max}}^{2n}} \sum_{\mathbf{k}} \mathrm{Tr} D^n(\mathbf{k}), \tag{87}$$

where $D(\mathbf{k})$ is the dynamical matrix of the crystal, whose elements are given by Eq. (16). In the Debye approximation, it is found from Eqs. (80) and (86) that

$$u_{2n} = 3/(2n+3), \tag{88}$$

so that Eq. (84) in this approximation becomes

$$C_v = 3rN\left[1 - \sum_{n=1}^{\infty} (-1)^{n+1} \frac{3(2n-1)}{2n+3} \times \frac{B_{2n}}{(2n)!}\left(\frac{\Theta_D}{T}\right)^{2n}\right]. \tag{89}$$

If we equate Eqs. (84) and (89) and regard the result as an equation for Θ_D, we find that in the high-temperature limit the latter is given by

$$\Theta_D(T) = \Theta_\infty\left[1 - \frac{1}{80}\left(\frac{1}{3}\frac{u_4}{u_2} - \frac{25}{14}u_2\right)\left(\frac{\hbar\omega_{\max}}{T}\right)^2 + O\left(\frac{1}{T^4}\right)\right], \tag{90a}$$

where Θ_∞, the Debye characteristic frequency at infinite temperature, is

$$\Theta_\infty = \left(\tfrac{5}{4}u_2\right)^{1/2}\hbar\omega_{\max}. \tag{90b}$$

From the result given by Eq. (90a) it appears as if the near constancy of the Debye temperature of NaCl at high temperature seen in Fig. 1 is due to the smallness of the coefficient of $(\hbar\omega_{\max}/T)^2$ for this crystal.

The series (84) converges only for $T > \hbar\omega_{\max}/2\pi$. A rearrangement of this series, based on Euler's summation formula, that yields a series convergent for all T has been presented by Sack *et al.* (1961).

An expansion similar to Thirring's for the high-temperature specific heat was obtained for the entropy by Stern (1916). The internal energy at high temperatures also possesses an expansion of this type.

4. LATTICE THERMAL CONDUCTIVITY OF INSULATORS

Up to now in this article we have considered only the contribution of phonons to equilibrium vibrational properties of crystals. However, these vibrational excitations of a crystal play an essential role in a variety of nonequilibrium processes as well. Among these are the electrical and thermal conductivities of metals and semiconductors, in which the departures from the perfect periodicity of a crystal caused by the atomic displacements scatter the conduction electrons and give rise to nonzero electrical and thermal resistivities. In such materials the phonons themselves also contribute to the thermal conductivity, but their contribution usually is smaller than that due to the conduction electrons. The situation is quite different in the case of insulating crystals, which lack conduction electrons. The thermal conductivity of these materials is due solely to the phonons in them, and it is this case that we will use to illustrate the role of phonons in nonequilibrium processes.

In discussing the lattice thermal conductivity of an insulator it is convenient to think of the phonons in it as particles that can propagate through it and be scattered by collisions with each other (through the anharmonic terms in the potential energy of the crystal that we have neglected until now), with crystalline imperfections, and with the boundaries of the crystal. Since a phonon with wave vector **k** and branch index j is an excitation of the normal vibration mode ($\mathbf{k}j$) of the crystal that involves all the atoms in the crystal, it may seem at first glance that a particlelike description of it is inappropriate. It can be justified, however, by the use of a wave packet synthesized from phonons whose wave vectors are within a narrow range $\Delta\mathbf{k}$ about the wave vector **k**. This wave packet then has a width in space of the order of $\Delta x \cong 1/\Delta k$, and can be regarded as a particle (Peierls, 1929).

Because the chemical potential of phonons is zero, Eq. (49), in phonon-mediated thermal conductivity phonons are created at the hot end of the sample and are absorbed at the cold end. The thermal conductivity tensor $\kappa_{\alpha\beta}(T)$ relates the components of the heat current in the crystal, **Q**, to the components of the temperature gradient ∇T present in it:

$$Q_\alpha = -\sum_\beta \kappa_{\alpha\beta}\frac{\partial T}{\partial x_\beta}, \qquad (91)$$

where the minus sign reflects the fact that heat flows from the hotter to the colder side of the crystal. It is an interesting property of this lattice thermal conduction that the heat flux, or equivalently the flux of phonons, is not accompanied by mass transport, as is the case, for example, in electrical conduction.

The thermal conductivity tensor is a symmetric, second-rank tensor $\kappa_{\alpha\beta}=\kappa_{\beta\alpha}$.

The heat current carried by all the phonons can be written as

$$\mathbf{Q} = \frac{1}{V}\sum_{\mathbf{k}j} E_{n_j(\mathbf{k})}\mathbf{v}_j(\mathbf{k}), \qquad (92)$$

where $E_{n_j(\mathbf{k})}$ is the energy of the phonon ($\mathbf{k}j$) and is given by $E_{n_j(\mathbf{k})} = \hbar\omega_j(\mathbf{k})[n_j(\mathbf{k}) + \frac{1}{2}]$ [Eq. (44)], $\mathbf{v}(\mathbf{k}j) = \nabla_{\mathbf{k}}\omega_j(\mathbf{k})$ is the group velocity of this phonon, and V is the volume of the crystal. Because the frequency $\omega_j(\mathbf{k})$ is an even function of the wave vector **k**, the group velocity $\mathbf{v}(\mathbf{k}j)$ is an odd function of **k**, $\mathbf{v}(-\mathbf{k}j) = -\mathbf{v}(\mathbf{k}j)$. Consequently, the zero-point energy does not contribute to the heat current, which takes the form

$$\mathbf{Q} = \frac{1}{V}\sum_{\mathbf{k}j} n_j(\mathbf{k})\hbar\omega_j(\mathbf{k})\mathbf{v}_j(\mathbf{k}). \qquad (93)$$

When we consider the motion of phonons of wave vector **k** and branch index j through a crystal in the presence of a temperature gradient, their number changes. This is because (Callaway, 1991, p. 169)

1. the number of phonons depends on the temperature gradient, so that $n_j(\mathbf{k})$ becomes a function of position, $n_j(\mathbf{k}) \to n_j(\mathbf{k};\mathbf{x})$, and the phonons tend to drift down the gradient; and
2. phonons collide with each other, with imperfections, and with the boundaries of the crystal.

As a result of these effects $n_j(\mathbf{k};\mathbf{x})$ deviates from its equilibrium value in the absence of the temperature gradient, $\bar{n}(\omega_j(\mathbf{k}))$. In a stationary state the total change in the phonon occupation number due to the temperature gradient, $(\partial n_j(\mathbf{k};\mathbf{x})/\partial t)_T$, and due to collisions, $(\partial n_j(\mathbf{k};\mathbf{x})/\partial t)_c$, must vanish:

$$\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_T + \left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_c = 0. \qquad (94)$$

This balance equation is called the *Boltzmann equation*. It expresses the fact that in a stationary state the number of phonons $n_j(\mathbf{k};\mathbf{x})d^3x$ contained in the volume elements d^3x at the point **x** in the crystal must be independent of the time.

The rate of change of $n_j(\mathbf{k};\mathbf{x})$ due to the temperature gradient can be obtained from the argument that as the phonons drift in the presence of the temperature gradient, the same number of phonons are in the volume element d^3x at **x** at the time t as were in the volume element d^3x at $\mathbf{x}-\mathbf{v}_j(\mathbf{k})t$ at the time $t-\Delta t$. The change in $n_j(\mathbf{k};\mathbf{x})$ in the time interval Δt is therefore equal to the difference of the number of phonons in these two volume elements:

$$\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_T \Delta t = n_j(\mathbf{k};\mathbf{x}-\mathbf{v}_j(\mathbf{k})\Delta t) - n_j(\mathbf{k};\mathbf{x}) \qquad (95)$$

in the limit as $\Delta t \to 0$. On expanding the right-hand side of this equation to first order in Δt we obtain

$$\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_T = -\mathbf{v}_j(\mathbf{k})\cdot\nabla n_j(\mathbf{k};\mathbf{x}). \tag{96}$$

However, $n_j(\mathbf{k};\mathbf{x})$ depends on $\mathbf{x}$ only through its dependence on the temperature, which is a function of $\mathbf{x}$, so that

$$\begin{aligned}\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_T &= -\mathbf{v}_j(\mathbf{k})\cdot\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial T}\nabla T\\ &\cong -\frac{\partial \bar{n}(\omega_j(\mathbf{k}))}{\partial T}\,\mathbf{v}_j(\mathbf{k})\cdot\nabla T\\ &= -\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k}))+1]\\ &\quad\times\frac{\hbar\omega_j(\mathbf{k})}{T^2}\mathbf{v}_j(\mathbf{k})\cdot\nabla T.\end{aligned} \tag{97}$$

In obtaining $(\partial n_j(\mathbf{k};\mathbf{x})/\partial t)_c$, which is due to the scattering of phonons from crystalline imperfections and from the boundaries of the crystal, and also to collisions among the phonons themselves, we have to differentiate between processes in which the total wave vector of the participating phonons is conserved and processes in which it is not. The scatterings of a phonon by crystalline imperfections (point defects, dislocations, etc.) and by the boundaries of the crystal are examples of processes in which the wave vector of the phonon scattered is not conserved. The collisions of phonons with each other are more complicated in that processes in which the total wave vectors of the initial and final phonons are the same can occur, together with processes in which they differ. This can be seen by considering the lowest-order term in the expansion of the potential energy of the crystal in powers of the atomic displacements that was neglected in obtaining the harmonic approximation, Eq. (4), viz.,

$$\Phi_3=\frac{1}{6}\sum_{l\kappa\alpha}\sum_{l'\kappa'\beta}\sum_{l''\kappa''\gamma}\Phi_{\alpha\beta\gamma}(l\kappa;l'\kappa';l''\kappa'')u_\alpha(l\kappa)u_\beta(l'\kappa')u_\gamma(l''\kappa''), \tag{98}$$

where $\Phi_{\alpha\beta\gamma}(l\kappa;l'\kappa';l''\kappa'')$ is the third-order atomic force constant,

$$\Phi_{\alpha\beta\gamma}(l\kappa;l'\kappa';l''\kappa'')=\left(\frac{\partial^3\Phi}{\partial u_\alpha(l\kappa)\partial u_\beta(l'\kappa')\partial u_\gamma(l''\kappa'')}\right)_0. \tag{99}$$

If we expand $u_\alpha(l\kappa)$ according to Eq. (33a),

$$u_\alpha(l\kappa)=\frac{1}{\sqrt{NM_\kappa}}\sum_{\mathbf{k}j}u_\alpha(\kappa|\mathbf{k}j)Q(\mathbf{k}j)e^{i\mathbf{k}\cdot\mathbf{x}(l)}, \tag{100}$$

where, to simplify the notation, we have defined

$$Q(\mathbf{k}j)=\tfrac{1}{2}[q(\mathbf{k}j)+q(-\mathbf{k}j)]+\frac{1}{2}\frac{i}{\omega_j(\mathbf{k})}[p(\mathbf{k}j)-p(-\mathbf{k}j)], \tag{101}$$

Eq. (98) takes the form

$$\Phi_3=\sum_{\mathbf{k}j}\sum_{\mathbf{k}'j'}\sum_{\mathbf{k}''j''}V^{(3)}(\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''j'')Q(\mathbf{k}j)Q(\mathbf{k}'j')Q(\mathbf{k}''j''), \tag{102}$$

with

$$\begin{aligned}V^{(3)}(\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''j'')&=\frac{1}{6N^{3/2}}\sum_{l\kappa\alpha}\sum_{l'\kappa'\beta}\sum_{l''\kappa''\gamma}\Phi_{\alpha\beta\gamma}(l\kappa;l'\kappa';l''\kappa'')\\ &\quad\times\frac{u_\alpha(\kappa|\mathbf{k}j)}{\sqrt{M_\kappa}}\frac{u_\beta(\kappa'|\mathbf{k}'j')}{\sqrt{M_{\kappa'}}}\frac{u_\gamma(\kappa''|\mathbf{k}''j'')}{\sqrt{M_{\kappa''}}}e^{i[\mathbf{k}\cdot\mathbf{x}(l)+\mathbf{k}'\cdot\mathbf{x}(l')+\mathbf{k}''\cdot\mathbf{x}(l'')]}.\end{aligned} \tag{103}$$

The coefficient $V^{(3)}(\mathbf{k}j;\mathbf{k}'j'\mathbf{k}''j'')$ is important in phonon–phonon interactions involving three phonons because time-dependent perturbation theory tells us, for example, that the rate at which phonons $(\mathbf{k}'j')$ and $(\mathbf{k}''j'')$ collide to create a phonon $(\mathbf{k}j)$ is proportional to $|V^{(3)}(-\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''j'')|^2$ (Peierls, 1929; Leibfried, 1955; Gurevich, 1986, pp. 54ff.). Now, the atomic force constant $\Phi_{\alpha\beta\gamma}(l\kappa;l'\kappa';l''\kappa'')$ appearing in the expression (103) for $V^{(3)}(\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''j'')$ is invariant against the addition of the same arbitrary cell index m to each of the indices l,l',l'':

$$\Phi_{\alpha\beta\gamma}(l+m,\kappa;l'+m,\kappa';l''+m,\kappa'') \\ =\Phi_{\alpha\beta\gamma}(l\kappa;l'\kappa';l''\kappa''), \qquad (104)$$

because of the invariance of the crystal against the displacement through the translation vector $\mathbf{x}(m)$. As a consequence, $V^{(3)}(\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''\mathrm{j}'')$ and $|V^{(3)}(\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''\mathrm{j}'')|^2$ are proportional to $\Delta(\mathbf{k}+\mathbf{k}'+\mathbf{k}'')$, where $\Delta(\mathbf{k})$ has been defined in Eq. (36). Three-phonon scattering processes proportional to $|V^{(3)}(\mathbf{k}j;\mathbf{k}'j';\mathbf{k}''j'')|^2$ in which $\mathbf{k}+\mathbf{k}'+\mathbf{k}''=0$ have been termed *normal processes;* those in which $\mathbf{k}+\mathbf{k}'+\mathbf{k}''=\mathbf{G}(h)\neq 0$ have been termed *Umklapp (flipping-over) processes.* An Umklapp process is a scattering process in which momentum is transferred to the crystal as a whole.

The central role in lattice thermal conduction in insulators is played by the scattering processes in which the wave vector of the participating phonons is not conserved. This is particularly readily seen at very low temperatures when only very low-energy acoustic phonons are excited. Thus, in this case, if we rewrite Eq. (93) as

$$\mathbf{Q}=\frac{1}{2V}\sum_{\mathbf{k}}\sum_{j=1}^{3} n_j(\mathbf{k})\hbar\nabla_{\mathbf{k}}\omega_j^2(\mathbf{k}), \qquad (105)$$

and make the simplifying assumption that the frequencies of acoustic phonons are independent of their direction of propagation,

$$\omega_j(\mathbf{k})=c_jk, \quad j=1,2,3, \qquad (106)$$

where c_j is the speed of sound for the jth branch of the phonon spectrum, we obtain for the heat current

$$\mathbf{Q}=\frac{1}{V}\sum_{j=1}^{3} c_j^2 \sum_{\mathbf{k}} n_j(\mathbf{k})\hbar\mathbf{k}=\sum_{j=1}^{3} c_j^2\mathbf{P}_j, \qquad (107)$$

where

$$\mathbf{P}_j=\frac{1}{V}\sum_{\mathbf{k}} n_j(\mathbf{k})\hbar\mathbf{k} \qquad (108)$$

is the total wave vector of the phonons in the branch j. If we assume further that the speeds of sound are the same for all three acoustic branches, viz., that $c_j=c$ for $j=1,2,3$, then the expression for the heat current $\mathbf{Q}$ reduces to

$$\mathbf{Q}=c^2\mathbf{P}, \qquad (109)$$

where

$$\mathbf{P}=\sum_j \mathbf{P}_j \qquad (110)$$

is the sum of the wave vectors of all the phonons in the crystal.

If only wave-vector–conserving scattering processes existed, the total wave vector of all the phonons in the crystal, $\mathbf{P}$, could not change. Thus, in this case collisions could not lead from a state with nonzero $\mathbf{P}$ to a state with zero $\mathbf{P}$. In equilibrium we must have $\mathbf{P}=\mathbf{0}$. In a state with $\mathbf{P}\neq 0$ a heat current exists, according to Eq. (109). Therefore, in the case of wave-vector–conserving processes only, if a heat current were established it would continue to flow even in the absence of a thermal gradient, which implies zero thermal resistance or an infinite thermal conductivity. However, wave-vector–destroying processes change the total wave vector of the phonon system, and thus are essential for the existence of a finite thermal conductivity of a perfect, unbounded crystal.

Although this conclusion has been reached on the basis of several simplifying assumptions, it has a more general validity. Thus in obtaining the contribution to $(\partial n_j(\mathbf{k};\mathbf{x})/\partial t)_c$ due to wave-vector–destroying processes we exploit the fact that they cause any deviation of $n_j(\mathbf{k};\mathbf{x})$ from its equilibrium value $\bar{n}(\omega_j(\mathbf{k}))$ to disappear if the temperature gradient is turned off. A commonly made approximation that describes this is to assume that because of the scattering of phonons by processes that change the total wave vector of the crystal, $n_j(\mathbf{k};\mathbf{x})$ relaxes to its equilibrium value $\bar{n}(\omega_j(\mathbf{k}))$ according to an exponential law,

$$\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_U=-\frac{n_j(\mathbf{k};\mathbf{x})-\bar{n}(\omega_j(\mathbf{k}))}{\tau_j^{(u)}(\mathbf{k})}, \qquad (111)$$

where $\tau_j^{(u)}(\mathbf{k})$ is the relaxation time for the mode $(\mathbf{k}j)$. It includes the contributions from all scattering processes that do not conserve the phonon wave vectors, e.g., scattering from point defects, and from sample boundaries and Umklapp processes. The result represented by Eq. (111) is called the *relaxation-time approximation.* Although Eq. (111) describes in a qualitative way how the deviation $n_j(\mathbf{k};\mathbf{x}) - \bar{n}(\omega_j(\mathbf{k}))$ decays to zero as a result of wave-vector–destroying phonon-scattering processes, in general it cannot be justified from first principles. An exception to this statement, however, is provided by elastic scattering processes in which the number of phonons is conserved, such as the scattering of phonons by point defects and by the boundaries of the crystal. For such processes Eq. (111) is exact, and explicit expressions for the inverse relaxation time $\tau_j^{(u)}(\mathbf{k})$ can be obtained (Maradudin, 1966, pp. 335–338; Grimm *et al.*, 1970).

The normal processes, which conserve the total wave vector of the phonons in the crystal, cannot relax the phonon distribution $n_j(\mathbf{k};\mathbf{x})$ to the equilibrium distribution. Instead they relax it to a displaced equilibrium distribution $\bar{n}(\omega_j(\mathbf{k}) - \mathbf{k}\cdot\mathbf{V})$ (Klemens, 1955):

$$\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_N = -\frac{n_j(\mathbf{k};\mathbf{x}) - \bar{n}(\omega_j(\mathbf{k}) - \mathbf{k}\cdot\mathbf{V})}{\tau_j^{(n)}(\mathbf{k})}, \tag{112}$$

where

$$\bar{n}(\omega_j(\mathbf{k}) - \mathbf{k}\cdot\mathbf{V}) = \{\exp(\hbar[\omega_j(\mathbf{k}) - \mathbf{k}\cdot\mathbf{V}]/T) - 1\}^{-1}, \tag{113}$$

and $\tau_j^{(n)}(\mathbf{k})$ is the corresponding relaxation time. The vector $\mathbf{V}$ has the physical interpretation of the drift velocity of the phonon gas in the temperature gradient (Gurevich, 1986, p. 120), and can be regarded as small (we will see that it is proportional to ∇T). Thus we can write to first order in $\mathbf{V}$ that

$$\bar{n}(\omega_j(\mathbf{k}) - \mathbf{k}\cdot\mathbf{V}) = \bar{n}(\omega_j(\mathbf{k})) + \frac{\hbar}{T}(\mathbf{V}\cdot\mathbf{k}) \times \bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k})) + 1]. \tag{114}$$

The total time rate of change of $n_j(\mathbf{k};\mathbf{x})$ due to scattering and collision processes is the sum of Eqs. (111) and (112) which, with the use of Eq. (114), is

$$\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_c = -\left(\frac{1}{\tau_j^{(n)}(\mathbf{k})} + \frac{1}{\tau_j^{(u)}(\mathbf{k})}\right)[n_j(\mathbf{k};\mathbf{x}) - \bar{n}(\omega_j(\mathbf{k}))] + \frac{(\mathbf{V}\cdot\mathbf{k})}{\tau_j^{(n)}(\mathbf{k})}\frac{\hbar}{T}\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k})) + 1]. \tag{115}$$

With this result and that given by Eq. (97), the Boltzmann equation (94) takes the form

$$-\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k})) + 1]\frac{\hbar\omega_j(\mathbf{k})}{T^2}\mathbf{v}_j(\mathbf{k})\cdot\nabla T - \left(\frac{1}{\tau_j^{(u)}(\mathbf{k})} + \frac{1}{\tau_j^{(n)}(\mathbf{k})}\right)[n_j(\mathbf{k};\mathbf{x}) - \bar{n}(\omega_j(\mathbf{k}))] + \frac{(\mathbf{V}\cdot\mathbf{k})}{\tau_j^{(n)}(\mathbf{k})}\frac{\hbar}{T}\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k})) + 1] = 0, \tag{116}$$

whose solution is

$$n_j(\mathbf{k};\mathbf{x}) = \bar{n}(\omega_j(\mathbf{k})) + \frac{\tau_j^{(n)}(\mathbf{k})\tau_j^{(u)}(\mathbf{k})}{\tau_j^{(n)}(\mathbf{k}) + \tau_j^{(u)}(\mathbf{k})}\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k})) + 1]\frac{\hbar}{T}\left\{\frac{\mathbf{V}\cdot\mathbf{k}}{\tau_j^{(n)}(\mathbf{k})} - \frac{\omega_j(\mathbf{k})}{T}\mathbf{v}_j(\mathbf{k})\cdot\nabla T\right\}. \tag{117}$$

The phonon drift velocity $\mathbf{V}$ is then obtained from the condition that the rate of change of the total phonon wave vector due to normal processes vanishes. This can be expressed by the statement

$$\sum_{\mathbf{k}j}\left(\frac{\partial n_j(\mathbf{k};\mathbf{x})}{\partial t}\right)_N \mathbf{k} = \sum_{\mathbf{k}j}\left(\frac{\bar{n}(\omega_j(\mathbf{k}) - \mathbf{k}\cdot\mathbf{V}) - n_j(\mathbf{k};\mathbf{x})}{\tau_j^{(n)}(\mathbf{k})}\right)\mathbf{k} = \mathbf{0}, \tag{118}$$

or, with the use of Eqs. (114) and (117),

$$\sum_{\mathbf{k}j} \frac{\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k}))+1]}{\tau_j^{(n)}(\mathbf{k})+\tau_j^{(u)}(\mathbf{k})} \frac{\hbar}{T}(\mathbf{V}\cdot\mathbf{k})\mathbf{k} = -\sum_{\mathbf{k}j} \frac{\tau_j^{(u)}(\mathbf{k})\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k}))+1]}{\tau_j^{(n)}(\mathbf{k})+\tau_j^{(u)}(\mathbf{k})} \frac{\hbar\omega_j(\mathbf{k})}{T^2}\mathbf{v}_j(\mathbf{k})\cdot\nabla T\mathbf{k}. \tag{119}$$

Thus, if we write the solution of this equation formally as

$$V_\alpha = -\frac{1}{T}\sum_\beta \beta_{\alpha\beta}\frac{\partial T}{\partial x_\beta}, \tag{120}$$

then from Eqs. (91), (93), and (117) we obtain for the thermal conductivity tensor

$$\kappa_{\alpha\beta} = \frac{1}{V}\sum_{\mathbf{k}j} \tau_j^{(c)}(\mathbf{k})C_j(\mathbf{k})v_{j\alpha}(\mathbf{k})\left[v_{j\beta}(\mathbf{k}) + \frac{1}{\omega_j(\mathbf{k})\tau_j^{(n)}(\mathbf{k})}\sum_\gamma \kappa_\gamma\beta_{\gamma\beta}\right], \tag{121}$$

where $C_j(\mathbf{k}) = [\hbar\omega_j(\mathbf{k})/T]^2\bar{n}(\omega_j(\mathbf{k}))[\bar{n}(\omega_j(\mathbf{k}))+1]$ is the contribution to the specific heat of the crystal from the mode ($\mathbf{k}j$), and $\tau_j^{(c)}(\mathbf{k})$ is the combined relaxation time defined by

$$1/\tau_j^{(c)}(\mathbf{k}) = [1/\tau_j^{(n)}(\mathbf{k})] + [1/\tau_j^{(u)}(\mathbf{k})]. \tag{122}$$

If it were not for the second term in brackets on the right-hand side of Eq. (121), this expression for $\kappa_{\alpha\beta}$ would have the form predicted by elementary kinetic theory (Kittel, 1976, pp. 143–144). The presence of the second term in brackets is a consequence of the fact that normal processes cannot relax a given phonon distribution $n_j(\mathbf{k};\mathbf{x})$ to the equilibrium distribution $\bar{n}(\omega_j(\mathbf{k}))$, but only to the displaced distribution $\bar{n}(\omega_j(\mathbf{k})-\mathbf{k}\cdot\mathbf{V})$.

It is clear that a central role in this approach to the thermal conductivity of an insulator is played by the relaxation times $\tau_j^{(n)}(\mathbf{k})$ and $\tau_j^{(u)}(\mathbf{k})$. It was shown by Herring (1954) that the relaxation time of a single low-energy mode of wave vector **k** due to three-phonon processes depends on **k** and the temperature T according to

$$1/\tau_j(\mathbf{k}) = k^a T^{5-a}, \tag{123}$$

where a is an exponent determined by crystal symmetry. The relaxation time for normal scattering processes $\tau_j^{(n)}(\mathbf{k})$ is usually written in the form (Callaway, 1959)

$$1/\tau_j^{(n)}(\mathbf{k}) = BT^3\omega_j^2(\mathbf{k}), \tag{124}$$

although an alternative form (Gurevich, 1986, p. 98),

$$1/\tau_j(\mathbf{k}) = B[T/v_j(\mathbf{k})]^5, \tag{125}$$

is also used in the limit of very low temperatures, $T \ll \Theta_{\mathrm{D}}$. Both of these forms are consistent with Herring's result, Eq. (123).

For the scattering of phonons by point defects the relaxation time $\tau_j^{(d)}(\mathbf{k})$ has the temperature-independent form (Pomeranchuk, 1942; Klemens, 1951, 1955, 1957)

$$1/\tau_j^{(d)}(\mathbf{k}) = A\omega_j^4(\mathbf{k}), \tag{126}$$

where the constant coefficient A is proportional to the concentration of point defects. Equation (126) is the Rayleigh law for the scattering of long-wavelength phonons by defects whose linear dimensions are smaller than the phonon wavelength. A derivation of Eq. (126) on the basis of defect lattice dynamics for the particular case of the scattering of phonons by isotopic impurities has been given, e.g., by Maradudin (1966, pp. 335–338).

For the scattering of phonons by the boundaries of the sample, the relaxation time $\tau_j^{(b)}(\mathbf{k})$ is frequency independent and temperature independent (Casimir, 1938),

$$1/\tau_j^{(b)}(\mathbf{k}) = v_j(\mathbf{k})/L, \tag{127}$$

where L is a length that is of the order of the linear dimensions of the sample. In a microscopic derivation of Eq. (127) by Grimm *et al.* (1970), $v_j(\mathbf{k})$ is replaced by the component of the group velocity $\mathbf{v}_j(\mathbf{k})$ normal to the boundary.

Finally, the relaxation time for the scattering of phonons by three-phonon Umklapp processes has the form

$$1/\tau_j^{(\mathrm{U})}(\mathbf{k}) = C\exp(-\alpha\Theta_{\mathrm{D}}/T) \tag{128}$$

at low temperatures (Gurevich, 1986, p. 123; Brüesch, 1987, p. 96), where α is a numerical factor of the order of, and smaller than, unity. The origin of this form can be understood by considering a scattering process in which two phonons with wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ interact to create a phonon whose wave vector $\mathbf{k}_1+\mathbf{k}_2$ extends outside the first Brillouin zone. At the low temperatures we are considering, only acoustic phonons are excited, and for simplicity we can ignore the distinction between longitudinal and transverse phonons, and can suppress the branch indices of the interacting phonons. This process is illustrated for a two-dimensional square lattice of lattice constant a in Fig. 3. The addition to $\mathbf{k}_1+\mathbf{k}_2$ of a reciprocal-lattice vector $\mathbf{G}=(-2\pi/a,0,0)$, whose magnitude is equal to the length of an edge of the Brillouin zone, transforms this vector into a vector $\mathbf{k}_3$ inside the first Brillouin zone. Here k_{1x} and k_{2x} are both positive, but k_{3x} is negative. This is the origin of the name "Umklapp" for scattering processes of this type. For an Umklapp process to be possible, $|\mathbf{k}_1+\mathbf{k}_2|$ must exceed $\frac{1}{2}G_{\min}$, where $G_{\min}$ is the magnitude of the shortest reciprocal lattice vector, which in the present case is $2\pi/a$. This requires in turn that the magnitude of at least one of the two wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ must exceed $\frac{1}{4}G_{\min}$. In the Debye approximation the Brillouin zone is replaced by a circle of radius k_{D} (in the two-dimensional case we are considering), whose area is equal to that of the Brillouin zone. Therefore k_{D} has a value $k_{\mathrm{D}}=2\sqrt{\pi}/a \gtrsim \frac{1}{2}G_{\min}$. From Fig. 3 we see that the frequency of the phonon created in this scattering process is therefore given by $\hbar\omega(\mathbf{k}_3) \lesssim \Theta_{\mathrm{D}}$, in the Debye approximation, where Θ_{D} is the Debye temperature, since $|\mathbf{k}_3| \lesssim k_{\mathrm{D}}$. The collision frequency of an Umklapp process is proportional to the product of the occupation numbers of the colliding phonons, $\bar{n}(\omega(\mathbf{k}_1))$ and $\bar{n}(\omega(\mathbf{k}_2))$, which, in the low-temperature limit, $T \ll \Theta_{\mathrm{D}}$, are given by Eq. (50):

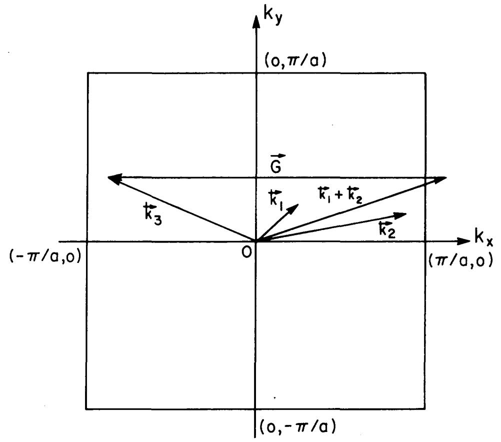

FIG. 3. The first Brillouin zone for a square lattice of lattice constant a, and the wave vectors of phonons participating in an Umklapp process.

$$\bar{n}(\omega(\mathbf{k}_1)) \cong \exp[-\hbar\omega(\mathbf{k}_1)/T],$$
$$\bar{n}(\omega(\mathbf{k}_2)) \cong \exp[-\hbar\omega(\mathbf{k}_2)/T], \qquad (129)$$

respectively. The product $\bar{n}(\omega(\mathbf{k}_1))\bar{n}(\omega(\mathbf{k}_2))$ is therefore given by

$$\bar{n}(\omega(\mathbf{k}_1))\bar{n}(\omega(\mathbf{k}_2)) \cong \exp\{-\hbar[\omega(\mathbf{k}_1)+\omega(\mathbf{k}_2)]/T\}. \qquad (130)$$

However, energy is conserved in the interaction, so that $\omega(\mathbf{k}_1)+\omega(\mathbf{k}_2)=\omega(\mathbf{k}_1+\mathbf{k}_2)=\omega(\mathbf{k}_1+\mathbf{k}_2+\mathbf{G})=\omega(\mathbf{k}_3)$, where we have used the result that the frequency $\omega(\mathbf{k})$ is a periodic function of $\mathbf{k}$ with period $\mathbf{G}$. It follows that the collision rate is proportional to

$$\bar{n}(\omega(\mathbf{k}_1))\bar{n}(\omega(\mathbf{k}_2)) \cong \exp[-\hbar\omega(\mathbf{k}_3)/T] = \exp(-\alpha\Theta_{\mathrm{D}}/T), \qquad (131)$$

where α is a number of the order of, and smaller than, unity. This result establishes Eq. (128).

In the high-temperature limit, $T \gg \Theta_{\mathrm{D}}$, an approximate microscopic calculation (Ludwig, 1964; Gurevich, 1986, p. 96) yields the result that the relaxation time for the scattering of phonons by three-phonon Umklapp processes has the form

$$1/\tau_j^{(\mathrm{U})}(\mathbf{k}) = D_j(\mathbf{k})T. \qquad (132)$$

This dependence on temperature can be understood (Kittel, 1976, p. 145) in terms of the number of phonons with which a given phonon can interact. At high temperatures, when all phonons are excited, the magnitudes of the relaxation times for normal and Umklapp processes become comparable, and we need not distinguish between these two types of scattering processes. In this limit the total number of excited phonons is proportional to the absolute temperature T [Eq. (50b)]. The collision frequency of a given phonon should be proportional to the number of phonons with which it can interact, and Eq. (132) follows from this argument.

The various scattering processes just described are assumed to be independent, so that the probabilities of their occurrence add, and consequently so do the inverse relaxation times. Thus we have that

$$\frac{1}{\tau_j^{(u)}(\mathbf{k})}=\frac{1}{\tau_j^{(d)}(\mathbf{k})}+\frac{1}{\tau_j^{(b)}(\mathbf{k})}+\frac{1}{\tau_j^{(\mathrm{U})}(\mathbf{k})}. \qquad (133)$$

The calculation of the thermal conductivity of an insulator by the procedure just described is usually carried out on the basis of the assumption of a Debye spectrum for the phonons with speeds of sound that are independent of the direction of propagation, and even that the speed of sound is the same for all three acoustic branches (Callaway, 1959). With such approximations it follows from Eq. (121) that at very low temperatures (usually below approximately 10 K), where the inverse lifetimes for the scattering of phonons by other phonons and by crystalline defects and impurities have essentially vanished, and the only scattering mechanism limiting the thermal conductivity is the scattering of phonons by the boundaries of the crystal, the thermal conductivity becomes proportional to the specific heat of the crystal, and thus increases with increasing temperature according to a T^3 law. For, in this case, if we denote by c the common speed of sound, from Eqs. (121), (127), and (133) we obtain

$$\begin{aligned}\kappa_{\alpha\beta}&=\frac{1}{V}\sum_{\mathbf{k}j}\tau_j^{(b)}(\mathbf{k})C_j(\mathbf{k})v_{j\alpha}(\mathbf{k})v_{j\beta}(\mathbf{k})\\ &=\delta_{\alpha\beta}\frac{cL}{3}\frac{1}{V}\sum_{\mathbf{k}j}C_j(\mathbf{k})\\ &=\delta_{\alpha\beta}\frac{cL}{3}\frac{C_v(T)}{V}. \end{aligned}\qquad (134)$$

At high temperatures, $T \gg \Theta_{\mathrm{D}}$, the dominant scattering processes leading to a finite lattice thermal conductivity are the three-phonon Umklapp scattering processes. In this limit, we obtain from Eqs. (121), (132), (133), and the fact that $C_j(\mathbf{k})\to 1$ as $T\to\infty$, the result that

$$\begin{aligned}\kappa_{\alpha\beta}&=\frac{1}{V}\sum_{\mathbf{k}j}\tau_j^{(U)}(\mathbf{k})C_j(\mathbf{k})v_{j\alpha}(\mathbf{k})v_{j\beta}(k)\\ &\xrightarrow[T\to\infty]{}\frac{1}{T}\frac{1}{V}\sum_{\mathbf{k}j}\frac{v_{j\alpha}(\mathbf{k})v_{j\beta}(\mathbf{k})}{D_j(\mathbf{k})}\\ &=\delta_{\alpha\beta}\frac{1}{3}\frac{c^2}{T}\frac{1}{V}\sum_{\mathbf{k}j}\frac{1}{D_j(\mathbf{k})}. \end{aligned}\qquad (135)$$

Thus, in this limit the thermal conductivity of all insulating crystals must decrease according to a T^{-1} law (Brüesch, 1987, p. 97; Callaway, 1991, p. 175). A maximum therefore appears at intermediate temperatures in the temperature dependence of the thermal conductivity. The thermal conductivity in the temperature range where this maximum occurs is determined primarily by the scattering of the phonons by crystalline defects and impurities. In quantitative calculations of the conductivity as a function of temperature, the coefficients in the expressions for the several relaxation times entering the theory are usually obtained by fitting the resulting theoretical curves to experimental data in the limiting cases of low and high temperatures. As an example of the kinds of results that can be obtained in this way, we present in Fig. 4 plots of the lattice thermal conductivity of almost isotopically pure ^{74}Ge and of normal Ge (Callaway, 1959), calculated with the inclusion of all the scattering processes described above. The thermal conductivity of the normal Ge is seen to be smaller than that of the isotopically pure Ge because of the additional thermal resistivity of the former sample due to the scattering from the isotopic impurities in it. The agreement between theory and experiment is quite good, suggesting that the essential physics has been incorporated into the theory. The discrepancies, particularly in the vicinity of the maximum, are presumably due to the use of a relaxation-time approximation

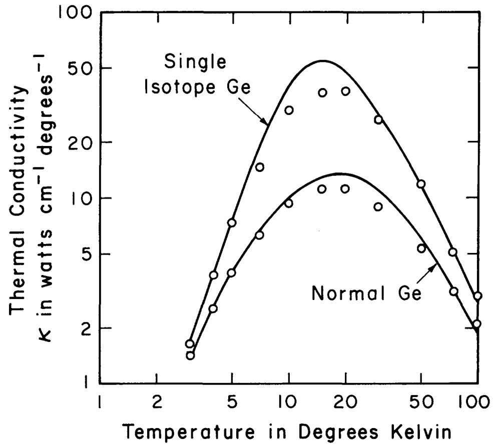

FIG. 4. The thermal conductivity of germanium. The solid curves are theoretical results calculated in the manner described in the text. The open circles are experimental data of Geballe and Hull (1958) (Callaway, 1959).

to describe three-phonon collision processes and to the neglect of the distinction between longitudinal and transverse phonons.

INTRODUCTION

True liquid crystals are fluids, in the sense that they cannot support shear stress. They possess order intermediate between the high degree of order of a perfect crystal and the disorder of a common isotropic liquid. For this reason they are often called *mesophases*, and molecules that tend to form liquid crystals are said to be mesogenic. The first reported observation of the liquid crystalline state was by the Austrian botanist Friederich Reinitzer (1888). In the intervening century these materials have been investigated not only for their potential applications, but also for their intellectual interest as a window into the variety of phases that can exist in condensed matter. The latter was recognized by the award of the 1991 Nobel Prize in physics to Pierre-Gilles de Gennes of the Collège de France.

In this article we shall describe the nature of the order found in the various known liquid crystal phases, their structure, and some of their optical and viscoelastic properties. As this is an encyclopedia of *applied* physics, we shall pay special attention to their applications in display devices or for other purposes.

The many liquid-crystal phases can be divided broadly into two classes. The first liquid crystals discovered, and the most studied, are those classified as *thermotropic*. These are commonly formed from a single organic compound, and the liquid-crystal phases are obtained as the temperature is changed. Many thermotropic phases are formed from "mixtures" of different compounds in order to obtain the liquid-crystal order over a desired temperature range, but these are really solutions in which the different components are distributed quite uniformly. Thermotropic liquid crystals can also be formed from polymers. These are usually classified into two types, depending on whether the polymer main-chain or attached side-chain units are mesogenic.

Most commonly, molecules exhibiting liquid-crystalline phases are rodlike, but disk-shaped molecules have also been found to have liquid-crystal phases (Chandrasekhar *et al.*, 1979). The important thing is that the molecules should have considerable shape anisotropy. For example, for mesomorphic rodlike molecules, the ratio of the length of the molecule to its breadth is typically about 5:1. Two typical thermotropic molecules are shown in Fig. 1. The thermotropic phases are broadly classified as nematic, cholesteric, and smectic; about a dozen different smectic phases have been identified.

Liquid crystals that involve molecules in solution, usually amphiphiles dissolved in water, are called *lyotropic*. As they are systems with at least two components, this provides an extra degree of freedom. The types of order that occur in lyotropic phases are analogous to those in thermotropic phases, but usually involve the ordering of aggregates of molecules. Materials that show lyotropic order may also, with somewhat different amounts of solvent or solute, show non-liquid-crystal phases, such as microemulsions, that are technologically useful.

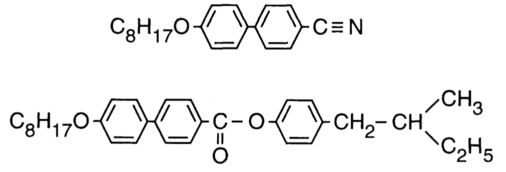

FIG. 1. The structure of two typical thermotropic liquid-crystal molecules.

1. NEMATIC LIQUID CRYSTALS

All liquid crystal phases have long-range orientational order of the molecules. The nematic phase, which is the simplest phase, has only this type of order to distinguish it from a disordered isotropic liquid. The name nematic comes from the Greek word for thread, and was given to this phase because defects in the order, somewhat analogous to the domain walls of ferromagnets, resemble threads when observed under a microscope. A schematic of the molecular order in a nematic phase is shown in Fig. 2. While the molecules are orientationally ordered, the nematic phase has continuous translational symmetry.

1.1 Optical Properties of Nematics

The optical polarizability of the nematic molecules is anisotropic, and so a phase in which molecules tend to orient parallel to one another will be birefringent. Most nematics are uniaxial; that is, there is a single optic axis that the molecules tend to align parallel to, and the material has rotational symmetry about that axis. The optic axis of the material is usually denoted by a unit vector field **n**, called the director, which is also the principal axis of the refractive-index tensor. (Recently, biaxial lyotropic nematics have been discovered; these would require two directors.) Choosing **n** to lie along the z direction, we may let θ be the angle between the symmetry axis of a molecule and the director as shown in Fig. 3. The nematic order may be described quantitatively by the order parameter

$$\mathscr{S}=\tfrac{1}{2}\langle 3\cos^2\theta-1\rangle, \qquad (1)$$

where the average is taken over a small, but macroscopic, volume. In Eq. (1), $\mathscr{S}$ has been defined to be 0 for randomly oriented molecules and 1 if all were perfectly aligned. It is also possible for $\mathscr{S}$ to be negative; the minimum value $\mathscr{S}$ can have is $-\frac{1}{2}$, which occurs when all molecules are randomly oriented in

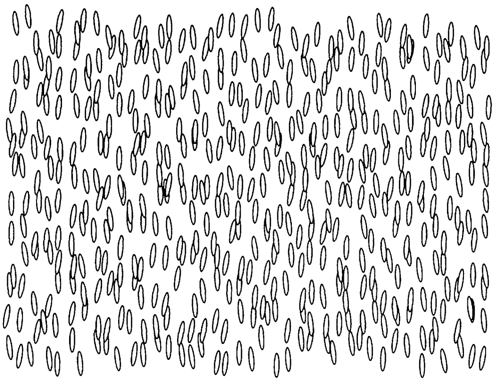

FIG. 2. Schematic of the local arrangements of molecules in a nematic liquid-crystal phase.

a plane perpendicular to the optic axis. The molecules also have an anisotropic diamagnetic susceptibility, largely due to the benzene rings most of them contain, and the diamagnetic susceptibility of the nematic will be given by

$$\chi_{\alpha\beta}=\tfrac{1}{3}\Delta\chi\mathcal{S}(3n_\alpha n_\beta-\delta_{\alpha\beta}), \tag{2}$$

where the subscripts α and β denote Cartesian components, and $\Delta\chi$ would be the anisotropy for a perfectly ordered nematic. A similar phenomenological relation can be defined to represent the optical birefringence by expressing the dielectric constant tensor as

$$\epsilon_{\alpha\beta}=\tfrac{1}{3}\Delta\epsilon\mathcal{S}(3n_\alpha n_\beta-\delta_{\alpha\beta}). \tag{3}$$

Equation (2) provides, in principle, a means to determine $\mathcal{S}$ from a macroscopic measurement if the fundamental diamagnetic properties of the molecule are known. The uncertainty of local field corrections makes it impossible to relate $\Delta\epsilon$ to molecular properties, and so Eq. (3) cannot be used in the same way. However, Eq. (3) does provide a quantitative description of the birefringence of nematic phases, which is large; a typical nematic has $\Delta\epsilon\simeq 1$. Because nematics are fluids, the birefringence can be modified by relatively modest applied forces, which makes them useful for displays.

1.2 Viscoelastic Properties of Nematics

The effect of electric fields, or other perturbations, on nematic liquid crystals is usually described in terms of distortions of the director field **n**. The lowest energy state of the nematic occurs when **n** is spatially uniform. Although the molecules themselves are not end-for-end symmetrical, all known nematic phases are unchanged if the direction of **n** is reversed. (If this were not so, they would be ferroelectric, and no ferroelectric nematics have been discovered.) A general distortion can be expressed in terms of three fundamental distortions commonly called splay, twist, and bend. Mathematically, these are represented by $(\nabla\cdot\mathbf{n})^2$, $(\mathbf{n}\cdot\nabla\times\mathbf{n})^2$, and $(\mathbf{n}\times\nabla\times\mathbf{n})^2$, respectively (de Gennes, 1974). The energy per unit volume of a distorted nematic in the presence of applied electric and magnetic fields is

$$\begin{aligned}\mathcal{F}_{el}=&\tfrac{1}{2}[K_1(\nabla\cdot\mathbf{n})^2+K_2(\mathbf{n}\cdot\nabla\times\mathbf{n})^2\\&+K_3(\mathbf{n}\times\nabla\times\mathbf{n})^2]+\tfrac{1}{2}\epsilon_a(\mathbf{n}\cdot\mathbf{E})^2\\&+\tfrac{1}{2}\chi_a(\mathbf{n}\cdot\mathbf{H})^2,\end{aligned} \tag{4}$$

where ϵ_a is the anisotropy of the dielectric constant at low frequencies, $\chi_a=\chi_\parallel-\chi_\perp=\Delta\chi\mathcal{S}$ from Eq. (2), and K_1, K_2, and K_3 are called the splay, twist, and bend elastic constants. Typical values for the elastic constants are $\sim 10^{-6}$ dyn, χ_a is about 10^{-7} cgs units for molecules with benzene rings, and ϵ_a is approximately 10 for a molecule with a cyano group, like the upper one in Fig. 1. Equation (4) can be used to calculate the size of applied

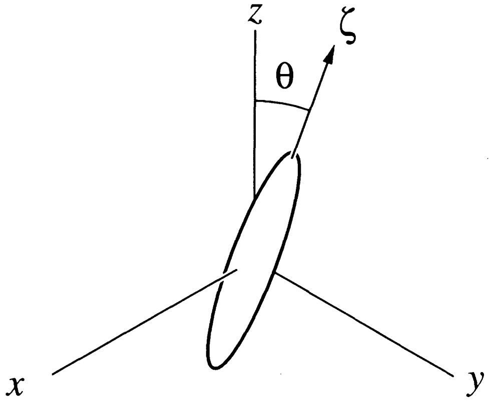

FIG. 3. The coordinates used to describe the orientation of nematic liquid-crystal molecules.

electric or magnetic fields required to cause changes in the orientation of the optic axis **n** (de Gennes, 1974). The sign of χ_a for most nematics is such that the director will orient parallel to an applied magnetic field. A molecule like the upper one in Fig. 1 has a large dipole moment due to the cyano group, and will readily orient parallel to an applied electric field. There are also nematic materials whose optic axis will orient perpendicular to an electric field, but they are little used in modern devices.

The viscosity of nematic liquid crystals is also a tensor, with five independent components (de Gennes, 1974). All of the components are roughly of equal size, ~10 cP, and they, in combination with the elastic constants, determine the frequencies of the director normal modes (Martin *et al.*, 1972) and the response time of devices using nematic liquid crystals. Thermal excitation of these normal modes gives rise to substantial scattering of light, so that the mean free path of a photon can be less than 1 mm. The attenuation of light by scattering in even perfectly aligned nematic materials can be an important consideration in the design of optical devices using these materials.

1.3 Device Applications of Nematics

Most liquid-crystal display (LCD) applications use the liquid crystal to alter the transmission of light through the device. A number of effects have been investigated for use in devices. One of these is the "guest–host" display, in which strongly absorbing dye molecules are dissolved in a nematic liquid crystal that orients them; by reorienting the director variable dichroism can be obtained. However, the dominant type of liquid-crystal display in use today is the kind known as "twisted nematic" (Schadt and Helfrich, 1971), or TN, illustrated in Fig. 4. These devices have become practical thanks to the pioneering work of Gray and co-workers (Gray, 1975) at the University of Hull in England in developing materials with the required properties.

1.3.1 Twisted Nematic Displays. The display cell consists of nematic material between two transparent plates separated by a distance *d*, which is typically about 10 μm. The inner surface of each plate is coated with a transparent conductor such as indium-tin oxide so that an electric field may be applied across the liquid crystal. The plate surfaces are also treated to orient the director of the material in contact with them so that the optic axis will follow a particular direction in the plane of the plate. The orientation directions of the two plates are generally set at a 90° angle, which causes the director of the material between the plates to follow smoothly a 90° twist. The cell is generally used to transmit light and placed between a pair of polarizers. Light incident upon the cell will have its plane of polarization rotated to follow the twist as it passes through the cell; it will pass through if the polarizers are crossed and be blocked if they are parallel. The materials used have $\epsilon_a > 0$, so that a voltage applied between the electrodes will try to align the molecules normal to the plates. Those in contact with the plates will retain their orientation, but at a rather sharply defined threshold most of the liquid crystal between the plates will switch orientation. When this happens, the cell will no longer rotate the polarization of light passing through it. By placing the cell between crossed or parallel polarizers, one may choose to have the electric field either block or permit the transmission of light. The chief advantage of this display is that the liquid crystals are excellent electrical insulators, so that the power consumption is very small. Another advantage is that the response is determined by the voltage between the electrodes, rather than the electric field, so that TN devices are less sensitive to minor variations in the electrode spacing than those using ferroelectric liquid crystals. Several considerations are important for practical TN devices. To avoid electrochemical polarization effects at the electrodes, low-

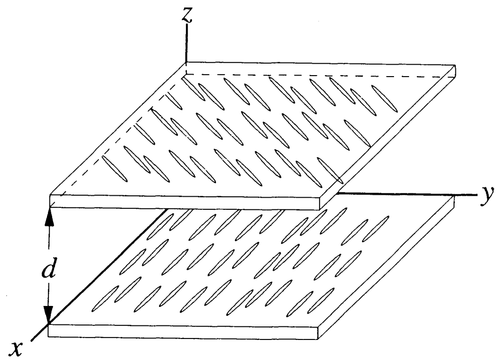

FIG. 4. Schematic of a twisted nematic display cell.

frequency ac fields must be used, rather than dc. The liquid crystal is often doped with small amounts of a chiral material to influence the choice of the twist direction. High information content displays for computer screens often employ a twist angle greater than 90°, frequently as high as 270°. Known as "supertwist," this improves the threshold response and makes possible greater levels of multiplexing and good contrast over a wider reviewing angle. The best displays now use thin-film transistors at each pixel to improve performance.

2. CHOLESTERIC LIQUID CRYSTALS

The name "cholesteric" comes from the historical fact that for a long time most of the known examples of this phase were esters of cholesterol. The molecules of cholesteric phases tend to order parallel to one another as the molecules of nematics do, but they are formed from chiral molecules. The chirality of the molecules causes them to pack in a locally helical structure; in the ordered liquid crystal phase there is a macroscopic precession of the director throughout the sample. Cholesterics have a helical axis to which the director is perpendicular and around which it precesses. The distance travelled along the helical axis for one full turn of the director is called the pitch. Both right- and left-hand cholesterics exist, and the length of the pitch is often comparable to the wavelength of visible light. A cholesteric phase formed from a racemic mixture (equal numbers of molecules with right- and left-handed chirality) will be nematic, and, thermodynamically, cholesteric liquid crystals are a class of nematic.

2.1 Optical Properties of Cholesterics

The magnitude of the pitch plays an important role in determining the optical, dielectric, and magnetic properties of cholesteric phases. Even when disordered, most cholesteric materials have a high value of optical activity; polarization rotations of 300° mm^{-1} are common. Cholesteric phases have a strong circular birefringence, and propagation of light through them (Chandrasekhar, 1977) can exhibit unusual effects. When the pitch is comparable to the wavelength of light, wavelength- and polarization-selective reflections occur, so that cholesteric materials often display bright colors when reflecting white light. The color is determined by the pitch, and is used in applications we shall now discuss.

2.2 Response of Cholesterics to Applied Fields

Because cholesterics are nematics with a macroscopic twist to the director, their response to applied fields can be discussed using a modified form of Eq. (4) in which the twist term is replaced by $K_2(\mathbf{n}\cdot\nabla\times\mathbf{n}+q_c)^2$, where the pitch length $2\pi/q_c$ is long compared to molecular dimensions. The esters of cholesterol have diamagnetic anisotropies about 100 times smaller than those of common nematic materials, and the effects of magnetic fields on them are correspondingly weaker. More recently developed materials in which the chirality comes from a branched chain, as seen in the second molecule in Fig. 1, have greater response to magnetic fields. For cholesterics, we should remember that the susceptibility for fields along the helical axis is $\chi_\perp$ or $\epsilon_\perp$ of Eqs. (2) and (3). For fields perpendicular to the pitch direction, the average susceptibilities $(\chi_\parallel+\chi_\perp)/2$ and $(\epsilon_\parallel+\epsilon_\perp)/2$ will be observed. So, in applying Eq. (4) to cholesterics, $\chi_a=(\chi_\parallel-\chi_\perp)/2$ and $\epsilon_a=(\epsilon_\parallel-\epsilon_\perp)/2$ should be used. If χ_a or ϵ_a is negative, the director will align perpendicular to the appropriate field and the pitch direction will align parallel to it. When χ_a or ϵ_a is positive, the system will align with the pitch direction normal to the field, and the effect of the field will be to unwind the helix. In fact, the pitch diverges logarithmically to ∞ at a critical field that is inversely proportional to the unperturbed pitch. At this point, the cholesteric has been converted to a nematic phase by the field.

Because the pitch modulates a number of properties of the cholesteric phase as one travels along the pitch direction, cholesterics can exhibit viscoelastic behavior analogous to smectic phases. These are discussed by de Gennes (1974).

2.3 Applications of Cholesterics

Most of the applications cholesterics have found to date stem from their selective reflection of colors of light. The color reflected depends upon the pitch, which can vary with temperature through a process analogous to thermal expansion. Cholesteric materials can therefore be used as thermometers with visible readout. They have found application in measuring skin temperatures and the detection of poor contacts and hot spots on printed circuit boards. When composite materials are subjected to a step in heat flux, the resulting surface temperature distribution can reveal information about internal flaws; it has been shown (Williams, 1983) that cholesteric liquid crystals can be used in this application to provide a nondestructive evaluation of flaws in fiberglass boat hulls. By synthesizing and mixing various materials, the temperature at which visible reflections occur can be varied from roughly 0 to 50 °C, and the temperature range over which the reflected color changes from red to blue can be adjusted from about 10 to 1 °C. The materials can also be obtained commercially encapsulated in micron-sized polymer capsules, which makes them easier to handle in many applications.

2.4 Cholesteric "Blue" Phases

An interesting puzzle that has been solved during the last decade is the nature of the "blue" phases exhibited by some cholesteric materials over a narrow temperature range just below their transition to the isotropic phase. The name derives from the bluish appearance they often have; they were first observed by Reinitzer (1888). Blue phases have proved interesting to theorists seeking to understand the significance and broader implications of the chiral term in the free energy, and they have provided a challenge to experimenters seeking to elucidate their structure (Collings, 1990).

By a combination of calculations and polarization-sensitive light scattering, it has been shown that the blue phases consist of an ordered lattice of defects in the cholesteric texture (the spatial orientation field of the director) that are able to accomodate a double twist. Three blue phases are known: blue phase I has body-centered symmetry, blue phase II is simple cubic, and the structure of blue phase III, sometimes called the "fog phase," is yet unknown. It turns out that the state in which the director throughout the sample precesses about a uniform pitch axis is not the lowest elastic free-energy state for these materials. The reason is that the cholesteric would have a lower free energy of interaction between the molecules if the director could twist in two directions at once. This is not possible topologically, but it can occur through the creation of singular line defects (regions where the order parameter goes to zero), which have, however, a high free-energy cost. The tendency to form a blue phase increases as the pitch becomes shorter. The blue phases exist only over narrow temperature ranges and have yet to find applications.

3. SMECTIC LIQUID-CRYSTAL PHASES

The smectic phases represent the next step towards crystalline order beyond the nematic phase. Each smectic phase is named by a letter; these were assigned roughly in the order in which they were discovered. At this writing, smectics *A* through *L* have been identified. In the past, the structure and molecular arrangements of many smectic phases were not known. Phases were identified by their appearance under a polarizing microscope, which gave some indication of the texture (the spatial orientation field of the director), and a new phase was identified as one which did not mix with other known smectic phases. The refusal to mix was a fairly reliable indication the phases had different symmetries. As more has been learned about the structure of smectics, it has become clear that about a third of them are not truly liquid-crystal phases, because they have three-dimensional long-range crystalline order. They are crystals with especially soft elastic constants. The smectic liquid crystal phases all have some translational order in addition to the molecular orientational long-range order of the nematic and cholesteric phases. Some also have a new kind of order, called bond-orientational order, which we shall now discuss.

3.1 Smectic-*A* Phases

The simplest smectic phase is called smectic-*A*. In this phase, the molecules tend to form "layers" that are perpendicular to the director, as illustrated in Fig. 5. The term "layer" is an overstatement of the ordering. In most smectic-*A* materials the layers are not well defined, and what one really has is more accurately described as a modulation of the density

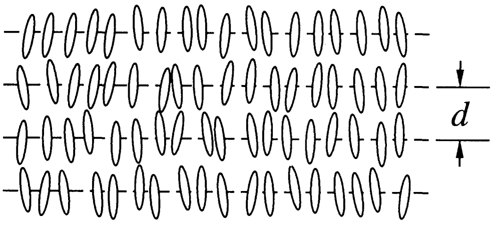

FIG. 5. Molecular arrangement in a smectic-*A* liquid crystal. The director is parallel to the density wave vector.

whose wave vector is along the director. In fact, the smectic-*A* order is commonly represented (de Gennes, 1972) by the order parameter ψ in the following expression for the density of the liquid:

$$\rho(\mathbf{r})=\rho_0[1+\mathrm{Re}\,\psi(\mathbf{r})e^{iq_0z}], \tag{5}$$

where $d = 2\pi/q_0$ is the wavelength of the density wave or the spacing of the smectic "layers." The order parameter ψ is a complex number with two degrees of freedom. The magnitude $|\psi|$ is the amplitude of the density modulation, and the phase represents a displacement of the "layers" in the wave-vector direction, which is usually taken to be z. Smectic-*A* order is really a one-dimensional density wave in a three-dimensional liquid, and can be said to be the simplest kind of freezing or melting to occur in nature. The smectic-*A* phase remains translationally invariant (liquid-like) in directions perpendicular to the density wave vector.

3.1.1 Analogy to Superconductivity.

de Gennes (1972), Kobayashi (1970), and McMillan (1971) all recognized that the two-component order parameter of the smectic-*A* phase was similar to the order parameter used in the Ginzburg-Landau phenomenological model (Ginzburg and Landau, 1950) of superconductivity. The analogy may be seen through the following argument. Suppose, while moving through the smectic-*A* material from point *A* to point *B*, we compute the line integral

$$\frac{1}{d}\int_A^B \mathbf{n}\cdot d\mathbf{r}. \tag{6}$$

This integral calculates the number of "layers" that have been crossed. If the smectic-*A* is free of defects, the result must be independent of the path followed, which means that the integral carried out around a closed path must yield 0. Applying Stokes's theorem, we find that $\nabla \times \mathbf{n} = 0$ in the smectic-*A* phase, and so, referring to Eq. (4), it is apparent that bend and twist director distortions are excluded from the smectic-*A* phase. This is analogous to the exclusion of magnetic fields from superconductors (the Meissner effect). In fact the phenomenological theories of the smectic-*A* to nematic phase transition and the superconducting to normal-state transition are mathematically similar. The liquid crystal director **n** is quite analogous to the magnetic vector potential **A** of the superconductor. As a smectic-*A* phase is approached in the nematic phase, the presence of smectic short-range order causes a divergence of the bend and twist elastic constants, which is the analog of fluctuation diamagnetism in superconductors. Recently a twisted grain-boundary phase has been observed (Goodby *et al.,* 1988) in smectic-*A* materials. This phase is analogous to a lattice of flux penetration vortices in superconductors (Toner, 1991).

3.1.2 Polymorphic Smectic-*A* and Smectic-*C* Phases.

The smectic-*A* phase discussed above has been assumed to have a layer spacing *d* that is approximately equal to the length *l* of a molecule. However, if the molecules have a strong longitudinal dipole moment, such as the top cyanobiphenyl one in Fig. 1, there will be near-neighbor antiparallel correlations. These correlations can lead to different polymorphic forms of the basic smectic-*A* symmetry, which can be characterized by the ratio d/l. These have largely been elucidated through the pioneering work of the Bordeaux group (Sigaud *et al,* 1979; Hardouin *et al.,* 1983). Four forms of smectic-*A* are now recognized: smectic-A_1 with $d \simeq l$, smectic-A_2 with $d \simeq 2l$, smectic-A_d with $l<d<2l$, and smectic-$\tilde{A}$ which has the same local symmetry as smectic-A_2 but with a transverse dipolar modulation of the structure. The existence of these polymorphic smectic-*A* phases has been explained by a phenomenological model (Prost and Barois, 1983) that has two coupled order parameters, the mass-density wave and a dipolar-density wave. This approach has predicted novel critical phenomena associated with the transitions between different polymorphic types. Many of these predictions have been verified experimentally (Garland, 1990). Analogous modulated variants of the smectic-*C* phase, introduced below, have also been found to exist (Hardouin *et al.*, 1983; Huang *et al.*, 1984; Safinya *et al.*, 1986a).

3.2 Smectic-*C* Phases

In smectic-*C* liquid crystals the molecules are disordered within the layers as in a smectic-*A* phase, but they are also tilted with respect to the layer normal (Fig. 6); in other words, the density wave vector and the director are not parallel. This means that smectic-*C* phases are optically biaxial; often this complication can be approximated by simply referring to separate components of a director in the plane of the smectic layers and normal to them. In a well-established smectic-*C* phase enough energy is required to change the tilt angle with respect to the layers (it is coupled to the layer thickness) that it fluctuates very little. The component of the smectic-*C* director in the plane of the layers is almost as free to fluctuate in orientation as the director of a nematic phase, and these fluctuations provide a time and space dependence to the refractive indices that can scatter light strongly.

In many cases, the smectic-*C* phase will form from a smectic-*A* by a continuous tilt of the molecules. This is a second-order phase transition that has the same symmetry properties as transition to a superfluid phase in helium. It should, therefore, exhibit critical behavior. Careful experiments have shown, however, that the growth of the tilt can be described by a mean-field model (Birgeneau *et al.*, 1983). The reason for this is that a large bare coherence length reduces the effect of the thermal fluctuations responsible for critical behavior to a region very close to the transition temperature (Ginzburg, 1960). In some materials, the smectic-*C* phase forms directly from the nematic without an intervening smectic-*A* phase. In these cases the tilt angle is usually large, about 45°, and only weakly temperature dependent. The smectic-*C* to nematic transition is first order because of the effect of thermal fluctuations.

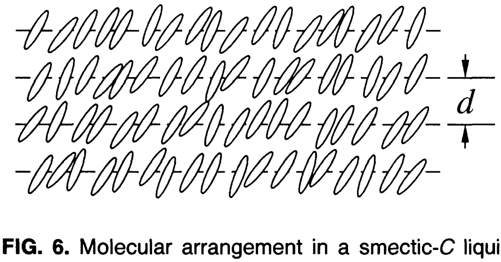

FIG. 6. Molecular arrangement in a smectic-*C* liquid crystal. The director is tilted with respect to the density-wave vector.

3.2.1 The Absence of True Long-Range Order. As the number of spatial dimensions is reduced, ordered phases lose their order. No long-range order is believed possible in one dimension, because the entropy of the disordered state is overwhelmingly higher. Many of the common three-dimensionally ordered phases cannot have long-range order in two dimensions at finite temperature. That is because thermally excited fluctuations will destroy the order. Solids, for example, cannot exist in two or fewer dimensions because the fluctuations of the atomic positions in the crystal lattice due to thermally excited lattice vibrations become infinite in two dimensions (Landau and Lifshitz, 1980). In the language of phase transitions, we say that the lower marginal dimensionality for the existence of solid crystals is two.

Smectic-*A* and smectic-*C* liquid crystals are examples of a one-dimensional density wave in a three-dimensional liquid. The marginal dimensionality for such a material is three (Caillé, 1972), so these smectic phases can, strictly speaking, only exist in more than three dimensions. Precisely at the marginal dimensionality, the effects of the fluctuations are subtle. Whether or not long-range order exists can be discussed quantitatively by defining a correlation function

$$\mathscr{G}(\mathbf{r}) = \langle e^{i\mathbf{G}\cdot[\mathbf{u}(0)-\mathbf{u}(\mathbf{r})]}\rangle, \qquad (7)$$

where $\mathbf{G}$ is a reciprocal-lattice vector of the crystal, and $\mathbf{u}(\mathbf{r})$ is the displacement of an atom at $\mathbf{r}$ from its equilibrium position. In the case of a smectic-*A* phase, $\mathbf{G}$ would be the smectic density wave vector q_0 and $\mathbf{u}$ the displacement of a smectic layer from its proper position. This function is useful because its Fourier transform gives the x-ray Bragg scattering from the crystal lattice or smectic density wave. If there is long-range order, $\mathscr{G}(\mathbf{r})$ will have a finite value as $r \to \infty$. If there is only short-range order, $\mathscr{G}(\mathbf{r})$ decays exponentially to zero as $e^{-\kappa r}$. At the marginal dimensionality, $\mathscr{G}(\mathbf{r})$ goes to zero at large distances, but does so algebraically as $r^{-\eta}$, where η is a small number ~ 0.1. When there is long-range order, the Bragg scattering will give a resolution-limited peak. Short-range order will give a broad peak whose width is proportional to κ. The algebraic decay at the marginal dimensionality gives a scattering peak that is a cusp and is very difficult to distinguish experimentally from the resolution-limited peak of true long-range order. The experimental trick is to use a high-resolution spectrometer with a sharply decaying resolution function (Als-Nielsen *et al.*, 1980) obtained from multiple Bragg reflections in perfect collimating crystals. Most of the properties of smectic-*A* and smectic-*C* liquid crystals are not significantly different than they would be if the order were truly long range. However, they have been of fundamental interest to demonstrate the existence of marginal dimensionality and to study in three dimensions behavior that occurs only in two dimensions in most other materials.

3.3 Ferroelectric Smectic-*C* Phases

Many liquid crystal molecules have dipole moments, and there appears to be no intrinsic reason why nematic phases could not be ferroelectric, but none has ever been observed. Meyer realized that it should be possible to obtain ferroelectricity in a smectic-*C* liquid crystal if the molecules were chiral (Meyer *et al.*, 1975). We can illustrate the idea by referring to Fig. 7. In the figure we represent the chirality by choosing molecules shaped like a hockey stick with a dot on the left side. Suppose the dot represents an electric dipole pointing from the side of the molecule. The second molecule in Fig. 1 is, in fact such a molecule. The top panel, Fig. 7(a), shows a smectic-*A* phase of these molecules. Two alternatives for a smectic-*C* phase are shown in the other two panels of the figure. Both have the end-for-end symmetry of liquid crystal phases, but the arrangement in Fig. 7(c) permits a much closer packing of the molecules and is the one that might be expected to occur once the molecules tilt. It also has the dots on the molecules visible and will have a net electric dipole moment in the plane of the smectic-*C* layers. This is the origin of the ferroelectricity that enables applied fields to control the molecular orientation and leads to the development of a device we shall discuss presently. Ferroelectric smectic-*C* phases are commonly referred to by the notation smectic-*C**. In a racemic mixture, half the molecules would have the dot on the left side, and half would have it on the right; hence there would be no net dipole moment.

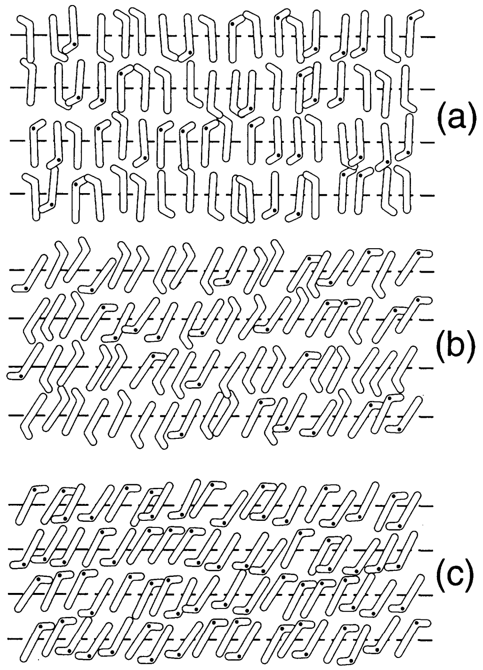

FIG. 7. Smectic phases of chiral molecules. (*a*) A smectic-*A* phase, (*b*) a tilted smectic-*C* phase with no ferroelectric order, and (*c*) a ferroelectric smectic-*C* phase.

3.4 Bond-Orientationally Ordered Phases

We mentioned earlier that the structure of many smectic liquid crystal phases was unknown until recently. The concept of bond-orientational order was the missing idea that was necessary to characterize the structure of the different smectic phases. The idea originated in theoretical investigations of melting in two dimensions. Liquids have both continuous rotational and continuous translational symmetries. In crystalline solids, both of these symmetries have been "broken" and are discrete. As we mentioned in Sec. 3.2.1 above, solids cannot have true long-range order in two dimensions. However, they can have a phase, different from a two-dimensional liquid, which has power-law decay of the correlation function given in Eq. (7). This is commonly called a Landau–Peierls state, in order to recognize earlier work of Peierls and Landau on the topic. In 1973, Kosterlitz and Thouless proposed a theory of melting in two dimensions, a dislocation-mediated transition between a two-dimensional Landau–Peierls state and a two-dimensional liquid. This was a model for breaking the continuous translational symmetry. Extending it to consider the rotational symmetry as well, Halperin, Nelson, and Young predicted the existence of an intermediate "hexatic" phase that had the discrete rotational symmetry of a crystal combined with the continuous translational symmetry of a liquid. The idea is illustrated by the sketch shown in Fig. 8. Even in a two-dimensional liquid, one might expect local arrangement of the molecules to be in hexagonal clusters whose size is a correlation length ξ, as shown in Fig. 8. There would, however, be no correlation between the positions or orientations of such clusters if they are separated by more than ξ in distance. If the material were to form a hexagonal crystal, such local clusters would be expected to have the same orientation of the imaginary lines joining near neighbors, and to be separated by an integral number of lattice vectors. In effect the translational and rotational corelation lengths have become infinite. In the hexatic phase, which has "bond orientational" order, there is no positional correlation between widely separated clusters, but lines joining near neighbors have the same orientation throughout the sample. Only the rotational correlation length is infinite. Thus the rotational symmetry is discrete although the continuous translational symmetry remains unbroken. It was recognized by Landau, and subsequently by Mermin, that it was theoretically possible for a phase with these properties to exist in nature. In effect, it would be a liquid in which one knew in which directions it was necessary to go to encounter a neighboring molecule, and these directions were the same throughout the liquid, but one did not know how far to go. Birgeneau and Litster (1978) proposed that extending these two-dimensional ideas to three dimensions might provide an explanation for some of the higher-ordered smectic phases, such as smectic-*B*, whose structure was unknown. They proposed that within the smectic layers there was bond-orientational order, but no translational order.

Although some smectic-*B* phases have three-dimensional long-range translational order (Pershan *et al.*, 1979), others have been found with only long-range bond-orientational order (Moncton and Pindak, 1979; Pindak *et al.*, 1981). These are usually called smectic-B_H to indicate the presence of hexatic order. Tilted analogs of the smectic-B_H are also known; these are the smectic-*F* and smectic-*I* phases. In the smectic-*I* the molecules tilt towards the position of their nearest neighbors, while in the case of smectic-*F* phases the tilt direction is between the nearest neighbors. There are no interlayer correlations in the smectic-B_H, but

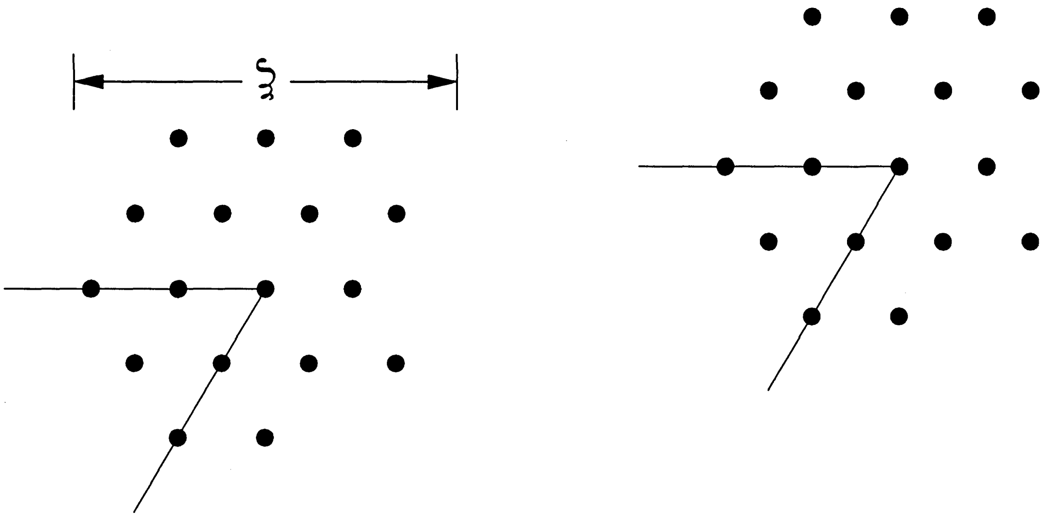

FIG. 8. Sketch to illustrate the concept of bond-orientational order. The two clusters have the same orientation but their positions are not correlated.

in the tilted phases the tilt applies an effective field to the bond-orientational order and causes interlayer correlations. In principle, the tilt will induce bond-orientational order in the smectic-*C* phase, changing it to an *F* or *I* phase. Strictly speaking, therefore, the smectic-*C* phase does not exist. This effect, so far, has been too small to detect and seems to have few practical consequences.

The smectic phases with bond-orientational order exist only over a narrow temperature range, and have not seen applications. They have, however, been studied extensively (Brock *et al.*, 1989) in order to elucidate the properties of a phase of matter whose existence would have greatly surprised most solid state physicists 15 years ago.

3.5 Higher-Order Smectic Phases

In addition to the fluid phases described so far, there are a number of smectic phases with true long-range translational order in three dimensions. These are the smectic-*B*, -*G*, -*J*, -*E*, and -*K* phases. There are differences in the molecular tilt, stacking of layers, and the extent of rotational disorder about the long axis of the molecules among these phases, but they are not true liquid crystals. They are crystalline solids, although in many cases the elastic constants can be as much as 10^6 weaker than the elastic constants of more common crystals.

3.6 Applications of Smectic Phases

3.6.1 Smectic-*A* Devices. Although the higher viscosity and greater force required to alter the texture of smectic-*A* phases renders them less suited for electro-optic displays, these are features that make them attractive for different types of memory devices (Coates, 1990). In one type of memory device the smectic-*A* is aligned "homeotropically" (molecules perpendicular to the substrate surface). This will provide a clear state for transmission of light between two glass substrates. A focused laser beam is used to heat a small area of liquid crystal into the isotropic state. When the laser is turned off, the liquid crystal cools rapidly to the smectic-*A* phase. The rapid cooling results in misalignment and the different texture scatters light, thus storing information that can be read out optically. The texture can be restored to homeotropic, and the stored information erased, either by the application of an electric field or by heating the entire liquid crystal to the isotropic state and cooling slowly. This makes possible a very high–information-content, although not particularly fast, read-and-write optical storage device.

The electroclinic effect in chiral smectic-*A* liquid crystals, such as in Fig. 7(a), can also provide device capability. In the electroclinic effect (Garoff and Meyer, 1977) an applied electric field can induce a tilt in the optic axis that is proportional to the applied voltage. This can, in principle, make possible features such as variable gray scale and analog phase modulation in a chiral smectic-*A* device.

3.6.2 Ferroelectric Smectic-*C* Applications. Ferroelectric smectic-*C** liquid crystals (FLCs) appear to have excellent potential for applications in fast electro-optic switching devices with memory. In such a device the basic configuration is the surface-stabilized ferroelectric liquid crystal (SSFLC) geometry in which the smectic-*C** material is contained between two transparent electrodes separated by about 2μm. The surfaces are treated to obtain a planar orientation of the molecules. Because they are chiral, smectic-*C** phases will have a precessing optical axis analogous to cholesteric phases. But, if the thickness of the SSFLC cell is less than the pitch of the optical axis helix, the interaction with the surfaces will unwind the helix. This produces a "bookshelf" geometry of Fig. 9 in which the smectic layers are perpendicular to the substrates and the molecular orientation is in the plane of the substrate making the tilt angle ω with respect to the layer normal. By reversing the polarity of the applied electric field, the molecules can be caused to flip to an orientation $-\omega$ with respect to the layer normal, hence rotating the optic axis by 2ω. The optimal value for ω is 22.5°, and switching times as fast as 0.1 μs have been demonstrated (Clark and Lagerwall, 1980). The switched state is also stable, and so the device provides storage, which greatly reduces the multiplexing problems of TN (twisted nematic) devices. The small electrode spacing and the fact that the response is determined by the electric field, not the applied voltage, has made these devices more difficult to manufacture. Efforts are also under way to synthesize ferroelectric liquid crystals with a significant dipole mo-

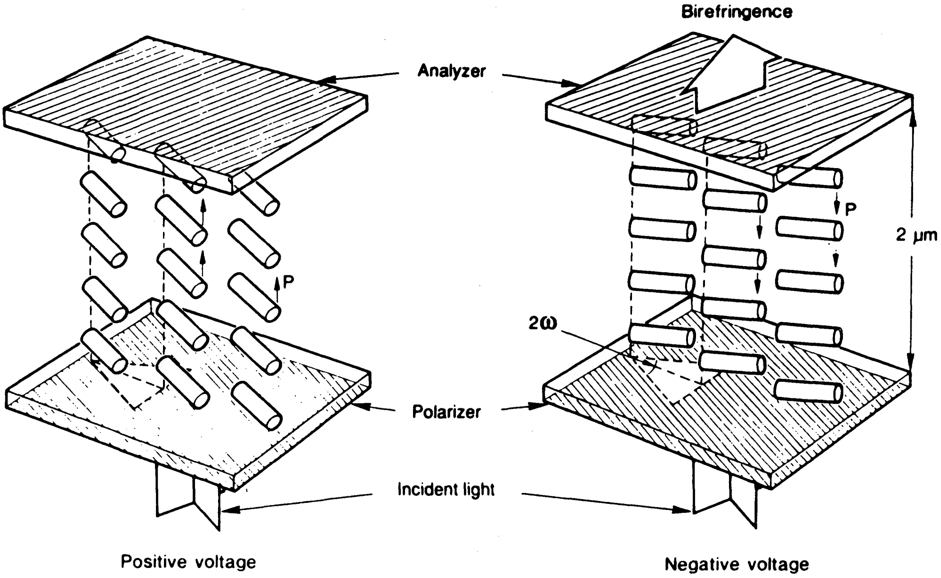

FIG. 9. The "bookshelf" geometry of a surface-stabilized ferroelectric liquid crystal display cell.

ment parallel to the long axis of the molecule; if the efforts are successful these materials could play an important role in FLC devices. Despite their fast switching times and the storage capability, SSFLC devices do not yet appear to have mounted a serious challenge to TN displays. However, this may change; at least one company (Canon Electric Company) has introduced ferroelectric liquid-crystal displays for its notebook computers.

4. DISCOTIC LIQUID CRYSTALS

Until recently it was believed that a prerequisite for the existence of a thermotropic liquid crystal phase was a rodlike shape of the molecules. However, liquid crystal phases have been demonstrated for disklike molecules (Chandrasekhar, 1979). Generally, the molecules have flat cores with long-chain substituents attached to the core. These molecules have been shown to exhibit two distinct types of mesophases: columnar and nematic. In the nematic phase, the disks are orientationally ordered without any positional order.

The columnar phases are formed by the molecules being stacked in columns, like poker chips, and then the columns are arranged in a hexagonal or rectangular fashion. A sketch of the local structure of a columnar discotic phase is shown in Fig. 10. Unlike the nematic phases of rodlike molecules, discotic nematics are usually optically negative ($\epsilon_{\parallel} < \epsilon_{\perp}$). Tilted columnar phases also exist. There is no translational order along the length of the columns. These phases are analogous to the smectic phases, except that they have a two-dimensional density wave in a three-dimensional liquid. This arrangement lacks the Landau-Peierls instability of the smectic-*A* phase and can have true long-range order.

5. POLYMER AND POLYMER-DISPERSED LIQUID CRYSTALS

5.1 Polymer Nematic and Smectic Liquid Crystals

5.1.1 Mesogenic Main-Chain and Side-Chain Polymers. Thermotropic liquid-crystal polymers evolved by researchers incorporating mesogenic monomers into polymer chains (Donald, 1992). They can be incorporated into the main polymer backbone chain, or by adding mesogenic side chains. Polymers with disklike mesogenic units are also known. The main-chain liquid crystal polymers tend to have very high melting temperatures and to be very slow in response to applied electric or

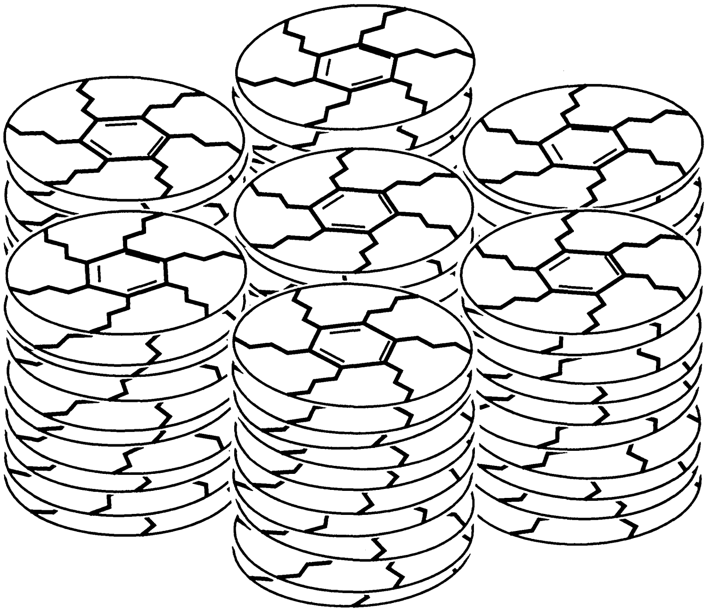

FIG. 10. Schematic of molecular arrangements in a columnar discotic liquid-crystal phase.

magnetic fields. However, one of the viscoelastic features of nematic liquid crystals is a very strong tendency to flow alignment. This can be exploited in polymer processing to produce fibers in which the polymers are oriented; such materials can have a much greater elastic modulus than those prepared conventionally from an isotropic melt. The best known example is Dupont's Kevlar®, which is spun from a nematic phase and has an elastic modulus comparable to that of steel.

The polymers with mesogenic side chains often offer response times to applied fields that are comparable to those of small-molecule liquid crystals. They can have not only nematic, but also cholesteric and smectic phases. Their viscosities and glass transition temperatures are much lower than main-chain polymers. They can be aligned easily by the same techniques (surface rubbing, skew evaporation, and surface texturing of the substrate) used for small-molecule liquid crystals. There is a potential for the polymer main chain to provide added stability to the liquid-crystal order, perhaps preserving some of the features in a solid phase, or to assist in obtaining better alignment of the liquid-crystal phase.

More recently, combined liquid crystalline polymers with mesogenic groups in both the main-chain and side groups have been synthesized. The degree of coupling of the main-chain and side-chain mesogenic groups depends on the molecular "spacer" used to attach the side groups to the main chain.

5.1.2 Applications of Polymer Liquid Crystals. Most of the work on polymeric liquid crystals has been motivated by the belief that these materials have many potential technological applications. The example of Kevlar® has inspired much of the effort. Mesogenic side-chain polymers offer potential for electro-optic displays, nonlinear optical applications, and pyroelectric applications. They may be attractive candidates for erasable holographic elements. This is an area of high current activity, and we shall have to await the results to see how valuable they turn out to be.

5.2 Polymer-Dispersed Liquid Crystals

These materials were the serendipitous result of efforts to improve the stability of liquid crystals aligned for NMR studies (Doane *et al.*, 1986). Liquid crystals can be mixed with the components of an epoxy resin; as the epoxy cures, a phase separation takes place in which much of the liquid crystal is expelled from the epoxy matrix. The result is approximately micron-sized droplets of small-molecule nematic liquid crystals dispersed in a polymer binder. Polymer-dispersed liquid crystals

(PDLCs) are now produced in several ways: solvent-induced precipitation, thermally induced precipitation, emulsion polymerization, or phase separation.

A material with a positive dielectric anisotropy can be aligned by a field applied when the PDLC is sandwiched between transparent electrodes. Normally the nematic droplets will scatter light strongly, and the material appears like a translucent shutter. If the ordinary refractive index of the liquid crystal is matched to that of the polymer matrix, the scattering will disappear when the field aligns the director. PDLCs offer the potential for high-transmission, large-area light shutters and displays with low power consumption. The absence of polarizers increases the transmission considerably, which makes them attractive for projection displays.

6. LYOTROPIC PHASES

The lyotropic liquid crystal phases contain amphiphilic or surfactant molecules. Because one end of the molecule prefers to be in contact with water and the other prefers oil, the molecules will go to the oil-water interface of a "solution" that contains both. If only oil or water is present along with the surfactant, various structures will form in order to segregate the oil-loving moiety, say, from water. The simplest type of aggregate formed by surfactant molecules in water is a micelle, shown in Fig. 11. The hydrophobic tails of the molecules can minimize contact with the water by segregating themselves in the center of the micelle. There is a price in reduced entropy as well as crowding of the hydrophobic tails to be be paid when this structure is formed. Usually double-tailed surfactants do not form micelles. In an oil solution, inverted micelles can form in which the hydrophilic moiety goes to the center of the micelle. When oil, water, and surfactants are mixed a wide variety of phases can form (Fontell, 1981). Only some of these phases have liquid crystalline order, but all are probably closely related and their existence and properties are determined by the same physical principles (Israelachvili, 1985). The surfactant phases are interesting because, as in biological systems, entropy plays a dominant role in their properties and behavior; some also provide interesting examples of two-dimensional physics. Lyotropic liquid-crystal phases are not yet as well studied or fundamentally understood as their thermotropic counterparts are.

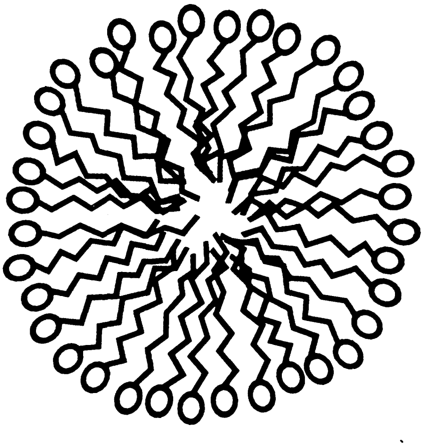

FIG. 11. Cross-sectional sketch of a micelle formed by amphiphilic molecules in water.

6.1 Phases with Ordered Micelles

Micelles are usually spherical, but under conditions that are not entirely understood, the micelle may not be spherical. Nonspherical micelles can order orientationally to form a nematic phase, and micellar nematic phases can be formed from either rodlike or disklike (Fujiwara and Reeves, 1980) micelles. As well as the usual hydrocarbon-tailed surfactants, micellar liquid crystals can be formed by surfactants with fluorocarbon tails (Tiddy, 1972; Boden *et al.*, 1979). The micellar nematic phases have viscoelastic properties (Haven *et al.*, 1981) and normal modes (Kumar *et al.*, 1983) that are closely similar to those of small-molecule thermotropic phases. In some materials the rodlike micelles can grow very long and order in a hexagonal array; these "middle soap" phases are probably the lyotropic analogs of the columnar discotic thermotropic phases. With chiral surfactants, lyotropic cholesteric phases are possible (Covello *et al.*, 1983).

6.2 Lyotropic Lamellar Phases

Many surfactants, especially biologically derived ones with double aliphatic tails, will form bilayers in aqueous solution. The phase formed depends sensitively on the spontaneous curvature of the bilayer. If it tends to be flat, then the system will form a lamellar structure as in Fig. 12; the resulting phase is closely similar to the thermotropic smectic-*A* phase; in the language of lyotropic liquid crystals (Tiddy, 1980), this phase is called L_α. If there is a tendency for the bilayer to curve, then interesting bicontinuous phases may form in which the bilayer forms a cubic lattice of intersecting curved surfaces (Gruner, 1989), sometimes referred to as the "plumber's nightmare."

The L_α phase has the same symmetry and normal-mode structure as the thermotropic smectic-*A* phase, and it also has the same lack of true long-range order in three dimensions (Safinya *et al.*, 1986b). The bilayers are more sharply defined than the smectic-*A* density wave, and the higher-order Bragg peaks are usually present in the x-ray scattering. With nonionic surfactants in water, such as the polyethylene glycol ethers (Strey *et al.*, 1990), or bilayers separated by oil (Appell *et al.*, 1989), it is possible to prepare highly swollen L_α phases in which bilayers a few nm thick are separated by many hundreds of nm. These systems are stabilized by repulsive forces between the bilayers, which can act over a very long range. In fact their properties are dominated by a previously unrecognized force predicted theoretically by Helfrich (1978). This force comes into play when any electrical forces between the bilayers are extremely weak and the bilayers are rather flexible. Its origin is entropic; the thermal fluctuations of the layers is sufficiently great that they repel through colliding with each other as they fluctuate. The highly swollen L_α phases are interesting systems in which to study the Helfrich force, as it is the dominant force stabilizing them. They are also interesting experimentally because Bragg scattering, which normally requires x rays, can be done with visible light. The energy resolution of 10^{15} available in light scattering enables a careful investigation of the dynamical behavior that one cannot obtain with x rays.

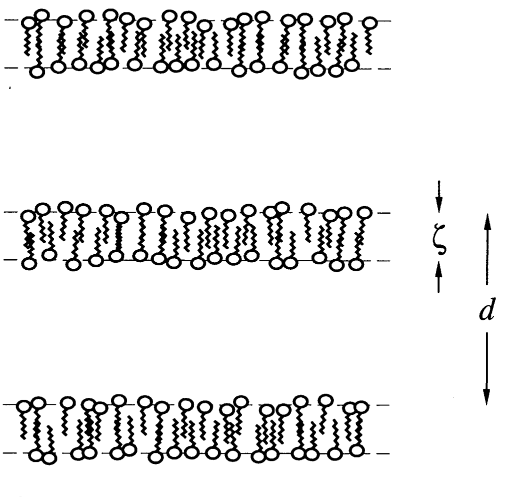

FIG. 12. A smectic-*A* lyotropic lamellar liquid-crystal phase. The surfactant bilayers of thickness ζ are separated by regions of water of thickness $d-\zeta$.

6.3 Applications of Lyotropic Liquid Crystals

Lyotropic liquid crystal phases usually occupy only a small part of the complicated phase diagrams that result when oil, water, salt, and one or more surfactants are combined. Surfactants are extraordinarily useful materials with many technological applications. These are usually connected with the ability of the surfactant molecules to reduce the interfacial energy (surface tension) between two liquids that would not ordinarily mix because of this high interfacial energy. A common example is the use of microemulsions in tertiary oil recovery. A microemulsion is a thermodynamically stable phase (Winsor, 1954; Kahlweit *et al.*, 1987) in which oil and water are separated by a random interface of surfactant. The surfactant can reduce the interfacial energy between oil and water, normally about 30 erg cm^{-2}, by 1000 times or more. This is important, for water is pumped into oil wells to force the oil out of small cracks in the rock, and reducing the oil–water surface tension greatly facilitates this process. The practice is not economical with current oil prices, but we shall undoubtedly see it at some time in the future.

The ordered liquid crystal lyotropic phases and their disordered relatives are interesting objects to study for those who seek a better understanding of classical statistical mechanics and random surfaces (Huse and Leibler, 1988), for they are systems in which thermal fluctuations and entropy play an important role. Understanding the ordered liquid-crystal phases can lead to better understanding of the forces and interactions that determine properties of other phases and materials containing biological surfactants such as phospholipids. For example, the viscoelastic properties of lyotropic liquid crystals can explain the shape of red blood cells (Deuling and Helfrich, 1976), and are believed to provide insight into biological membrane functions such as endocytosis, membrane fusion, and cell fission (Gruner, 1989) as well as the formation of vesicles and tubules (Lubensky and Prost, 1992). It also seems that studies of lyotropic liquid-crystal ordering should offer some insight into the self-assembly process (Deckman *et al.*, 1988) of Langmuir–Blodgett films.

7. CONCLUSIONS

In this article we have felt it was important to give an introduction to the structure of the various ordered phases, to indicate their role in the intellectual development of both physical chemistry and condensed matter physics, to point out special viscoelastic and optical properties of thermotropic liquid-crystal phases, and to comment upon the applications they have found. The reader should consult the literature references for more information. The journals of the Institute for Electrical and Electronic Engineers, the Society for Information Displays, and SPIE–The International Society for Optical Engineering (Jacobs, 1992) are especially good sources of information about display uses of thermotropic liquid crystals, which remains their major area of application.

ACKNOWLEDGMENTS

One of us (J.D.L.) would like to express thanks to the National Science Foundation for support from Grants No. DMR-9022933 and No. DMR-9014886 during the preparation of this article and for support of the research some of it is based on.

GLOSSARY

Amphiphile: A molecule consisting of two parts, one being soluble in water, the other in oil.

Birefringence: The condition of having two different refractive indices; the one observed depends on the polarization state of the light.

Bond-Orientational Order: A type of order in which the imaginary lines joining the centers of neighboring molecules are ordered, but the positions of the molecules are not. (See Sec. 3.4.)

Chirality: A chiral object is one which has either right- or left-handed symmetry, analogous to the difference between right- and left-handed screw threads.

Correlation Length: Sometimes called coherence length, the distance over which fluctuations in a quantity, usually an order parameter, are correlated. Commonly, the relative strength of correlations at two points separated by a distance r weakens as $e^{r/\xi}$, where ξ is the correlation length.

Director: A name given to a unit vector field that points along the local orientation of the optic axis of a liquid crystal. (See Sec. 1.1.)

Ferroelectric: A material that posesses a permanent electric polarization.

Mesogen: A term used to indicate a molecule that tends to form a liquid-crystal phase, which is sometimes called a mesophase. (Mesophase means "in-between phase.")

Micelle: Roughly sperical aggregate of amphiphilic molecules. (See Sec. 6.1.)

Optical Activity (Circular Birefringence): An optically active material is one whose refractive index differs for right and left circularly polarized light.

Order parameter: A quantity used to describe quantitatively the amount of order in a phase; see Sec. 1.1 for an example describing molecular orientational order in a nematic liquid crystal. It is defined to be zero in a disordered phase.

INTRODUCTION

Although all liquids, and solid glasses too, are structurally disordered, or noncrystalline, there are many varieties of structure, some of which may be called *simple*. What differentiates one great class of liquids from another—say, liquid metals from molten salts—is the different nature of the intermolecular forces or, one could equally well have said, the different kinds of molecule. To see which liquids might reasonably be labeled as simple, we must therefore refer to the interparticle forces. We shall adopt four criteria of simplicity which, though not logically equivalent, are such that, if one holds, it will not be surprising if the others do too.

First, the molecules should be small. Second, they should interact by force fields which, if not spherically symmetrical, depart from this by such a small amount that it may be specified by at most a few nonspherical terms. Third, it should be true to a high degree of approximation that the internal structure of the molecule is an independent entity not affected by the position of neighbors. Fourth, the molecules should act by pairwise additive forces—a well-tried assumption in the physics

of simple liquids. Thus the ideal case might well be liquid argon composed of stable monatomic molecules with spherical force fields. Among the simple liquids are metals—although it was a considerable achievement of metal physics to show under what conditions the fourth criterion holds. Also simple are those molten salts in which the long-range interaction is Coulomb attraction or repulsion between ionized atoms as in NaCl. The second criterion allows us to admit small molecules like N_2 or CCl_4, but molecules with quite small numbers of atoms, such as glycerol ($CH_2OHCHOHCH_2OH$), can have shapes and dipole moments which call all four criteria into question. The remaining sections will therefore discuss liquid noble gases, a few molecular liquids, metals, and molten salts.

The criteria exclude several kinds of liquid. The structures of many nonmetallic glasses, both liquid and solid, are formed from ramifying networks of directed covalent bonds; even some elements, such as Te and Se, are excluded for this reason. Liquid crystals have rodlike or otherwise nonspherical molecules that cause structural order in one or two dimensions. Liquid polymers or solutions containing highly complex molecules such as proteins are clearly not simple. Additional complications that exclude liquids from present consideration are macroscopic quantum behavior, as in liquid He; the intermolecular bridges formed by hydrogen bonds, as in water; or large solute particles, as in colloidal solutions. Nevertheless, the diffraction techniques mentioned below for simple liquids remain important even for the complex cases we are excluding. The reader will find discussions of more complex liquids in the articles on LIQUID CRYSTALS, STRUCTURE OF; POLYMERS, STRUCTURE OF; and GLASSES.

1. WHAT IS MEANT BY THE STRUCTURE?

The structure of a pure perfect crystal is totally defined by its unit cell, and the elegant science of crystallography has solved the problem of determining unit cells. Liquids do not have unit cells, and to visualize the atomic arrangement as billiard balls jumbled in a bag is to make a good first guess. The numerous symmetries that control crystal structure mean that the environment of an atom in its unit cell is identical with that of every corresponding atom in every other unit cell. In a liquid no two atoms have the same environment or, if they happened by chance to do so, it would only be transiently, because the atoms are continually interdiffusing and changing neighbors. It follows that structure must be a statistical concept in liquids. For example, in a crystalline binary alloy of *A*-type and *B*-type atoms one can answer the question: Where exactly are the *A* atoms relative to the *B* atoms? In the liquid alloy one can answer a limited number of questions such as: What is the average number of *B* atoms that are nearest neighbors to an *A* atom? How far away are they on the average? In what follows we shall assume that our materials are homogeneous and isotropic. This not only reduces the amount of vector symbolism but is intrinsically reasonable for liquids in thermodynamic equilibrium. It might well be inadequate for strained glasses, which are not isotropic, or multiphase systems, which are not homogeneous.

2. DISTRIBUTION FUNCTIONS

2.1 The Pair Distribution Function

Let us define with some care one of the fundamental quantities for a pure liquid. Extensions of the formulas can then be made more summarily. Suppose N atoms are confined in a macroscopic volume V. Then $n_0 \equiv N/V$ is the average number density. The position of a spherical atom means the point occupied by its center. Imagine a spherical shell of radius r and thickness δr centered on any atomic position. The volume of the shell is $4\pi r^2 \delta r$, but the number of atomic centers in the shell is not necessarily $4\pi r^2 n_0 \delta r$. For example, if r is approximately the radius of an atom, the number of centers in the shell will be zero because atoms strongly resist overlap. On the other hand, if r is about the atomic diameter, the number could be up to 12 because twelve spheres can touch simultaneously a central one of equal size. In general, therefore, the number of centers in the shell is $4\pi r^2 n_0 g(r) \delta r$, where the factor $g(r)$ allows the actual number density in the shell, i.e., $n_0 g(r)$, to depart from n_0 for the geometrical packing reasons just referred to or, more generally, because of the forces of attraction and repulsion between atoms, which determine the number and distance of neighbors. $g(r)$ is to be an average. It can be looked upon as the time average of its value around any one atom, or the average at any one time of the values around all the atoms. In thermodynamic equilibrium these will be the same. $g(r)$ is called the *pair distribution function* or PDF. The quantity $4\pi r^2 g(r)$ is given the symbol $\rho(r)$ and the name *radial distribution function* or RDF: $n_0\rho(r)\delta r$ is the average number of atoms positioned in the shell of radius r.

Figure 1 shows the PDF of a simple metal. It is zero for $r \leqslant 2.4$ Å, which represents the distance of closest approach of two atoms. At larger distances the curve is *continuous*, which shows that two atoms may be at any distance apart; this is in marked contrast to crystal spacings, which are precise and discontinuous. Strictly, the crystal spacings are between abstract points about which the atoms vibrate; the liquid spacings are between the actual atomic positions. The high peak of $g(r)$ indicates the crowding of neighbors around the atom at the origin. Their number is given by the integral

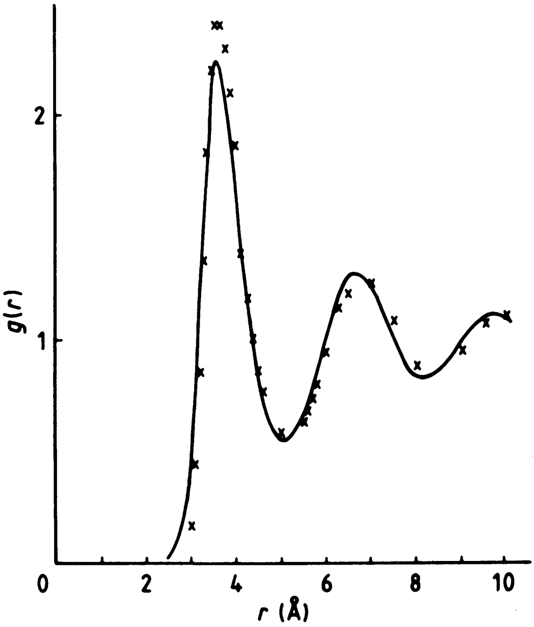

FIG. 1. The pair distribution function $g(r)$ of liquid Na. Full curve, molecular-dynamics calculation with a ϕ_{eff} (see Sec. 8.3). Crosses, experimental points from Waseda (1980).

$$n_1 = n_0 \int_{r_l}^{r_r} \rho(r)dr,$$

where r_l and r_r are the left- and right-hand boundaries of the peak. The values of both r_l and r_r are to some extent arbitrary, particularly if the peak has distortions or shoulders. In principle, n_1, often called the *coordination number*, is not a well-defined integer in a liquid; in a simple liquid it may be about 10. The radial distance to the first peak is the *nearest-neighbor distance*. Other peaks represent successive shells of neighbors, but not many can be seen. For $r > 10$ Å, the curve smooths out and $g(r) \rightarrow 1$.

2.2 Long- and Short-Range Order

By defining $g(r)$ we have taken one step towards saying what structure means in a liquid. It is helpful to think of $n_0 g(r) d^3r$ as the probability of finding an atom positioned at the infinitesimal volume d^3r at a distance r from another atom at the origin. Where $g(r) = 1$, this probability is just $n_0 d^3r$ and the atom may be anywhere with equal probability. Thus at large r randomness has replaced order and there is said to be no *long-range order*, (LRO). Crystals do have LRO, which in a large single crystal extends over macroscopic distances. The first high peak of $g(r)$ reveals a clear departure from randomness, which is called *short-range order* (SRO). Peaks further out indicate *intermediate-range order* (IRO), which is currently much discussed in more complex materials such as glasses (see AMORPHOUS MATERIALS, STRUCTURE OF).

If there is an atom at the origin at time $t = 0$, the probability of another in the volume element d^3r at a distance r is, as we have seen, $n_0 g(r) d^3r$. If we ask the probability of the second one at time $t > 0$, a whole new field is opened up because the motion of the atoms is involved, not just their positions. In thermodynamic equilibrium this is the natural thermal motion associated with the temperature, and, to a first approximation in a simple liquid, it is an irregular oscillation about a center whose position wanders diffusively. We shall see in Sec. 3 that the PDF is explored by elastic scattering. It is *inelastic scattering* that is required to examine the *time-dependent PDF*, which is the generalization of $g(r)$ taking thermal motion into account. The articles on LATTICE VIBRATIONS, STATISTICS OF; PHONONS IN CRYSTAL LATTICES; and VIBRATIONAL STATES IN DISORDERED SYSTEMS deal with this quantity.

2.3 More Distribution Functions

$g(r)$ refers only to the distance between two atoms; it offers no directional information. It is not difficult to conceive of more informative distribution functions. For instance, the probability of finding three atomic positions in a triangle in the volume elements d^3r_1, d^3r_2, and d^3r_3 is written $n_0^3 g^{(3)}(\mathbf{r}_1,\mathbf{r}_2,\mathbf{r}_3)d^3r_1d^3r_2d^3r_3$, and $g^{(3)}$ is called the *triplet distribution*. $g^{(4)}$, $g^{(5)}$, etc., can be correspondingly defined. The more of these functions we know, the more completely defined is the structure. In fact, very little is known even about $g^{(3)}$. It is not possible to derive $g^{(3)}$ from $g(r)$; indeed, an infinite number of $g^{(3)}$'s are compatible with the same $g(r)$. Experiments yielding any information about $g^{(3)}$ are few and far between, but theory and computer simulations are used to study it. However, the vast majority of our knowledge of the structure of simple liquids and mixtures is confined to $g(r)$'s and to numbers such as n_1 that can be derived from them.

2.4 Pair Distributions in Binary Systems

Suppose we have a liquid made of atoms of two types, A and B. After the discussion of $g(r)$, the reader will probably grant that there will now be four pair distribution functions to be labeled $g_{AA}(r)$, $g_{BB}(r)$, $g_{AB}(r)$, and $g_{BA}(r)$. The first two measure the probability that two like atoms are at distance r; the last two do the same for unlike atoms. Since the number of A–B and B–A interparticle distances is the same, $g_{AB}=g_{BA}$, and only three of the four g's are independent. The g_{ij}'s are called *partial pair distribution functions*, where i, j can be A or B. From these, *partial RDFs* $\rho_{ij}(r)$ can be defined. To take an example: if there are N_B B-type atoms in the volume V, their number density is $n_B \equiv N_B/V$. The number of B atoms within a distance r_1 of an A atom is

$$n_B \int_0^{r_1} g_{AB}(r)4\pi r^2 dr = n_B \int_0^{r_1} \rho_{AB}(r)dr. \tag{1}$$

If this integral were taken over the first peak, we should have the *partial coordination number* n_{AB}, giving the number of B-type nearest neighbors to an A atom. There are four partial coordination numbers in a binary system. If g_{AB} has a large peak at small r, the $A \leftrightarrow B$ attraction favors SRO with B atoms near A atoms and vice versa. If g_{BB} has a large peak at small r, then B atoms are tending to cluster together.

In principle, triplet and higher distributions can be defined for ternary and more complex liquids. To know all these functions would be to know completely the structure of the system. Such knowledge is scarce enough even for the partial pair distributions of binary liquids, and nothing more complicated will be considered here. Therefore we now move on to consider how $g(r)$ and g_{ij} are measured.

3. DIFFRACTION STUDIES OF PAIR DISTRIBUTION FUNCTIONS

"Measured" is too strong a word; $g(r)$ is inferred by a long train of reasoning from diffraction experiments. It is true that clues to the existence of SRO may be picked up from, *inter alia*, densities, known chemical affinities, x-ray absorption, analogy with crystals of similar composition, nuclear magnetic resonance (see MAGNETIC RESONANCE AND QUADRUPOLE RESONANCE, NUCLEAR; NUCLEAR MAGNETIC RESONANCE, DETERMINATION OF STRUCTURES BY), or the dependence of electrical resistivity or volume on concentration in alloys. But most knowledge comes from measuring the scattered intensity as a function of angle when a collimated monochromatic beam is transmitted or reflected by the sample. If the beam is of x rays, the technique corresponds to x-ray crystallography (*q.v.*), though the lack of crystallinity implies the absence of Bragg peaks. To help avoid confusion we refer first to x-ray diffraction from pure monatomic liquids.

3.1 The Structure Factor

The fundamental diagram is Fig. 2. $\hbar\mathbf{k}_i$ and $\hbar\mathbf{k}_f$ are the momenta of incident and deflected photons scattered elastically by the atoms in the liquid. $\mathbf{k}$ is the wave vector of the radiation. The momentum change $\hbar\mathbf{Q}$ and its relation to the scattering angle θ are

$$\hbar\mathbf{Q}\equiv\hbar(\mathbf{k}_i-\mathbf{k}_f),\quad |\mathbf{Q}|=2k\sin(\theta/2). \tag{2}$$

If there were only one scattering atom, the amplitude and intensity at the distant detector would be proportional to $f(\theta)$ and $|f(\theta)|^2$, respectively, where $f(\theta)$ specifies the probability with which x rays are scattered by one atom in the θ direction and is known and tabulated for all atoms. The scattered waves from all the atoms arrive at the detector with different phases and interfere with one another more or less destructively depending on θ, resulting in an angular intensity variation, $I(\theta)$. The phase differences depend on the atom-to-detector path differences and therefore on the atomic positions, which can be denoted by vectors $\mathbf{R}_1, \mathbf{R}_2, \ldots, \mathbf{R}_N$. Consequently the function $I(\theta)$ contains information about the positions. This fact underlies the possibility of inferring structural information from diffraction. The formulas are derived with care in numerous references [see, e.g., Waseda (1980); Cusack (1987); Guinier (1963); we shall refer to these again as "the cited texts"]. The fundamental result for the detected intensity is

$$I(Q)=\alpha N|f(\theta)|^2S(Q). \tag{3a}$$

N and f have already been defined and f is characteristic of the element in the sample. $S(Q)$, called the *structure factor*, depends only on the positions of the atoms according to the formula

$$NS(Q)\equiv\left|\sum_{i=1}^{N}\exp(i\mathbf{Q}\cdot\mathbf{R}_i)\right|^2. \tag{3b}$$

Equation (3b) results from summing the amplitudes of all the scattered waves and then squaring to obtain the intensity. It is usual to use Q instead of θ to express the angular dependence; and, in Eq. (3b), $S(Q)$ depends only on the magnitude of Q, not the direction, because of the isotropy of liquids. Note that no units are specified for the intensity here, and the constant of proportionality, α, will depend on how the intensity is measured, e.g., by photon counting rates, and on the sample and equipment geometry and numerous experimental conditions such as absorption of the beam by the sample and its container (essential for liquids).

A great deal of subsidiary experimentation, calibration, corrections, and experience go into establishing a reliable value for α. We refer the reader to the cited texts for these details and will assume that $S(Q)$ can eventually be obtained from laboratory measurements of $I(\theta)$. The observed $S(Q)$ for liquid sodium is shown in Fig. 3, and an overall accuracy of $\sim\pm2\%$ in $S(Q)$ results from good practice in this field. The problem is how to relate $S(Q)$ to the structure.

A crucial point is that the derivation of Eq. (3) assumes that scattering is improbable and that a photon scattered by one atom is not scattered by another. In other words, *multiple scattering* is absent. This is a reasonable assumption for x-rays; but multiple scattering always occurs to some extent and has to be ignored or subtracted in the data processing. This leaves only the distances between any two atoms to produce the path differences that determine $I(\theta)$. The latter therefore contains information only about these distances, i.e., about $g(r)$. Multiple scattering would involve $g^{(3)}$, $g^{(4)}$, etc., but as well as being a minor effect in these experiments, it is hard to relate in a usable way to the higher distribution functions. The problem therefore reduces to relating $S(Q)$ to $g(r)$.

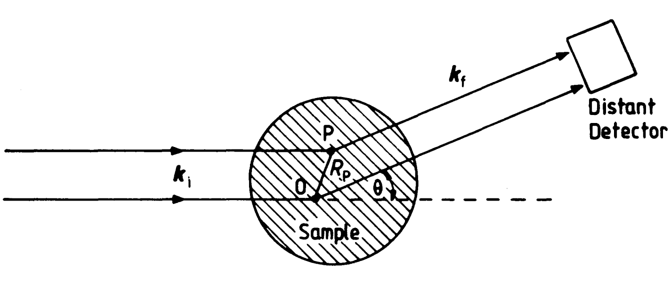

FIG. 2. Definitions of quantities in the coherent scattering calculation. O and P are two atomic positions illustrating the path difference.

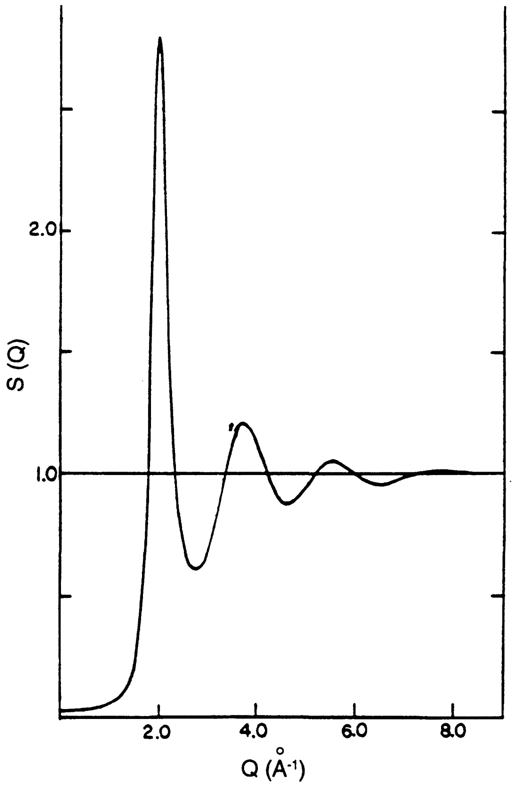

FIG. 3. $S(Q)$ for liquid Na. This curve and that of Fig. 1 mutually transform by Eq. (4).

3.2 Structure Factors and the PDF

$S(Q)$ and $g(r)$ are related by the following Fourier transform equations:

$$g(r)=1+\frac{1}{8\pi^3 n_0}\int_0^\infty [S(Q)-1] \times\frac{\sin Qr}{Qr}\,4\pi Q^2 dQ; \tag{4a}$$

$$S(Q)=1+n_0\int_0^\infty [g(r)-1]\frac{\sin Qr}{Qr}\,4\pi r^2 dr; \tag{4b}$$

$$S(Q)\to 1 \quad \text{as } Q\to\infty; \quad g(r)\to 1 \quad \text{as } r\to\infty. \tag{4c}$$

These are theoretical results demonstrated in the cited texts. Equation (4a) shows that $g(r)$ can be found by an integration over the observed $S(Q)$. Although such calculations are easily done nowadays, the most powerful computer cannot remedy a lack of experimental data, and it is clear that $S(Q)$ will not be measured as $Q\to 0$ (because observation is impeded by the strong unscattered beam at $\theta=0°$) nor as $Q\to\infty$ [because $I(\theta)$ is very small at large angles]. In many x-ray experiments $\sim 0.5 < Q\,(\text{Å}^{-1}) < 12$, but modern sources such as synchrotrons for x rays and spallation sources for neutrons extend Q to 40 Å^{-1} and more. Even so, some extrapolations or approximations in the integration, and the intrinsic errors in $S(Q)$, are unavoidable and lead to uncertainty in $g(r)$.

3.3 Partial Structure Factors in Binary Systems

A-type and B-type atoms will have different scattering amplitudes f_A and f_B. In the sum of scattered amplitudes at the detector, leading to Eq. (3), there will be terms in f_A with phases dependent on the positions of the A atoms, and corresponding terms in f_B. On squaring to get the intensity, terms in f_A^2, f_B^2, and $2f_Af_B$ will appear. As in Eq. (3), these terms will have multiplying factors depending on the A–A, B–B, and A–B distances, respectively. In other words, there will be three *partial structure factors*, S_{ij}. These are related to the $g_{ij}(r)$'s of Sec. 2.4 by relations like Eq. (4). For binary mixtures with concentrations $c_A=N_A/(N_A+N_B)$ and $c_B=N_B/(N_A+N_B)$, the detailed calculations leads to

$$I(Q)=\beta F(Q), \tag{5a}$$

$$\begin{aligned}F(Q)\equiv{}& f_A^2[c_Ac_B+c_A^2S_{AA}(Q)]\\ &+f_B^2[c_Ac_B+c_B^2S_{BB}(Q)]\\ &+2f_Af_B\,c_Ac_B[S_{AB}(Q)-1],\end{aligned} \tag{5b}$$

$$S_{ij}(Q)=1+n_0\int_0^\infty [g_{ij}(r)-1] \times\frac{\sin Qr}{Qr}\,4\pi r^2 dr, \tag{5c}$$

$$g_{ij}(r)=1+\frac{1}{8\pi^3 n_0}\int_0^\infty [S_{ij}(Q)-1] \times\frac{\sin Qr}{Qr}\,4\pi Q^2 dQ, \tag{5d}$$

$$S_{AB}=S_{BA}, \tag{5e}$$

where β is a calibration constant like α in Eq. (3a). This shows that, if experiments could provide the S_{ij} separately, Eq. (5d) would provide the partial pair distributions and coordination numbers.

3.4 Neutron Diffraction and Isotopic Substitution

The S_{ij} were measured separately for the first time in 1966 (Enderby *et al.*, 1966). Since the experiment relied on neutron diffraction we refer to that first.

Equations (3)–(5) apply to any kind of scattered waves if the quantities f, α, and β are reinterpreted and if the data processing is altered to accommodate different kinds of correction. Neutron beams of wavelength suited to structure studies are available at international facilities, and spectrometers are well developed. The x-ray quantities f and $|f|^2$ must be replaced by b and $|b|^2$ where b, the *scattering length*, expresses the probability of neutron scattering by the nucleus. At the wavelengths used, b is independent of θ and is usually well known. We note that $F(Q)$ contains one contribution, called *coherent scattering*, dependent on the structure factors and another, $c_A c_B (f_A - f_B)^2$, called *incoherent scattering*, dependent on the difference between the two f's. Since the system (neutron +nucleus) can exist in two spin states with two different b's, even a single isotope shows incoherent scattering. Moreover, a chemically pure element will usually contain several isotopes with a range of b values. In short, b_A and b_B in the formulas must be understood as averages weighted for both spin states and isotopic mix. Multiple scattering occurs with neutrons, and so does inelastic scattering, which is quite serious for low-Z samples; both must be subtracted from the data. In these and other ways, the data processing for neutrons and x rays differs, but both are aimed at correcting the measured $I(Q)$ to reveal its coherent elastic part, which gives $S(Q)$ and thence $g(r)$.

For binary liquids, separating the three unknown functions S_{ij} requires, for each concentration, three measurements of $F(Q)$, which are independent of each other on account of significantly different ratios of b_A to b_B or of f_A to f_B. Varying the concentration is not an option because this will in general change S_{ij}. Varying b is practicable nowadays because isotopic abundances can sometimes be changed at will in samples of constant chemical nature. Three mixtures $A_x B_{1-x}$, in which either or both A and B vary in isotopic composition, could then give three functions $F(Q)$ solvable as simultaneous equations for S_{AA}, S_{BB}, and S_{AB}. There are other possibilities. Three experiments using x-ray, neutron, and electron scattering might serve the purpose. It is also possible to use x rays alone by exploiting the fact that, for the anomalous scattering close to an x-ray absorption edge, f for a given Q depends quite strongly on wavelength. Thus measurement at three different wavelengths effectively varies the ratio of f_A to f_B.

In practice, none of these methods is without substantial difficulties, ranging from the high cost of isotopes to the enhancement of errors when three functions, each subject to experimental inaccuracy, are combined. The methods have been applied to glasses, aqueous solutions, molten salts, and alloys, but rather few partial structure factors for liquid systems have been thoroughly investigated.

The reader may wonder whether $S_x(Q)$ from x-ray diffraction should be the same as $S_n(Q)$ from neutrons. It is true that x rays are scattered by the electron density distribution and that in metals this is mainly concentrated in the ion cores. $f(Q)$ relates to spherical ions or atoms centered on the nucleus, and if this were the only scattering, the two $S(Q)$'s would be the same. But the free electrons characteristic of metals permeate the entire system including the interstices between the ions, and their density distribution will be distorted by all the electrostatic forces. Insofar as they cause scattering, they make $S_x(Q) \neq S_n(Q)$. The difference is just detectable in experiments designed to find it and can be safely neglected for the present purpose. (See Takeda *et al.*, 1990, for metals and Dore, 1990, for molecular liquids.)

4. INTERMOLECULAR FORCES AND LIQUID-STATE THEORY

Later sections will deal separately with noble-gas liquids, metals, molecular liquids, and molten salts, referring to their special characteristics. This section makes some points relevant to all of them.

The preceding sections explain what structure means in a liquid and outline the way $S(Q)$ and $g(r)$ can be found from diffraction experiments. The PDF and RDF are often referred to loosely as "the structure," but it was emphasized that they relate only to the average radial interparticle distances. Since $S(Q)$ and $g(r)$ are mutually transformable, they contain the same information. A rise in temperature increases motion and disorder, but the repulsive forces still define a nearest-neighbor distance. Heating broadens and lowers the first peak in $g(r)$ but alters its position very little. This shows that thermal expansion reorganizes the SRO and reduces n_1 without changing the nearest-neighbor distance—an important difference from the behavior of crystals.

The theory of liquids aims to derive the macroscopic properties, including the structure, from the intermolecular force. If we assume this to be pairwise and additive—not strictly true but a generally accepted approximation for simple liquids—the potential energy of two molecules i and j may be written

$$\phi_{ij}=\phi_{ij}(\mathbf{r}_{ij};\ \omega_i,\omega_j), \tag{6}$$

where $\mathbf{r}_{ij}$ is the separation of representative points or centers in the two molecules and ω symbolizes the three angles necessary to specify a molecular orientation. For linear molecules, ω reduces to two polar angles, and for spherical atoms or ions ω is irrelevant.

The dependence of ϕ on $\mathbf{r}_{ij}$ contains attractive and repulsive parts. We take for granted that there is a strong short-range repulsion, though this is in fact a subtle and profound property of matter (see, e.g., Lieb, 1976, who discusses why a stone, say, is so big). The repulsion is often approximated by an infinite force, which, without an attractive force, gives us the hard-sphere (HS) model. The structure of a dense random packing of hard spheres has been much investigated by computer simulation, and its $g(r)$ is well known. It is not dissimilar from Fig. 1 and represents approximately the structure of those simple liquids whose particles have undirected attractive forces that simply pack the molecules together as closely as the repulsive forces allow. When they freeze, such liquids generally adopt one of the closer-packed crystal structures such as face-centered cubic, which are a few percent denser than their melts.

A more realistic potential represents the attractive and repulsive parts by power laws, and another much used model, named after Lennard-Jones (LJ), has two parameters characteristic of the species, viz.,

$$\phi(r)=4\epsilon\left[\left(\frac{\sigma}{r}\right)^{12}-\left(\frac{\sigma}{r}\right)^{6}\right]. \tag{7}$$

It is shown in Fig. 4. This serves well for noble gases. Many more complicated potentials have been devised for other liquids and will be exemplified below. From any chosen intermolecular potential there are two routes to the structure: statistical mechanical theory and computer simulation.

4.1 Liquid-State Theory

Statistical mechanical texts show that all thermodynamic properties, including the structure, may be obtained from the partition function, of which the classical form suits all but a few quantum liquids like He at low temperatures. For a liquid of N similar particles at temperature T, acting by a pairwise additive potential $\phi(r)$, some formulas which

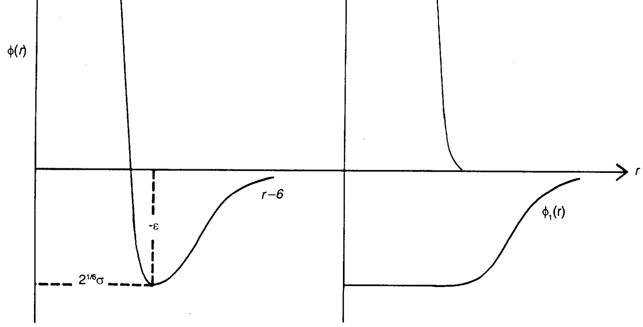

FIG. 4. The Lennard-Jones potential of Eq. (7) and its decomposition according to Eq. (11).

relate $g(r)$ to $\phi(r)$ are as follows. The total potential energy is

$$\Phi=\frac{1}{2}\sum_{i,j}\phi(r_{ij}). \tag{8}$$

Then

$$g(r_{12})=n_0^{-2}Q^{-1}N(N-1)\times\int\exp(-\Phi/k_BT)d^3r_3\cdots d^3r_N, \tag{9}$$

$$Q(V,T)=\int\exp(-\Phi/k_BT)d^3r^{(N)}. \tag{10}$$

Q is called the configuration integral. k_B is Boltzmann's constant and $\mathbf{r}^{(N)}$ stands for the set of N position vectors $\mathbf{r}_1,\ldots,\mathbf{r}_N$ of the particles.

Equation (9) can be generalized by including orientational coordinates and a variety of particle species; but, even without this, its solution is a central problem of liquid-state theory, leading to hierarchies of equations, density expansions, and variation and perturbation methods for which the reader will require one of the treatises on liquid-state theory such as Hansen and McDonald (1986). This will show that there is no inherent mystery in the subject but that the technical complexity is great. The various approximate solutions give very good agreement with observed $g(r)$'s when well chosen $\phi(r)$'s are used. Specimen cases will be outlined below.

4.2 Computational Aids

Liquid studies, like the rest of condensed-matter physics, have benefited from two decades of computer simulation. *Molecular dynamics* (MD) (*q.v.*) is much used and, reduced to its barest outline, it works as follows (see also MONTE CARLO METHODS).

A computer is given the following information: coordinates and velocities for N particles of specified nature in a volume V, often cubic; the interparticle potential, $\phi(r)$; and the boundary conditions—frequently periodic to ensure that N is representative of a much larger number and that if a trajectory takes a particle out at one face, an identical one enters at the opposite face to keep n_0 constant. With use of the classical equations of motion, the computer then

1. calculates the resultant interparticle force acting on each particle at time $t=0$;
2. finds all the new positions and velocities Δt seconds later;
3. repeats for successive Δt's.

When sufficient time has elapsed for the system to be in thermodynamic equilibrium, some property, say the total kinetic energy or $g(r)$, is computed after each of many successive steps and the average taken. Thus the average equilibrium property is found. N may be $\leqslant 10^3$, $\Delta t \sim 10^{-14}$ s, and there will be many hundreds of steps. The method is of great power and versatility and there are many versions and techniques.

A new and already valuable computational aid to the interpretation of scattering data works as follows. Suppose the N particles in the box with periodic boundary conditions are allocated, not $\phi(r)$'s, but neutron scattering lengths b. Starting with an arbitrary configuration, the computer calculates $g(r)$ and Fourier transforms it to $S(Q)$. The next task is to compute a suitable statistical measure, χ^2, of the difference between $S(Q)$(calc.) and $S(Q)$(expt.) in terms of the experimental error in $S(Q)$. One particle is now displaced randomly, subject to a minimum distance of approach, and χ^2 recalculated. The new configuration is accepted in place of the old with probability $p=1$, if $\chi^2(\text{new})<\chi^2(\text{old})$, or $p=\exp[\chi^2(\text{old})-\chi^2(\text{new})]<1$ if $\chi^2(\text{new})>\chi^2(\text{old})$. Repetition of this process makes χ^2 approach a minimum and the configuration for $\chi^2(\text{min})$ is saved. A number of saved configurations could be so generated and are deemed to be statistically independent. They are all structures that reproduce the observed $S(Q)$ within experimental error. The $g(r)$'s and, in the binary case, the $g_{ij}(r)$'s can be extracted and averaged and regarded as the experimental results. Other properties of the structure, even the triplet distribution, are also available for study, and no intermolecular potential has been involved in this. The method is called *reverse Monte Carlo* (RMC) and for its implementation, including a discussion of the definition of χ^2, see, e.g., McGreevy and Pusztai (1988), McGreevy and Pusztai (1990) for molten salts, Sec. 10.2, and Howe (1990) for molecular liquids, Sec. 9.3.

5. LIQUID ARGON AND SIMILAR SYSTEMS

Liquid argon has been much studied because its liquid range is not too difficult to attain experimentally and its interatomic potential is relatively easy to envisage. At large separations the attractive force originates in fluctuations in the electron clouds, which mutually induce electric multipoles in otherwise spherical charge distributions. The dipole-dipole interaction is the strongest of these and varies as r^{-6} as in Eq. (7). At close quarters the resistance of the electron clouds to overlap creates the strong repulsion approximated by the r^{-12} term in Eq. (7) but theoretically more like $\exp(-r/r_0)$, where r_0 is a parameter. The intuitive expectation therefore is that the attractive force, which is spherically symmetrical, simply draws in the neighbors and provides the cohesion while the SRO is the result of the dense random packing of the spheres delineated by the strong repulsions. Crystalline Ar has the densest possible packing, namely face-centered cubic, but on melting near the triple point the order decreases and the density falls by about 14%. This is approximately the same as the corresponding change for hard spheres. It is now widely accepted that the shapes of curves like Figs. 1 and 5 are well approximated by hard-sphere packings for both noble-gas liquids and simple liquid metals. Structure factors have been computed for LJ and HS fluids and are almost identical (see, e.g., Hansen and McDonald, 1986). These general remarks apply to dense liquids; near the liquid-vapor critical point, the relative effect of the attractive forces on the structure increases as the distinction between the liquid and gas phases vanishes.

A good example of the application of the methods of Sec. 3 to liquid Ar is the neutron-scattering experiment of Yarnell *et al.* (1973). Figure 5 shows $g(r)$ obtained experimentally and also points calculated by computer simulation. $\phi(r)$ of LJ form is quite capable of reproducing $g(r)$ very well, and the simulation confirms that the curve is largely determined by the repulsive force.

We must omit general discussion of how to calculate $g(r)$ from $\phi(r)$ since this is a major problem of liquid-state theory. One class of approaches to it uses perturbation theory, and

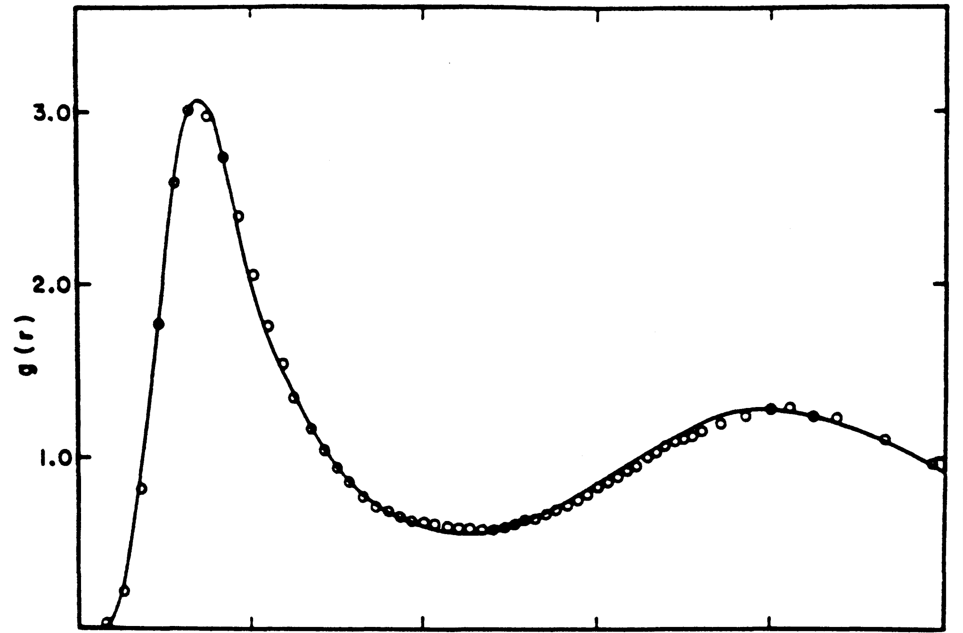

FIG. 5. $g(r)$ for liquid Ar at 85 K, $n_0 = 0.02125$ atom/Å^3. Full curve, experimental results; circles, computer simulation points from Eq. (7).

to give a flavor of this we refer briefly to the influential work of Weeks *et al.* (1971). The idea is to divide $\phi(r)$ into repulsive and attractive parts, ϕ_0 and ϕ_1, respectively, and to treat the hypothetical system represented by the subscript 0 as a reference system of well-known properties. This is then perturbed or corrected by the effect of ϕ_1 to describe the real system. The theory will be convenient and accurate if the perturbation corrections are small and preferably confined to one or two terms of a perturbation expansion. For the LJ potential, $\phi_{\min}=-\epsilon$ and occurs at $r=2^{1/6}\sigma$; so, for the present case (see Fig. 4),

$$\phi_0(r)=\begin{cases}\phi(r)+\epsilon, & r<2^{1/6}\sigma,\\ 0, & r\geqslant 2^{1/6}\sigma;\end{cases}$$
$$\phi_1(r)=\begin{cases}-\epsilon, & r<2^{1/6}\sigma,\\ \phi(r), & r\geqslant 2^{1/6}\sigma.\end{cases} \tag{11}$$

Now define $y_0(r)$ by

$$g_0(r)=y_0(r)\exp[-\phi_0(r)/k_BT].$$

Since $\phi_0=0$ outside the repulsion, $y_0(r)$ is the PDF of the reference system outside the repulsion. But in precisely this region it is plausible that the PDF resembles that of a hard-sphere system, so the next step is to replace y_0 by y_d, where d refers to a system of hard spheres with diameter d; thus

$$g_0(r)\simeq y_d(r)\exp[-\phi_0(r)/k_BT]. \tag{12}$$

Once d is chosen, $g_0(r)$ can be calculated from $\phi_0(r)$ and known properties of the HS system and can then be used as the first approximation to the theoretical $g(r)$—at least at those densities for which the structure reflects the geometry of sphere packing. In practice, Weeks *et al.* showed that, near the triple point, $g_0(r)$ represented excellently the exact result for the LJ potential given by computer simulation and therefore the experimental result too (e.g., Fig. 5). It remains, however, to see how to choose d. This is done by requiring the HS system to have the same equation of state as the reference system. Imposing this condition selects d because there is a connection between the equation of state and $g(r)$ given by statistical mechanics, viz.,

$$k_BT\left(\frac{\partial n_0}{\partial p}\right)_T=1+n_0\int[g(r)-1]d^3r, \tag{13}$$

where p is the pressure. The equation for d is therefore

$$\int[y_d(r)\exp(-\phi_0/k_BT)-1]d^3r$$
$$=\int[y_d(r)\exp(-\phi_d/k_BT)-1]d^3r$$

in which $\phi_d=\phi_{\mathrm{HS}}$ with diameter d.

It might be expected that $g_0(r)$ and the exact $g(r)$ agree less well when the density is lower and repulsive forces cease to dominate the structure. This is true, and corrections involving ϕ_1 become necessary. Furthermore, even at high density, thermodynamic quantities, such as the Helmholtz free energy F, require F_0 (known) to be supplemented by the first-order perturbation term $(Nn_0/2)\times\int\phi_1(r)g_0(r)d^3r$ before good results are obtained. But it is not possible to pursue thermodynamic properties here.

Similar but fewer structure studies exist for other liquified noble gases, and $\phi(r)$ functions carefully constructed from solid and gaseous state data are available for them. For example, $S(Q)$ for Kr over a range of densities was measured by Egelstaff *et al.* (1983) but does not quite agree with the computer simulation using the ϕ's just referred to. Presumably the pairwise interaction assumed for the liquid is in question here. Even if three- or many-body forces are significant, it may be possible to *adjust* the parameters in a two-body expression like Eq. (7) so that it seems sufficient by itself. But the two-body ϕ would then be to some extent fictitious, and so the interplay of the quantum theory of atomic interactions and observation of the liquid-state continues.

6. METALS: SOME OBSERVATIONS

Sections 6–8 will deal with the structures of pure metals and binary alloys. Nevertheless, such examples as there will be of chemical thermodynamics and liquid-state theory, as opposed to metal theory, are in principle applicable to nonmetals also and can be regarded as examples of general approaches.

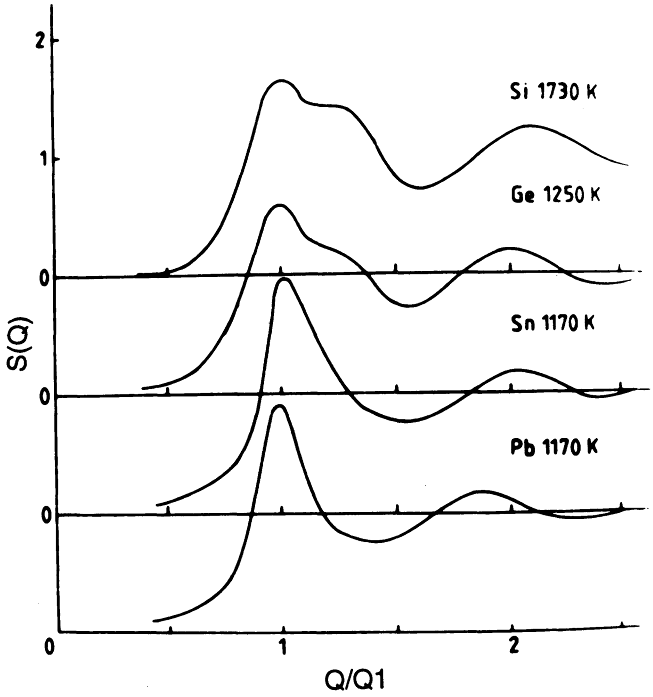

FIG. 6. Rather complicated $S(Q)$ shapes in Si and Ge; distorted first peak in Sn, tending to more close packed hard-sphere structure in Pb (see Sec. 8.4). From Hafner and Kahl (1984).

Figures 1 and 3 are typical of metals in group I of the periodic table for which $9.0 < n_1 < 10.5$. They are the simplest metals and, like noble-gas liquids, have PDFs quite close to that of a close-packed disordered system of hard spheres. The first peaks are symmetrical and the radial distances of the first and second peaks in $g(r)$ are in the ratio ~1.91. Be, Mg, Al, and Pb are like this also. In group-IIB metals, Zn, Cd, and Hg, the high-r and high-Q sides of the first peaks are spread out giving an asymmetrical peak though n_1 is still about 10. Although molten Si and Ge are metallic, not semiconducting like their crystals, n_1 is lower at ~6.6 and the ratio of the first two peak positions is higher at 2.0 to 2.3. These group-IV elements, and Ga and Sn also, have even more distorted peaks with shoulders or subsidiary maxima. Ge is discussed in detail below.

Thus there are noticeable structure trends through the periodic table and some examples are given in Fig. 6. It is plausible to see correspondence between these trends and those in crystalline elements, viz., close-packed metallic structure in groups I to III; distorted structures in group IIB and Ga, but more metallic close packing again in In and Tl; open covalent structure in group IV (Si and Ge) tending to metallic close packing at higher atomic number (Sn and Pb). Fundamental metal theory ought to account for this in both solids and liquids—see Sec. 8 below.

It is not easy to classify binary alloy structures. A random mixture of hard spheres of two different sizes would have the nearest-neighbor A–B distance between the A–A and B–B distances; the first peaks of the S_{ij} would behave similarly. The S_{AA} and S_{BB} would resemble those of pure A and B. The alloy Na-K in Fig. 7 is an example of this, and there are others, e.g., Al-Mg, Pb-Sn. There are cases, however, where the first peak of S_{AB}, but not S_{AA} or S_{BB}, has a well defined prepeak that has been interpreted as evidence of a larger size structural unit probably due to unlike-atom attraction. Figure 8 is an example with strong unlike-pair attractions.

Ordering (a preference for unlike neighbors) or *clustering* (preference for like neighbors), both departures from random mixing that should show up in S_{ij} and g_{ij}, must result from interparticle attractions and repulsions characteristic of the chemical nature of the components. The remarkable properties of some binary alloys at special compositions strongly reinforce this idea.

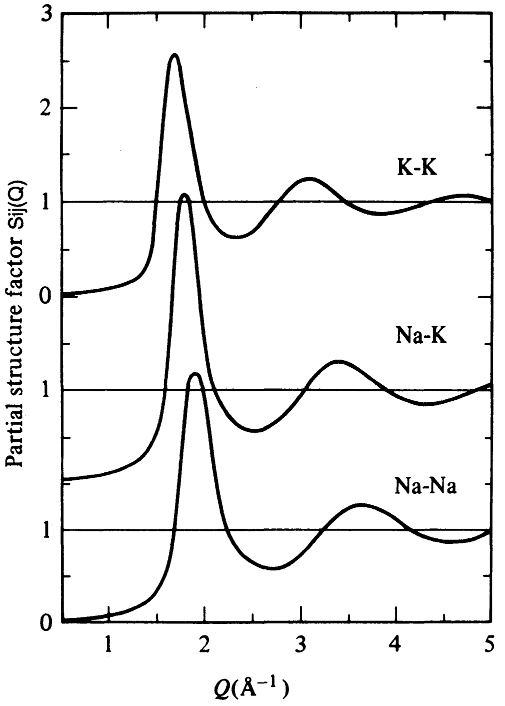

FIG. 7. Partial structure factors in Na-K; from Waseda (1980).

7. CHEMICAL SHORT-RANGE ORDER

There are surprises in the behavior of some liquid alloys that raise questions about the structure. For example, Ga and Hg form a two-phase liquid for some ranges of composition and temperature; liquid $Au_{0.5}Cs_{0.5}$ has very low electrical resistivity and behaves like a molten salt, which suggests that oppositely charged Au and Cs ions have each other as nearest neighbors (Kilic *et al.*, 1990). Anomalies such as very low electrical resistivity are often accompanied by extrema in thermodynamic properties, such as the entropy or volume of mixing, and in magnetic or thermoelectric behavior. Liquid systems well known for this include Li-M where M=Pb,Bi,Tl; Na-Sn; Cs-Pb; Mg-Bi; and Tl-Te. The significant point is that these systems have a special composition (Li_4Pb; Mg_3Bi_2; Tl_2Te, etc.), or possibly two, at which the anomalies appear most intense and that these compositions have stoichiometric proportions which suggest a chemical relation of the elements. There are usually crystalline compounds of the same composition. These liquids are often called *compound-forming alloys*. This leads to the hypothesis that SRO is caused by associations or complexes of chemically determined composition that are most in evidence when the overall concentration has the stoichiometric composition, e.g., Li_4Pb. This is called *chemical SRO*. The local associations are not conceived as stable molecules but as groupings of finite lifetime whose existence affects the $g_{ij}(r)$. This idea emphasizes the distinction between alloys of chemically attracting species and merely random mixtures.

7.1 Chemical Thermodynamic Models

On this basis many workers have tried to fit the observed thermodynamic properties by a chemical SRO model of the system. The fitted parameters enable the concentration of the hypothetical complexes to be calculated, and this knowledge allows discussion of other properties such as electrical conductivity. This is a very indirect and phenomenological way of investigating SRO, and there is considerable latitude in the fitting of numerous parameters. Nevertheless, the approach is an interesting halfway house towards a fundamental *ab initio* theory of structure, which presents profound difficulties (see below). Most workers are convinced that chemical SRO exists in the compound-forming alloys.

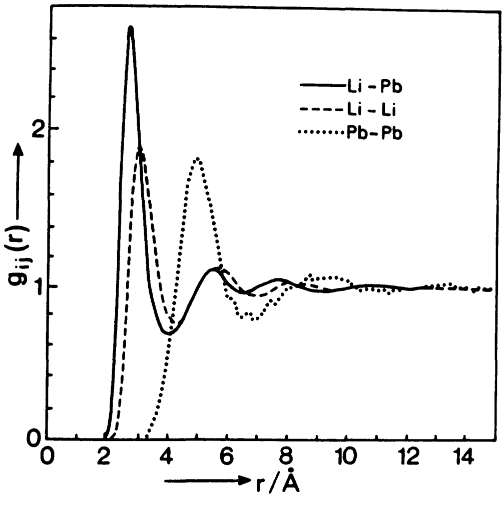

FIG. 8. Partial pair distribution functions in Li_4Pb derived by molecular dynamics. Note the preference for unlike near neighbors shown by the Li-Pb peak at 2.6 Å. From Jacucci *et al.* (1985).

Omitting detailed calculations, which can be found in Bhatia and Hargrove (1974) and Gray *et al.* (1980), the scheme is as follows. Elements A and B are attributed a tendency to form complexes $A_\mu B_\nu$, which have a Gibbs free energy of formation of $g(T)$ per mole at temperature T. The thermodynamic properties of mixing, such as the heat of mixing ΔH, can be derived from an expression for the total Gibbs free energy $G(p,T,c,N)$ of N moles of the binary mixture in volume V. This is

$$G=\sum_{i=1}^{3} n_i G_i^{(0)}+RT\sum_i n_i \ln \varphi_i + \tfrac{1}{2}\sum\sum_{i\neq j} n_i\varphi_j\chi_{ij}, \qquad (14a)$$

$$\sum_{i=1}^{3} n_i G_i^{(0)}=NcG_1^{(0)}+N(1-c)G_2^{(0)}-n_3 g, \qquad (14b)$$

where the symbols have the following meanings: i or $j=1, 2, 3$ denote respectively atoms A and B and the complex $A_\mu B_\nu$; χ_{ij} is an interaction energy between i and j; $\varphi_i \equiv n_i v_i/V$, where n_i is the number of moles and v_i the partial molar volume of species i; c is the fraction of A atoms in the original binary mixture; $G^{(0)}$ is the free energy per mole of a pure constituent. The condition for chemical equilibrium is

$$\left(\frac{\partial G}{\partial n_3}\right)_{T,p,N,c}=0. \qquad (15)$$

A plausible assumption based on chemical knowledge or observed anomalous composition is made for μ and ν; e.g., $\mu=4$, $\nu=1$ for Li_4Pb. Then $\Delta H(c)$, say, is computed from Eqs. (14) and (15) in terms of the parameters g and χ_{ij}, which are evaluated by fitting the observed $\Delta H(c)$. From this the three n_i can be calculated as functions of c. Having done this, Hoshino and Young (1980), for example, assumed that Li_4Pb conducted by virtue of n_1 free electrons from the n_1 Li atoms (valency 1) and $4n_2$ from the n_2 Pb atoms (valency 4) while the complexes contributed no free electrons. The thermodynamic model thus led to a curve of resistivity versus concentration which reproduced quite well the large peak observed at Li_4Pb.

7.2 Chemical SRO and Structure Factors

There is an interesting relation between the chemical SRO of compound-forming alloys and the $S_{ij}(Q)$'s of Sec. 3.3. Mathematically, a set of three new structure factors, formed by linear combinations of the $S_{ij}(Q)$'s, can be achieved in an infinite number of ways. A particular set turns out to have a useful physical interpretation and was first given a statistical mechanical basis by Bhatia and Thornton (1970). They are known as the *Bhatia-Thornton structure factors* and, omitting the argument Q, they are

$$S_{NN}=c_A^2 S_{AA}+c_B^2 S_{BB}+2c_A c_B S_{AB}, \qquad (16a)$$

$$S_{Nc}=c_A c_B[c_A(S_{AA}-S_{AB})-c_B(S_{BB}-S_{AB})], \qquad (16b)$$

$$S_{cc}=c_A c_B[1+c_A c_B(S_{AA}+S_{BB}-2S_{AB})]. \qquad (16c)$$

The subscripts have the following significance. If many small equal volumes of alloy were sampled for the number of atoms in them, and for their concentration, both properties would reveal *fluctuations*, which are a fundamental property of macroscopic systems. Let ΔN and Δc stand for these fluctuations, i.e., for the departures of N and c from their average values. S_{NN} is a measure of the fluctuations in number density. S_{cc} expresses the concentration fluctuations. S_{Nc} represents the correlation between the two. In the limit $Q\rightarrow 0$, usually called the *long-wavelength limit*, $S_{NN}(0)=\langle(\Delta N)^2\rangle/\langle N\rangle$, where N is the number of atoms in the small volume in question and angular brackets indicate a statistical or ensemble average. Thus $S_{NN}(0)$ gives the mean square number density fluctuation. Similarly, $S_{Nc}(0)=\langle\Delta N\Delta c\rangle$ and $S_{cc}(0)=\langle N\rangle\langle(\Delta c)^2\rangle$. The value of these results is enhanced by the fact that for $Q\rightarrow 0$ the Bhatia-Thornton structure factors have thermodynamic expressions. The most widely used of these is

$$S_{cc}(0)=\frac{RT}{(\partial^2 G/\partial c_A^2)_{T,p,N}}=\frac{k_B T(1-c_A)}{(\partial\mu_A/\partial c_A)_{T,p,N}}. \qquad (17)$$

In Eq. (17), k_B is Boltzmann's constant and μ_A is the thermodynamic quantity known as the activity of species A.

There are various thermodynamic and electrochemical ways of measuring $G(c,p,T)$ and $\mu(c,p,T)$. Equation (17) then gives $S_{cc}(0)$ as a function of c for one temperature at a time, usually for $p \sim 0$. The value of this in our present context is that the resulting curve can give strong indications about the SRO. For example, it can be shown that $S_{cc} = c_A c_B$ for a random mixture—often called an ideal solution; consequently, departures from this indicate some degree of ordering. In the extreme case $S_{cc}(0) = 0$, concentration fluctuations must have vanished—which is to say that a well-defined compound exists at the composition for which $S_{cc}(0) = 0$. At the other extreme, $S_{cc}(0) \rightarrow \infty$, the concentration fluctuations are as large as conceivable, i.e., the alloy separates into two phases. Figure 9 shows a hypothetical but not absurd case in which two tendencies to compound formation and one to phase separation are suggested. Measurements of $S_{cc}(0)$ have often stimulated the use of the chemical model of Eq. (14) by suggesting the values of μ and ν for a complex. Figure 10 shows a measured $S_{cc}(0)$ fitted by a model for a compound-forming alloy.

Since the Bhatia-Thornton structure factors are linear combinations of S_{ij} and therefore contain the same structural information, it must be possible to express the quantity $F(Q)$ of Eq. (5b) in terms of them instead of S_{ij}. Thus for neutron scattering we have

$$F(Q) = \langle\langle b \rangle\rangle^2 S_{NN} + (\Delta b)^2 S_{cc} + 2\Delta b \langle\langle b \rangle\rangle S_{Nc}, \tag{18}$$

where $\langle\langle b \rangle\rangle \equiv c_A b_A + c_B b_B$ and $\Delta b \equiv b_A - b_B$. Some elements have isotopes with both $b<0$ and $b>0$. Suppose the isotopes were mixed to give $\langle\langle b \rangle\rangle = 0$. Then one measurement of $F(Q)$ gives $S_{cc}(Q)$ directly since the other terms in Eq. (18) vanish. Likewise, an isotope mixture devised to have $\Delta b = 0$ would give $S_{NN}(Q)$ directly from $F(Q)$. Naturally the possibilities of such manipulations are limited but are being tried out, particularly with metallic glasses, and are potentially powerful ways of measuring the partial structure factors separately.

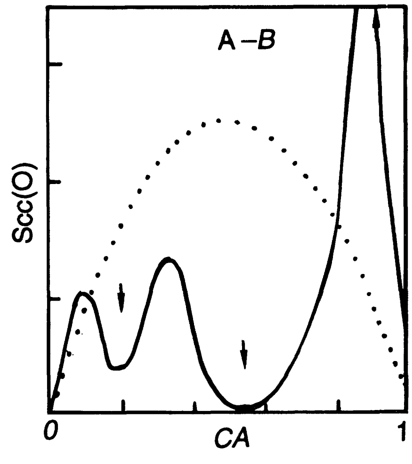

FIG. 9. A hypothetical $S_{cc}(0)$. The arrows indicate possible compositions for complex formation and the peak shows a tendency to phase separation. The dotted curve is for a random mixture or ideal solution for which $S_{cc}(0) = c_A c_B$.

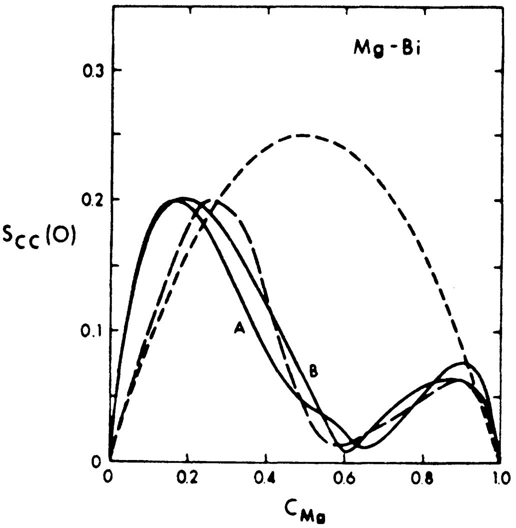

FIG. 10. A measured $S_{cc}(0)$ for Mg-Bi (long dashed curve), with $S_{cc}(0)$ ideal (short dashes) and two alternative model fittings *A* and *B* based on the ideas of Sec. 7.2. Note the tendency to compound formation at Mg_3Bi_2. From Bhatia and Hargrove (1974).

8. STRUCTURE AND THE THEORY OF METALS

It is possible in principle to take the properties of an atom and deduce theoretically the structure of the condensed element. Perhaps the least exacting such exercise is to infer the structure of simple ionic crystals like NaCl from the nature of the Na^+ and Cl^- ions. Liquid metals probably present the most demanding of such tasks for three reasons: the interatomic forces are very complicated in metals; the structures are very disordered in liquids; and these two problems interact. Nevertheless, since about 1970, ways of combining liquid-state theory with metal physics have been devised, and by 1990 there was a reasonable understanding of why metallic elements, crystalline and liquid, have the structures they do.

This required a major effort of theoretical physics and the following sections therefore have the limited objective of setting out the nature of the arguments and giving a few conclusions. The following ingredients are needed for the discussion:

1. the general concept of a metal;
2. the pseudopotentials, the interionic potential, and the energy;
3. perturbation and similar techniques in liquid-state theory;
4. molecular dynamics.

8.1 The General Concept of a Metal

A pure liquid metal is a gas of electrons permeating a fluid of positively charged ions. There are about 10^{28} electrons/m^3, one per ion in Na, two in Ca, and so on according to valency z. They are loosely called *free electrons* and move through the entire system. Free electrons are responsible for the characteristic properties such as conductivity and metallic reflectivity. In a binary alloy the electron density n_e is $n_A z_A + n_B z_B$, unless complicated by compound formation as in Sec. 7.

8.2 Forces and Energy

The ions contain electrons tightly bound to nuclei. The free electrons flow through the ions under the control of two major influences:

1. the electrostatic attraction of the positive ions, and
2. a complicated response to the other electrons bound in the ions.

A powerful development of the wave-mechanical theory of solids made it possible to treat influence **2** mathematically as if it were an electrostatic force like **1** except that it is a repulsion that partially cancels the attraction **1**. The net effect of the two is quite small and is called a *weak pseudopotential.*

An electron passing through an ion may therefore be thought of as deviated by the appropriate pseudopotential. However, the ion does not suddenly exert its influence as the electron crosses a well-defined ionic boundary. As the ions are positively charged and the electron gas is mobile, the ions exert long-range influence on the gas by attracting electrons to themselves. Meanwhile the electrons are also repelling each other and a complex balance of forces sets in whose ultimate effect is to envelop each ion in a free-electron cloud. This cloud, being negative, neutralizes the effect of the positive ion rather completely at large distances, say a few atomic diameters, and less completely at smaller distances. The cloud of electrons piled up near an ion is called the ion's *screening cloud* and the total effect on an approaching electron of the ion and its cloud is called the *screened pseudopotential.*

In summary we may say that, from the point of view of one electron passing through a liquid metal, it encounters the screened pseudopotential of the ions (the nearest ones being felt more strongly) and is scattered by them. The total effect of all the ions, acting though their weak screened pseudopotentials, on all the free electrons is to produce the very electron clouds that do the screening.

Any two positive ions repel one another electrostatically, but in a metal, they have another, indirect, mutual influence because they both exert forces on the same electron gas, e.g., on each other's screening cloud. The latter contribution must depend on the density of the system because this determines the free-electron density, n_e. This contrasts with intermolecular forces in nonmetals, which are independent of density to a good approximation. However, *for a fixed density,* it turns out that the total ion-ion interaction in a metal can be treated just like the forces in nonmetallic liquids. In particular, the ions have *pairwise interaction.* The exact form of the ion-ion potential function will vary from metal to metal and differ from those of nonmetals; it depends on the screened pseudopotential. In general, it will have, as in nonmetals, a short-range repulsive core and a long-range attractive part, which, however, unlike nonmetals, exhibits maxima and minima called *Friedel oscillations* (see Fig. 11). This effective pairwise potential, $\phi_{\text{eff}}(r,n_e)$, controls the structure for any given density. It can be inserted into liquid-state theory to calculate thermodynamic properties and structure.

The expression for the energy of a metal is complicated but its structure is simple, viz.,

$$E(\text{per ion}) = E_{i,\text{ke}} + E_{\text{vol}} + E_{\text{str}}. \qquad (19)$$

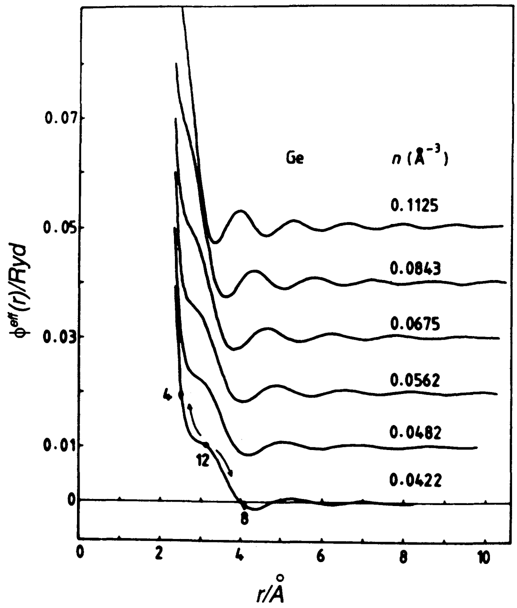

FIG. 11. ϕ_{eff} for Ge at various densities. From Arnold *et al.* (1989).

Here $E_{i,\mathrm{ke}}$ is just the kinetic energy of the ions and is $3k_BT/2$ because their motion, unlike that of the electrons, can be treated classically. E_{vol} is independent of structure and embodies the idea that a free-electron gas has a kinetic energy that rises if the volume falls. E_{str} is due to the mutual forces of the ions. Because ϕ_{eff} is pairwise, E depends on the interparticle distances and therefore contains $g(r)$ or $S(Q)$, but also involves n_e. So far these remarks apply equally to crystals and liquids.

8.3 Structure from $\phi_{\mathrm{eff}}(r)$ in Metals

The theory referred to in Sec. 4 assumes pairwise potentials and can therefore be taken over for liquid metals once pairwise potentials for these have been devised—provided, of course, due respect is paid to the volume-dependent aspects.

To exemplify the great progress of the 1970s (see, e.g., Ashcroft and Stroud, 1978), we first note that all the thermodynamic properties are derivable from the Helmholtz free energy, $F(\text{per atom})=E-TS$ where S is the entropy per atom. Now there is a remarkable theorem, true in classical and quantum statistical mechanics, which works as follows. Suppose the real system, in our case a liquid metal, has its free energy conceptually divided into that of a hypothetical reference system (F_0) plus the rest (F_1) so that $F=F_0+F_1$. Choose the reference system to consist of hard nonattracting spheres. Then the theorem says that $F\leqslant F_0+\langle H_1\rangle_0$, where H_1 is the difference in energy between the real liquid metal and the reference system. $\langle H_1\rangle_0$ means the average of H_1 over all configurations of the reference system. The choice of hard-sphere reference system has advantages for this exposition, viz.,

1. the potential is zero for $r>\sigma$, the hard-sphere diameter, so that H_1 means simply the terms $E_{\mathrm{str}}+E_{\mathrm{vol}}$ while $E_{i,\mathrm{ke}}$ just contributes to F_0;
2. all the properties of the hard-sphere (HS) reference system are well known and tabulated, including $S(Q)$, and depend only on σ and the density;
3. the hard-sphere $S(Q)$ is known to fit some liquid metals well, and so the reference system is structurally near to the real system.

Inserting the entropy term TS into the free energy we have

$$F\leqslant F_0+F_1$$
$$=(3k_{\mathrm{B}}T/2-TS_{\mathrm{HS}})+(E_{\mathrm{vol}}+E_{\mathrm{str}}-TS_{\mathrm{eg}}), \tag{20}$$

where eg stands for electron gas. In calculating E_{str}, the $S(Q)$ for the HS system must be used because the theorem requires F_1 to be averaged over the *reference* system. The final step is a computing exercise to find the value $\sigma=\sigma_{\min}$ that minimizes F_0+F_1, keeping the volume at the observed value for whatever temperature is assumed. The minimum F_0+F_1 should be a good approximation to F and can be used to derive all the thermodynamic properties such as S, specific heat, etc. Furthermore, the hard-sphere $S(Q)$ for $\sigma=\sigma_{\min}$ is the theoretical prediction for the metal. Of course, the possibility of doing this depends on there being expressions for E_{str} that depend on $S(Q)$—which is exactly what the pseudopotential theory of metals provides. The same arguments apply to binary alloys, though the three S_{ij} and the three $(\phi_{ij})_{\mathrm{eff}}$ cause technical complication.

This outlines the use of the Gibbs-Bogoliubov theorem with the hard-sphere reference system. Naturally, improvements proliferated. Better choices of reference system led to more general and reliable results at the expense of denser theory and heavier computing. But the essence remained of dividing ϕ_{eff} into an inner repulsive reference part (but not necessarily infinitely repulsive like hard spheres) and a long-range oscillatory part (like Fig. 11), together with a minimization or optimization procedure to choose the best parameters. For detailed examples see, e.g., Hafner (1977) and Hafner and Kahl (1984). The reader will have noticed that this variation method is similar in spirit to the perturbation approach of Sec. 5.

The concept of $\phi_{\text{eff}}(r)$ in metals, *for a given density*, makes molecular dynamics readily available for liquid metals. $g(r)$ and $S(Q)$ are therefore available in three ways: by diffraction experiments; by MD using $\phi_{\text{eff}}(r)$; and from liquid-state theory using $\phi_{\text{eff}}(r)$. An example comparing all three will be given below.

The problem is that $\phi_{\text{eff}}(r,n_e)$ depends on the free-electron states that are the solutions of Schrödinger's equation of motion. But these states depend on the structure, which in turn depends on ϕ_{eff}. In short, the structure and the electronic states ought to be solved in a self-consistent way. Procedures have been tried that avoid the excessive computation needed for a truly self-consistent calculation. For example, ϕ_{eff} is first obtained from a simple form of the pseudopotential theory that does not need details of the electron states. Two branches are now possible: use ϕ_{eff} with one of the forms of liquid-state theory to derive $g(r)$(theor.); or use ϕ_{eff} and MD to find $g(r)$(comp.). Either or both of these $g(r)$'s may now be compared with $g(r)$(expt.). Assuming agreement is encouraging, use the now known structure from MD to recalculate or improve knowledge of the electron states. This is a formidable program even for simple metals [see Hafner (1990)]. For transition metals (Fe, Ni, etc.) with partially occupied 3*d* shells of electrons, there is the additional rather intractable complication of incorporating the not wholly free *d* electrons into the expression for ϕ_{eff}. [See, e.g., Hausleiter and Hafner (1990) for an approach to this problem for the glassy transition metal alloy $Ni_{33}Y_{67}$.]

8.4 A Successful Example

Figure 11 shows $\phi_{\text{eff}}(r)$ for various densities of Ge calculated from the ideas of Sec. 8.2. The features are

1. a steep repulsive screened ion core—though not infinitely steep as in hard spheres;
2. an intermediate- and long-range oscillating part characteristic of metals and depending on the density of the electron gas;
3. an evolving relation of these as the changing density alters the position of the oscillations and spreads out the core.

If liquid Ge were controlled by the repulsive core acting alone, its structure would resemble a hard-sphere packing with $\sigma \sim 2.72$ Å$=r_1$ say, a second peak at $\sim 1.9r_1$, and $n_1 \sim 10$ to 11. But the density near the melting point is about 0.045 atom/Å^3, and Fig. 11 shows that ϕ_{eff} is distinctly structured. The observed peaks in $g(r)$ are at $1.6r_1$ and $2.25r_1$, which coincide with minima in the oscillatory part of ϕ_{eff}. Thus the atoms reduce overall energy by adjusting their positions in response to the superimposed demands of geometric sphere packing (with a periodicity fixed by σ) and an oscillatory tail (with wavelength $\lambda \propto n_e^{-1/3}$). The conflicting effects of the two different periodicities cause the peaks in $g(r)$ to peter out after ~7 Å. The atoms in the oscillatory troughs reduce what would have been the high peak of close-packed neighbors at $r_1 \sim 2.72$ Å and thus lower n_1 to the observed value of ~6.5. Using the ϕ_{eff} of Fig. 11, $g(r)$ and $S(Q)$ can be calculated by MD or liquid-state theory and compared with experimental results. Figures 12 and 13 show that

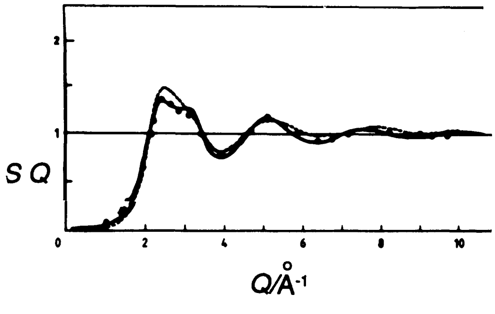

FIG. 12. $S(Q)$ for liquid Ge at ~1300 °C showing agreement between MD (full curve) and neutron diffraction experiments (dotted curve and circles). From Arnold *et al.* (1989).

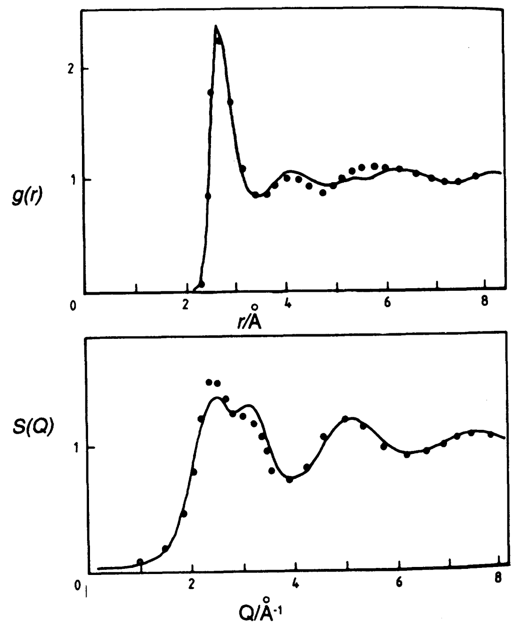

FIG. 13. *g*(*r*) and *S*(*Q*) in liquid Ge showing good but not perfect agreement between MD (full curve) and liquid-state theory (points). From Arnold *et al.* (1989).

these three approaches are beginning to agree well. [For the full theory, see Arnold *et al.* (1989).]

Figure 11 also shows that if the core radius and n_e are appropriate (e.g., the highest curve), the geometrical packing at $r \sim \sigma$ is encouraged rather than reduced by the position of the oscillatory minima: the two periodicities (σ and λ) are compatible, and structure resembling hard-sphere packing results. Calculations with suitable pseudopotentials and densities for the group I and IIA metals of the periodic table show that this is just what happens, leading to $g(r)$'s like Fig. 1. In this way detailed examination, element by element, can rationalize the trends through the periodic table referred to in Sec. 6 [see Hafner and Kahl, 1984). Both MD and liquid-state theory can be extended to alloys with the increasing complication due to three interionic potentials all dependent on the electron density, which is itself a function of composition. If chemical SRO in compound-forming alloys is due to ionic or covalent bonding forces becoming important at special compositions, then additional hypotheses for the forms of these forces are required. (For the use of exponentially screened ionic forces and application of MD to Li_4Pb, see, e.g., Jacucci *et al.*, 1985.)

9. MOLECULAR LIQUIDS

Even the simplest diatomic molecule, say N_2 or CO, involves Eq. (6) and raises the question whether the PDF is affected by the relative orientation of the molecules or whether, on the other hand, liquids of stable molecules approximate to hard-sphere packings to the extent that argon does.

Although homonuclear diatomic molecules and other special cases will not be dipoles, molecules in general will have electric dipole and quadrupole moments. The electric force fields will be nonspherical on this account and can be attractive or repulsive depending on orientation. The short-range repulsive force may also have an angular dependence. In special cases there can be a nonspherical magnetic force as in O_2. Much of the somewhat limited structural study of molecular

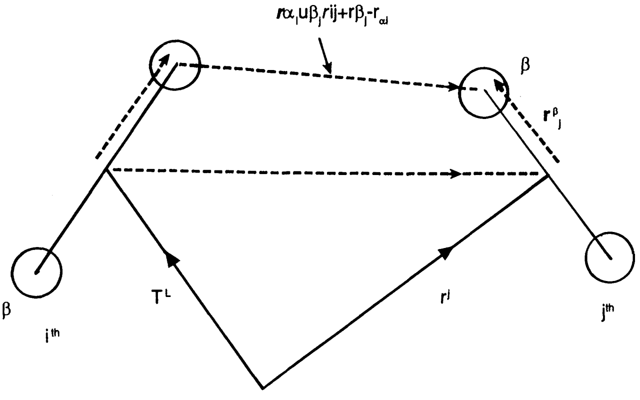

FIG. 14. The angles and distances between the *i*th and *j*th diatomic molecules composed of atoms of types α and β.

liquids has addressed the question of the orientation dependence of the pair distribution $g(\mathbf{r}_{ij}; \omega_i, \omega_j)$. This is a complicated quantity, and Fig. 14 shows the angles and distances relevant to neighboring diatomic molecules to which this account will largely be restricted. Even if the three $g_{ij}(r)$ for the two kinds of atoms in, say, CCl_4 were fully determined by the methods of Sec. 3.4, they would not contain enough information to give $g(\mathbf{r}_{ij}; \omega_i, \omega_j)$ uniquely, and a single diffraction experiment is even less informative.

The interaction potential can be modeled in various ways. For example, a simple and much used suggestion is

$$\phi_{ij}(\mathbf{r}_{ij}; \omega_i,\omega_j) = \sum_{\alpha,\beta} \phi_{\alpha\beta}(\mathbf{r}_{\alpha_i \beta_j}) + \text{electric multipole terms.} \tag{21}$$

Here $r_{\alpha_i \beta_j}$ is the intermolecular distance between atoms of types α and β, and $\phi_{\alpha\beta}$ could be given the LJ form of Eq. (7). In a diatomic molecule the summation would have four terms. For comparison we quote without detailed discussion a potential used by Rodger *et al.* (1988) for Cl_2, viz.,

$$\phi(r_{ij}) = K \exp\{-\alpha[r-\sigma_0-\sigma(\Omega)]\} + C[r+\xi_0-\sigma(\Omega)]^{-6}+E_s, \tag{22}$$

where E_s is a dipole plus quadrupole term on each atom chosen to give the correct overall quadrupole for the molecule; Ω is the relative orientation of the two molecules, and $\sigma(\Omega)$ is expressed in terms of several spherical harmonic functions and contains a number of parameters which, with the other parameters in the expression, were chosen to give agreement with known properties of chlorine such as the crystal structure. This model implies orientation dependence of both attractive and repulsive forces and shows that a simple molecule can demand a quite complex potential. It is, of course, intuitively reasonable that a diatomic molecule should be dumbbell shaped, and at close quarters some relative orientations should favor closer approaches than others.

9.1 Structure Factors of Molecular Liquids

As in Sec. 3.3, the structure factor of a system of two species of atom, say CO or $GeBr_4$, is found by summing the scattered amplitudes and squaring to get the intensity. For a molecular assembly it is helpful to separate those contributions of interfering wavelets originating *within* one molecule from those coming from *different* molecules. $S_M(Q)$, now given a subscript to indicate a molecular liquid, may then be written

$$S_M(Q) = f_1(Q) + D_M(Q), \tag{23a}$$

where

$$f_1(Q) = \left(\sum_\alpha b_\alpha\right)^{-2} \left\langle \left| \sum_\alpha b_\alpha \exp(i\mathbf{Q}\cdot\mathbf{r}_\alpha)\right|^2 \right\rangle \tag{23b}$$

and

$$D_M(Q) = N_M^{-1} \left(\sum_\alpha b_\alpha\right)^{-2} \left\langle \sum_{i\neq j} \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}) \times \sum_{\alpha_i,\beta_j} b_\alpha b_\beta \exp[i\mathbf{Q}\cdot(\mathbf{r}_{\beta_j}-\mathbf{r}_{\alpha_i})] \right\rangle. \tag{23c}$$

In these formulas N_M is the number of molecules and α or β can be either A or B for molecules of two different kinds of atom. $f_1(Q)$, called the molecular form factor, is often calculable from the known molecular structure or available from electron diffraction studies of the gas phase. If so, a measurement of $S_M(Q)$ yields $D_M(Q)$, which includes the effect, if any, of orientation. $f_1(Q)$ can be refined by an additional factor $\exp(-\gamma_{\alpha\beta}^2 Q^2/2)$, where $\gamma_{\alpha\beta}$ is the rms thermal-vibration amplitude of the bond length, but this is often put equal to zero, thus treating the molecule as rigid with respect to internal motion; by hypothesis rigidity under intermolecular forces is already assumed. $D_M(Q)$ takes on a special form if there is no correlation of orientation at any r_{ij}. In that case, r_{ij}, r_{α_i}, and r_{β_j} are all statistically independent, and from Eq. (23c) it follows that

$$D_M(Q) = f_{2u}(Q) N_M^{-1} \left\langle \sum_{i\neq j} \exp(i\mathbf{Q}\cdot\mathbf{r}_{ij}) \right\rangle, \tag{24a}$$

where

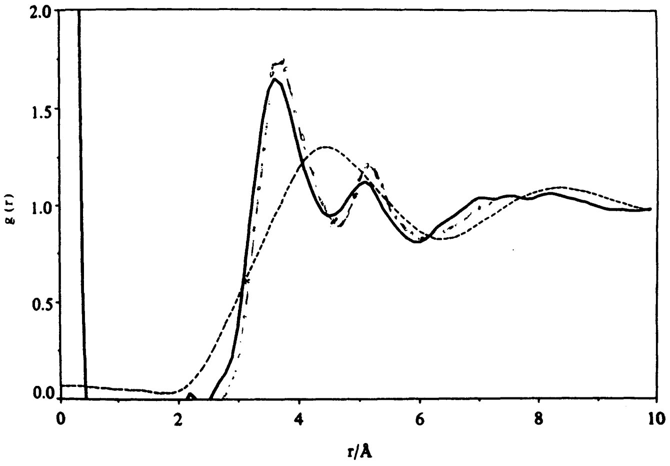

FIG. 15. Intermolecular $g(r)$ in liquid chlorine. Full line, from neutron diffraction; dashed line, calculated for an uncorrelated model; dot-dashed line, MD calculation (see text).

$$f_{2u}(Q) \equiv \left| \sum_{\alpha} b_{\alpha} \right|^{-2} \left| \sum_{\alpha} b_{\alpha} \langle \exp(i\mathbf{Q} \cdot \mathbf{r}_{\alpha}) \rangle \right|^{2} . \tag{24b}$$

Like $f_1(Q)$, $f_{2u}(Q)$ is calculable from the molecular structure: e.g., for a homonuclear diatomic molecule it is $\sin^2(Qd/2)/(Qd/2)^2$, where d is the bond length. Thus, measuring $D_M(Q)$ leads to the quantity

$$N_M^{-1} \left\langle \sum_{i \neq j} \exp(i\mathbf{Q} \cdot \mathbf{r}_{ij}) \right\rangle .$$

By direct analogy with Eq. (3b), this expression could be called $S_c(Q)-1$, where the subscript indicates a structure factor for molecular centers and 1 is subtracted because the $i=j$ term is omitted from the summation. For uncorrelated orientation, therefore,

$$D_M(Q) = f_{2u}(Q)\,[S_c(Q)-1]. \tag{25}$$

These equations have been written with neutron-scattering lengths. Similar formulas have been used for x rays, though it is a dubious approximation to treat the x-ray scattering factors for molecules as simple summations of the effect of the constituent atoms because the bonding will distort the electron distribution somewhat.

9.2 A Representative Experiment

Recent practice in this field is exemplified in a neutron experiment by Bellissent-Funel *et al.* (1990) on Cl_2. For values of $Q \leqslant 16$ Å^{-1}, at temperatures of 202 and 286 K, $S_M(Q)$ was measured and $D_M(Q)$ obtained by Eq. (23). By a Fourier transformation of $D_M(Q)$ analogous to Eq. (4a), a $g(r)$ was found, which, however, excludes the intramolecular Cl-to-Cl distance by virtue of the definition, Eq. (23c). Suppose that S_c is now calculated for a hypothetical set of molecular centers with no orientation correlation. It could then be inserted, together with f_{2u} for Cl_2, into Eq. (25) and an uncorrelated D_M calculated. The hypothetical $S_c(Q)$ was computed by MD for a monatomic liquid with an LJ potential [Eq. (7)] in thermodynamic states corresponding to those of the Cl_2 samples. The result shows that the observed $D_M(Q)$ differs markedly, having two peaks where the uncorrelated curve has one. Indeed the two peaks are thought to be a hallmark of correlated orientation in diatomic molecules. Figure 15 shows the corresponding $g(r)$'s and also one calculated by MD from the potential in Eq. (22). This potential, which builds orientation correlation into the interaction, gives a rather good fit. Furthermore, the ratio r_1/r_2 of the two peak positions in $g(r)$ is ~ 1.4, much lower than the ~ 1.95 characteristic of uncorrelated diatomic, and also monatomic, liquids. The peaks may therefore be interpreted as the effect of orientation modifying the first shell, not as two separate shells of neighbors. From these and other related arguments, it seems clear that orientational correlation exists in liquid Cl_2, but the conclusion remains rather qualitative. It is not obvious which correlations are preferred: e.g., do neighboring molecules tend to be parallel or antiparallel, or in perpendicular formation?

9.3 Some General Remarks about Structure in Molecular Liquids

It should be evident from the preceding paragraphs that even homonuclear diatomic molecules present substantial difficulties in the interpretation of data and the formulation of potentials. Hydrogen and deuterium halides evade our criteria of simplicity because hydrogen bonding plays a strong role in them; it cannot be said that their structure is well understood. Liquid N_2, CO, O_2, and the halogens have been studied by methods comparable with the Cl_2 experiment just referred to, and it appears that whereas definite orientation correlation is detectable in Cl_2, Br_2, and, especially, I_2, there is little or none in N_2, CO, and F_2. A detailed review is presented by Andreani *et al.* (1991). As indicated for Cl_2, MD simulations with comprehensive potentials are becoming available, and the understanding of molecular liquids is bound to grow as MD and experiments interact in future. In this connection an interesting development is the application of RMC (see Sec. 4.2) to halogen liquids by Howe (1990). From experimental data available up to about 1988 and RMC molecular distributions that can reproduce them, it appears that orientation correlation in the halogens persists little further than the first shell of neighbors.

Although this account has emphasized diatomic molecules for reasons of space and simplicity, the MD techniques are powerful enough to handle more complex cases, and diffraction experiments can likewise be involved with advantage, especially if isotopic substitution can be achieved. Thus there have been studies of linear triatomic molecules such as CS_2 (e.g., Tildesley and Madden, 1981), the tetrahedral molecule CCl_4 (e.g., McDonald *et al.*, 1982), and even mixtures of the two (Mittag *et al.*, 1989). In these cases the intermolecular potential had the form of Eq. (21) with LJ $\phi_{\alpha\beta}$'s and no multipole term. Thus between two CS_2 molecules there will be four S-S, four S-C, and one C-C interactions. It would be fair to say that in these cases the S_c's and $g(r)$'s from neutron and x-ray experiments, including some with isotopic substitution, are well reproduced by the computer simulations but that comparison is sometimes made difficult by discrepancies between one experiment and another and by inaccuracies in the computations. It is a measure of the difficulty of interpreting the data that firm statements about the orientation correlations cannot yet be confidently made.

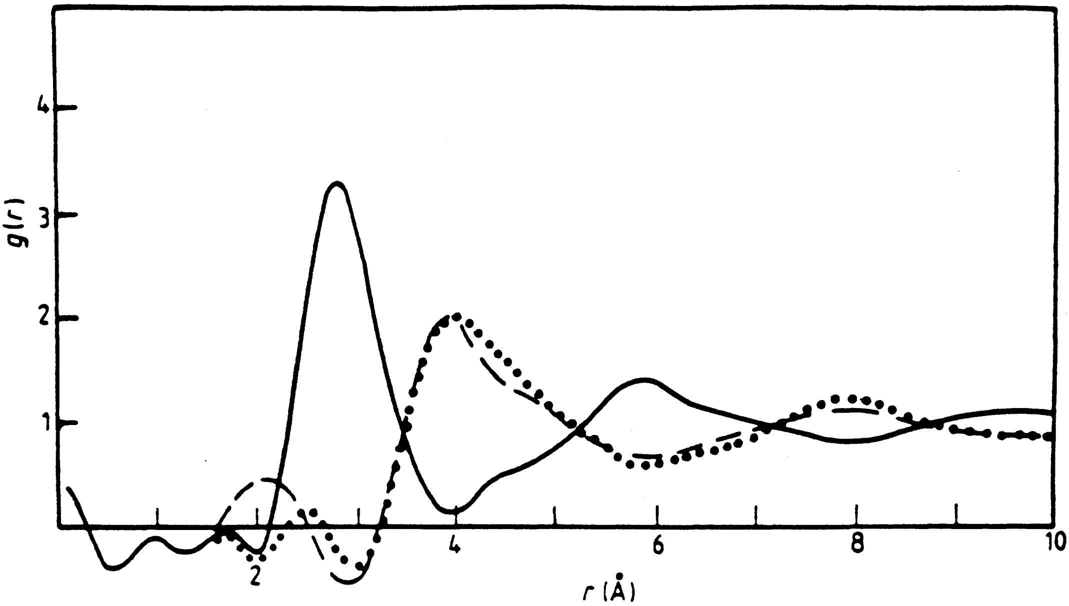

FIG. 16. Partial pair distributions in liquid NaCl; from Biggin and Enderby (1982). Full curve, g_{NaCl}; broken curve, g_{NaNa}; dotted curve, g_{ClCl}.

10. MOLTEN SALTS

The first crystalline structures determined by x-ray crystallography were those of alkali halides, and nowadays it seems natural that they should be interpenetrating lattices of positive and negative ions such that each ion has nearest neighbors of opposite sign. There seems no obvious reason why melting should alter this general picture since it does not radically change relevant properties, e.g., ionic conductivity persists. But it was not until 1975 that this was explored directly by the isotopic substitution method of Sec. 3.4 (Edwards *et al.*, 1975; Derrien and Dupuy, 1975). As in previous sections, the accumulated work in this field will be illustrated by representative examples.

10.1 Halides

Enderby and co-workers (see, e.g., Biggin and Enderby, 1982) changed the isotopic state of Cl in NaCl and obtained the three partial PDFs in Fig. 16. Using + and − to indicate cations (metal) and anions (Cl), we see that g_{++} and g_{--} are very similar with a major peak at ~4 Å; that the *nearest*-neighbor peak is in g_{+-} at 2.72 Å; and that for $r \geqslant 4$ Å, the phases of the curves conspire to cancel the charge almost completely. The similarity in g_{++} and g_{--} results from a corresponding similarity in S_{++} and S_{--}, and the first peaks in these structure factors coincide with a sharp dip in S_{+-} (see Fig. 17). There is, however, a small intrusion of like species into the first shell of unlike neighbors. The coordination number n_1, now more explicitly called n_{+-}, is 3.9. Thus the overall picture is indeed

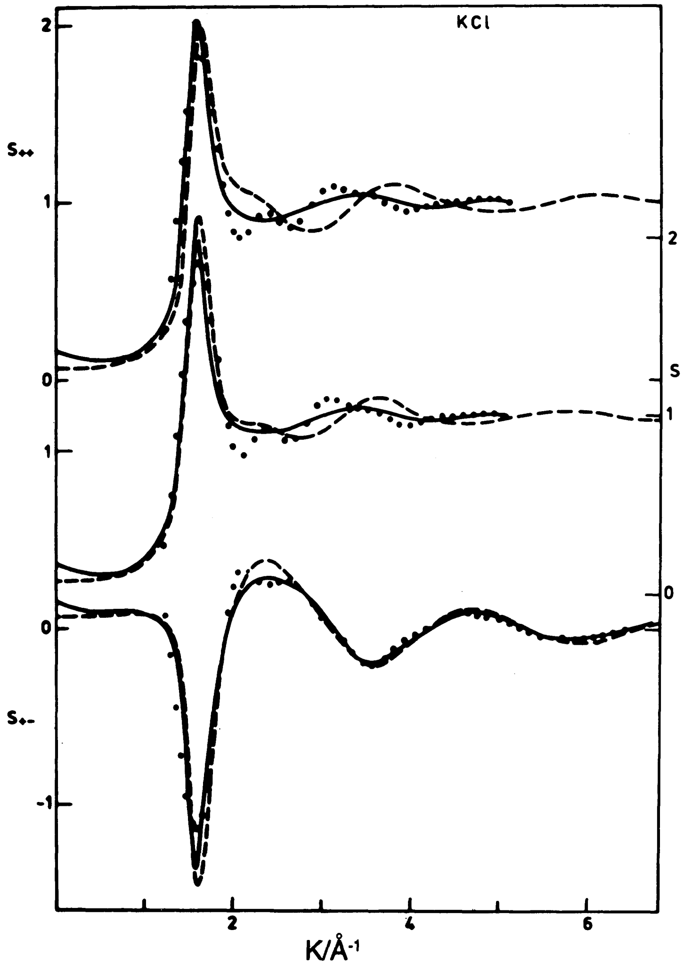

FIG. 17. $S_{ij}(Q)$ in liquid KCl. Full curve, HNC theory (see text); points, MD calculation; dashed curve, a less satisfactory theoretical result discussed by the authors. From Abernethy *et al.* (1981).

of ions surrounded by about four neighbors of opposite sign and with a next shell of mostly similar sign. However, this is only SRO, and the disordering effect of melting means that interparticle distances $\gtrsim 6$ Å are equally likely to be between like or unlike charges.

The clear interdependence of the g_{ij} in molten salts is in marked contrast to the behavior of these quantities in binary alloys. The explanation lies in the fact that the concentrations of positive and negative species in ionic melts are not independent because electrical neutrality must prevail. In binary alloys neutrality is preserved by the free electrons and the concentrations of the species can vary; there is then nothing to secure any unique relation between the peaks and troughs in g_{ij} or S_{ij}.

Group-II halides—$ZnCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$, etc.—are somewhat different (see, e.g., McGreevy and Mitchell, 1982). As the cation size increases from Zn to Ba there are trends of behavior believed to be associated with this size change. Let us assume a Cl^- ion at the origin; then, from Zn to Ba, while the first peak of g_{--} remains at about the same place (3.7 Å) and yields a roughly constant coordination number (3.7 to 3.8), it diminishes in height and spreads out. At the same time the penetration of Cl^- ions into the first shell of cations increases, as shown in Fig. 18. In $BaCl_2$, unlike NaCl, g_{++} and g_{--} are quite different. This is partly due to the different size of charge on Ba^{2+} and Cl^- but is also thought to be a consequence of the greater mobility of the anion. With the smallest cation, Zn^{2+}, there is a well-defined peak in g_{+-}, implying $\sim 4.3 \pm 0.3$ Cl^- ions around each Zn^{2+} ion, and the sharpness of this peak decreases progressively from Zn to Ba. These experiments yield no evidence of special Zn–Cl distances to be associated with complexes of substantial lifetime, such as Zn^+Cl or $ZnCl_3^-$ (compare Sec. 7).

10.2 Computer Simulation and Theory

The foregoing shows some of the inferences that can be drawn from neutron scattering with the isotopic method. Deriving them theoretically requires appropriate interionic potentials. As with the other types of liquid, there are model potentials of various degrees of complexity, but, for molten salts, they will be dominated by the Coulomb forces. These account for the bulk of the cohesive energy and cause the SRO of the charge distribution. A much used potential is

$$\phi_{ij}(r)=A\,\frac{z_iz_je^2}{r}+\beta\exp[-\alpha_{ij}(\sigma_{ij}-r)]-\frac{C_{ij}}{r^6}-\frac{D_{ij}}{r^8}, \qquad (26)$$

in which z_ie and z_je are the ionic charges giving electrostatic attraction or repulsion $\propto r^{-2}$; the second term is the strong repulsion

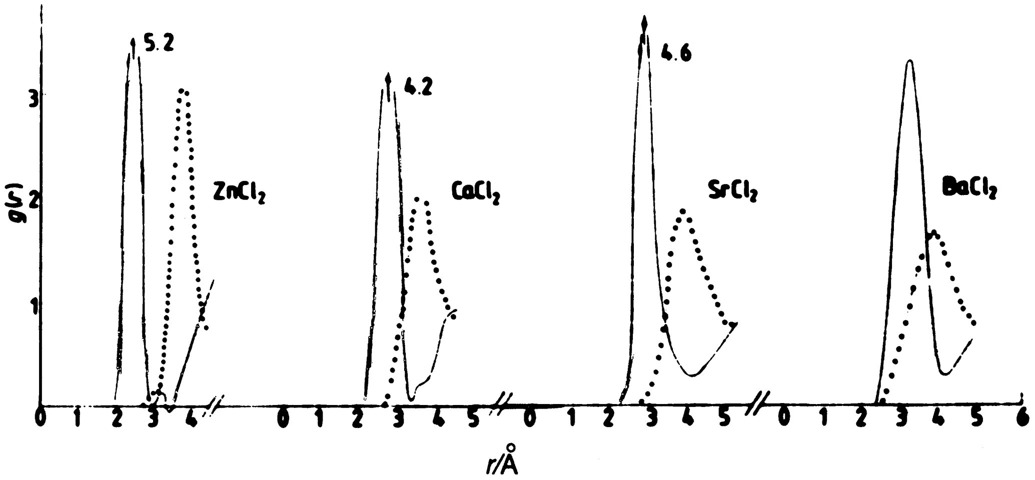

FIG. 18. Development of the penetration of like ions into the first shell of unlike neighbors as cation size increases, according to Biggin and Enderby (1981). The $SrCl_2$ curve is from molecular simulation, the others from neutron scattering. Full line, $g_{+-}(r)$; dotted line, $g_{--}(r)$.

due to overlap (an alternative to the r^{-12} term in the LJ model), and the remaining terms are the induced multipole terms (see Sec. 5) giving interactions of longer range than the repulsion but much shorter than the Coulomb field. A depends on the units, and the other symbols are parameters usually fixed by making ϕ compatible with the properties of the crystalline phases (see, e.g., Sangster and Dixon, 1976, for a detailed discussion of ϕ). With this potential, MD calculations of $g_{ij}(r)$ can be made, and the outcome is satisfactory for the alkali halides but less so for the group-II halides, suggesting that ϕ needs improvement.

Indications were given above of the perturbation method for $g(r)$ in liquid Ar and the Gibbs-Bogoliubov variation method in metals and alloys. For ionic liquids a third of the very numerous approximate methods in the theory of liquids will be invoked. The reader will appreciate that that justice can hardly be done to any of these methods short of a systematic exposition of liquid theory. What is needed is a solution of Eq. (9). Discussion is often facilitated by introducing two more correlation functions: $h(r)$, the *pair correlation function,* and $c(r)$, *the direct,* or *Ornstein-Zernike, correlation function.* These are defined for liquids by

$$h(r) \equiv g(r) - 1, \tag{27}$$

$$h(r_{12}) = c(r_{12}) + n_0 \int c(r_{13}) h(r_{23}) d^3 r_3. \tag{28}$$

$c(r_{12})$ has the effect of splitting the positional correlation $h(r_{12})$ of atoms 1 and 2 into a part depending directly on their positions and an indirect part depending through the integral on the correlated positions of all the other atoms. The range of $c(r)$ is much shorter than that of $h(r)$ or $g(r)$ and is comparable with that of $\phi(r)$. A considerable chain of reasoning, with approximations (see, e.g., Hansen and McDonald, 1986), then introduces another relation between $h(r)$, $c(r)$ and $\phi(r)$, viz.,

$$c(r) \simeq h(r) - \ln g(r) - \phi(r)/k_B T. \tag{29}$$

If this is inserted into Eq. (28), there results

$$\ln g(r_{12}) + \frac{\phi(r_{12})}{k_B T} = n_0 \int \left(h(r_{13}) - \ln g(r_{13}) - \frac{\phi(r_{13})}{k_B T} \right) h(r_{23}) d^3 r_3. \tag{30}$$

This is an integral equation soluble numerically for $g(r)$ once $\phi(r)$ is given. Equations of similar form hold for the $g_{ij}(r)$ in binary systems. This is known as the *hypernetted chain (HNC) approximation.* Unlike other approximate theories with which it is often compared in the literature, it works quite well for liquids with long-range Coulomb interactions. The $g_{ij}(r)$ and $S_{ij}(Q)$ for all the molten alkali halides have been computed by HNC and by MD, using the ϕ of Eq. (26), and the agreement, exemplified in Fig. 17, is good (Abernethy *et al.*, 1981).

With the help of the measured $S_{ij}(Q)$ and the RMC method (Sec. 4.2), it is possible to extend insight into molten salt structures because the RMC results are three-dimensional arrays consistent with the isotopic substitution experiments but not dependent on any assumed potential. For example, the first shell of neighbors can be analyzed by means of a quantity $C_{ij}(n)$, which is the fraction of ions of type i that have n ions of type j in their nearest-neighbor shell. $C_{ij}(n)$ can be extracted from the RMC structure. It turns out, for example, that ~ 0.4 of Na^+ ions have five Cl^- ions in the first shell in liquid NaCl; the corresponding numbers in CsCl are ~ 0.38 and ~ 6. Other Na^+ ions may have, though with lower probability, three, four, six, or seven Cl^- neighbors, giving an overall coordination number $n_{+-} = \Sigma n C_{+-}(n) = 4.85$. This emphasizes how disordered the shell is in the liquid compared with the well-defined one in the crystal and how limited the information is in a single coordination number. We also recall from Sec. 2.1 that particular n_{+-} values depend on the definition adopted by their authors. Another limitation partly removed by the RMC structures, as also by MD and MC, is the absence of angular information. If two lines are drawn from one Na^+ ion to two of its nearest-neighbor like ions, what is the distribution of the angle θ_{+++} between them? This, and the corresponding question for θ_{ijk}, where i, j, k can each be either + or −, can be answered at least approximately and begins to elucidate the triplet distribution. These angular distributions are in fact rather broad for θ_{ijk} in the alkali halides but show peaks at ~48° for θ_{+++} and θ_{---} compared with 45° in the crystal, and near 90° and 180° for θ_{-+-} and θ_{+-+}. (For a more detailed discussion of such inferences, see McGreevy and Pusztai, 1990.)

We refer finally to $ZnCl_2$ for which the isotopic method, with or without RMC, suggests strongly that each Zn^+ ion is surrounded by a tetrahedron of four Cl^- ions. Since four anions per cation are not available, there is some vertex sharing of the tetrahedra similar to, though less orderly than, that in the crystal from which the material melts. Unlike the alkali halides, $ZnCl_2$ is very viscous just above its freezing point; its ionic conductivity is low and it readily forms a glass. These facts begin to suggest that its liquid and glassy forms depart from purely ionic interparticle forces towards ramifying networks of directional bonds more like those in glassy materials such as $GeSe_2$ or even the most well-known glass SiO_2. If so, $ZnCl_2$ would exclude itself from "simple liquids" as defined by our original criteria, and it is not surprising that, at the time of writing, it is one of several materials attracting more detailed study (Salmon, 1991.)

11. LIQUIDS AND GLASSES

One of the numerous ways of making glasses, indeed the normal way for most glasses, is to quench a liquid so rapidly that it has no time to crystallize. The result is a structurally disordered solid. All the concepts of Sec. 1–3.4 apply as well to glasses as to liquids. Much of Secs. 4.2 and 7–10 do also; e.g., glasses may be simulated by MD or discussed with pseudopotentials. The basic difference between liquids and glasses is that only the former are in thermodynamic equilibrium and therefore have their structures fully determined by the prevailing temperature and pressure. Since glasses are not in thermal equilibrium, their structure is not stable and in general changes slowly with time. Thus it is not uniquely defined: it depends on the history of the sample and especially on its mode of preparation and heat treatment. While the $g_{ij}(r)$ of a glass may well bear a general resemblance to those of a liquid of the same composition, they are rarely identical, and the glass may show more detailed features characteristic of short- or intermediate-range order. (See GLASSES.)

12. CONCLUSION

The reader may feel that the structure of simple liquids is somewhat unspectacular—all PDFs are continuous curves showing a few rather featureless peaks which soon peter out at r greater than a few atomic diameters. This just observation results from the fact that liquids are, to a first approximation, irregular packings of spheres. Size differences, the Friedel oscillation in ϕ_{eff} in metals, chemical binding forces in alloys, the orientation of nonspherical molecules, or Coulomb forces between ions all impose on the general randomness various forms of SRO and IRO that give the PDFs such features as they have. Understanding these is part of the general challenge presented by condensed matter including crystals. Determining structure from basic theory has never been easy because the energy differences between various alternative structures are small, so that quite accurate theories are necessary to establish which is the preferred structure of lowest energy. The period from 1970 to 1990 saw sufficient development in the theory of liquids and in computer simulations to justify a claim that structures are beginning to be understood from first principles even in disordered liquids. The subject is not closed, however. Apart from the problems of embracing more complex cases such as larger molecules or transition metals, there remain both experimental and theoretical difficulties in the way of understanding how structures change with density on the way to the liquid-vapor critical point. The triplet distribution and the effect on particle interactions of many-body forces also remain as challenges.

GLOSSARY

Ensemble Average: Average of a property over a large number of replicas of a system called collectively an ensemble; a basic device in statistical mechanics (*q.v.*).

Fourier Transform (FT): $F(y)$ is the FT of the function $f(x)$ if

$$F(y)=\int_{-\infty}^{\infty} f(x)\exp(-2\pi ixy)dx.$$

f is then the inverse FT of F and

$$f(x)=\int_{-\infty}^{\infty} F(y)\exp(2\pi ixy)dy.$$

There are many equivalent and related forms.

Free Energy: A fundamental thermodynamic property of any macroscopic system from which other properties may be derived. Gibbs free energy $G=E-TS+pV$; Helmholtz free energy $F=E-TS$.

Heat of Mixing: The heat given out, or taken in, when a mixture is formed from constituents.

Pairwise Interaction: Force between two particles that is unaffected by the presence of other particles.

Partition Function: The quantity $\Sigma \exp(-E_n/k_BT)$, where E_n is the energy of the nth allowed quantum state of a macroscopic system and the sum is over all states. It is fundamental for the calculation of thermodynamic properties by statistical mechanics (*q.v.*).

Stoichiometric Proportion: The proportion of constituents involved in chemical combinations.

INTRODUCTION

The class of devices to be considered here are used for energy conversion with electrical energy as one component. In motors, conversion is from electrical to mechanical energy. In generators and alternators, the energy flow is reversed. Usually, the mechanical energy is supplied by means of a rotating drive, and the majority of motors supply rotational motion, but there are an increasing number of applications in which electrical energy is used to

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

provide linear motion. In the following, motors utilizing dc, ac, and modulated power supplies are discussed, and dc generators and ac generators, usually called alternators, are considered. A final section treats the electronic control of electrical machines.

1. PRINCIPLES

All of the devices to be discussed employ a magnetic flux to produce a voltage, with the basic underlying principle being Faraday's law of magnetic induction. The calculation of the magnetic flux requires the application of Ampère's circuital law, and forces are calculated by using suitable formulations of the Lorentz force equations.

Computation of machine characteristics requires the calculation of fluxes in magnetic circuits containing ferromagnetic elements, often a difficult task complicated by the geometrical structures encountered. Hence, simplifying assumptions are usually made and magnetic circuit models employed, with circuit parameters obtained from tests on the machine. Also, computational methods are becoming increasingly available for magnetic flux computations; these are considered in the articles NUMERICAL METHODS and PHYSICS APPLICATIONS OF COMPUTERS—MODELING. Ampère's circuital law is the basic tool used for flux calculations:

$$\oint_{\mathscr{L}} \mathbf{H} \cdot d\mathbf{l} = \int_S \mathbf{J} \cdot d\mathbf{s}, \tag{1}$$

where **H** is the field intensity vector, integrated over a closed path $\mathscr{L}$, **dl** is a length increment tangential to the path, and **J** is the current density vector, which is integrated normal to the area S enclosed by the path $\mathscr{L}$ over which the field is integrated. When **J** consists only of currents in windings (wires), i.e., there are no substantial eddy currents in the iron, the above equation is often simplified to

$$\sum Hl = \sum Ni. \tag{2}$$

Here the individual terms Hl, known as magnetomotive forces (mmfs), are summed around a closed magnetic circuit, represented in a simplified manner by lumped magnetic circuit elements, and the current in each winding linking the magnetic circuit contributes a term Ni equal to the number of ampere turns carried by it. It should be noted that the above holds independent of the source of the current, external or induced by changing magnetic fluxes in the device.

In the magnetic circuits used in machines, ferromagnetic materials such as iron constitute the major portion of the magnetic flux path. These materials display a very nonlinear B vs H relation, where B is the flux density vector, or flux per unit area. B saturates at a flux density typical for each magnetic material (actually, not B but the magnetization M saturates—the reader is referred to the article MAGNETOSTATICS for a discussion of these concepts).

Faraday's law for lumped circuits simply states that the induced voltage V across an N-turn winding is given by

$$V = N\frac{d\phi}{dt}, \tag{3}$$

where $d\phi/dt$ is the time rate of change of the magnetic flux ϕ linking all N turns. For sinusoidal flux variation, $\phi = \phi_m \sin\omega t$ where ϕ_m is the amplitude of the total flux and $\omega = 2\pi f$ where f is the frequency of the flux variation. In the sinusoidal case, therefore,

$$V = \omega N \phi_m \cos\omega t. \tag{4}$$

The amplitude of the voltage $V_M = \omega N \phi_m$, and

$$V_M = \sqrt{2} V_{\text{rms}} = 2\pi f N \phi_m. \tag{5}$$

With $\phi_m = B_m A$, where B_m is the amplitude of the flux density, assumed to be uniform over the area A enclosed by the coil,

$$\begin{aligned} V_{\text{rms}} &= (2\pi/\sqrt{2}) f N \phi_m \\ &= 4.44 f N \phi_m \\ &= 4.44 f N B_m A. \end{aligned} \tag{6}$$

In case of relative motion between flux sources and windings in which voltages are induced, it can be shown that these induced voltages can be calculated in the same manner, even if sliding contacts are involved. The literature often uses the concept of motional emf (electromotive force), which leads to the simple formula

$$V = u\,B\,l \tag{7}$$

where V is the voltage across a straight conductor of length l moving at a velocity u perpendicular to a magnetic flux density B (i.e., u, B, and l are mutually perpendicular); in a more general case

$$V = \oint_{\mathscr{L}} \mathbf{u} \times \mathbf{B} \cdot d\mathbf{l}. \tag{8}$$

The calculation of voltages induced in case of "general motion" requires care, but its discussion is beyond the scope of this article. In most rotating or linear-motion machines, the simple arguments mentioned in the previous paragraph are quite adequate. Equation (4) is only meaningful for a closed circuit (only a few elements may contribute to the voltage V; which ones may depend on the choice of observer in this formulation).

Forces are calculated by using the Lorentz force equation, which takes the form

$$d\mathbf{f} = I\, d\mathbf{l} \times \mathbf{B}, \tag{9}$$

where $d\mathbf{f}$ is the force exerted on a conductor element $d\mathbf{l}$ carrying a current I, located in a field B—note vector relations. Analogously to the case of an induced voltage, the force on a straight conductor of length l carrying current I, located in a field B, is given by

$$f = I\, lB, \tag{10}$$

with f, l, and B mutually perpendicular.

2. DESIGN CONSIDERATIONS

Limiting design considerations are those leading to premature failure of the machine. There are essentially three failure mechanisms: thermal, mechanical, and electrical breakdown (there is no equivalent magnetic breakdown, except due to excessive forces, covered under mechanical breakdown).

It must be understood that the concern here is not only with immediate failure but also "decreased lifetime" of the device. Hence, the design decision involves economic factors as well as "years of expected use." Sound scientific judgment is not always available for the last criterion.

2.1 Thermal

In a stationary device, there are copper (I^2R) losses in the conductors, magnetic losses due to cyclic magnetization of the (iron) core, and stray losses due to induced currents or alternating magnetic fields in the adjacent structure. To these must be added frictional and other losses due to motion in rotating machines. The copper losses are obtained from an integration of $J^2\rho$ (J is current density, ρ is effective resistivity) over the entire copper volume. In this calculation, proper account has to be taken of the skin effect in the conductors. Dielectric losses are usually small at power frequencies and are neglected here.

Losses in the iron path of an electromagnetic device depend on the magnetic flux density and frequency. Just as the current is not uniform over the cross section of a conductor, the flux density is largest at the surface of the magnetic material, if it is conducting. Loss calculations are much more difficult in this case and are usually based on empirical knowledge (test data) of, for instance, the particular lamination thickness of the magnetic steel used in different portions of the magnetic circuit. The situation is further complicated by the fact that the losses are anisotropic in the laminations, i.e., they depend strongly on the direction of the magnetic flux density vector $\mathbf{B}$, as do the magnetic properties, in general, in the iron parts of an electrical machine. Iron losses are described in detail in the article MAGNETIC MATERIALS. The maximum value of B that is appropriate in a given portion of the magnetic circuit is not only dictated by thermal considerations but is limited by the saturation of the magnetic flux density—too high a value of B will lead to larger magnetizing currents, which increase the no-load loss and decrease the amount of current that can be safely carried for energy conversion purposes.

The total heat generated, at given values of magnetic loading (B) and electric loading (J), depends on the volume (L^3, where L is the "linear dimension") of iron and copper. Without artificial cooling, dissipation of heat is a function of surface area, which increases only as L^2. Hence, it is clear that for optimum use of a machine, additional means of cooling must be provided as the device becomes larger. In many electric machines, the surface area is increased by the provision of fins in larger units, and fan blades are usually mounted on the armature/rotor shaft to provide additional air flow for cooling larger units. More elaborate methods of cooling may also be used.

2.2 Electric Breakdown

In the design of electrical machines, the maximum voltage must not produce electric fields that cause dielectric breakdown (failure of the insulation), corona, or sparkover. Clearly, the actual voltages must be such as to provide a margin of safety. As in other matters, the effect of aging on insulation has to be taken into account to provide trouble-free operation over the estimated lifetime of the machine. Transients are another important consideration, as the applied voltage may not be distributed evenly over all the turns during rapid voltage changes.

2.3 Mechanical Failure

Mechanical failure results from the forces that act on current-carrying conductors in a magnetic field—the same forces that provide the driving force in electric motors. Forces also arise in motors and generators as a result of their motion, specifically centrifugal forces in rotating machines. Torques on drive shafts cause torsion forces that can lead to shaft breakage. Electromagnetic forces can be calculated from the Lorentz force equation [Eqs. (9) and (10)].

Generally speaking, the important parameters in the design of a machine are the maximum flux density, determined by material properties (saturation magnetization and iron losses), and the current density J, usually dictated by thermal considerations. In the operation of the machine, the total flux and total current rather than their densities are of concern. Hence, the amount of iron and copper (dictated, in part by their cross-sectional areas) and the size of a machine are all related to the magnetic and electric "loading" of the iron and copper, at a given voltage and current rating. In ac machines, with the voltage dependent on the frequency—Eqs. (4) to (6) clearly show how voltage relates to both frequency and magnetic flux—the size of a machine at a given rating varies inversely with frequency. One can also have different ratios of copper to iron volumes, a fact emphasized in transformer design. Hence, economic factors play an important part not only in the construction but also in the operation of electric machines.

This illustrates both the economy of scale and difficulties with scale changes in a general way. An important result is the increase in power handling capability at a given size of device with frequency.

3. DIRECT-CURRENT MOTORS AND GENERATORS

3.1 General Description

A dc machine usually consists of a fixed field structure with evenly spaced salient-pole pieces (in multiples of two) with current-carrying windings to provide a magnetic field. Additional, smaller pole pieces are placed in the space between the main poles in larger dc machines (interpoles—see later discussion). Permanent magnets instead of current-carrying coils are used in many modern electric machines, especially in the smaller sizes, to produce the desired magnetic flux. Laminated pole faces are often provided in large machines to reduce eddy currents produced by magnetic field fluctuation due to armature slotting (see below).

The rotating armature consists of a steel shaft with a steel hub on which sheet-steel disks with slots on the outer periphery are placed. There is a small air gap between the field structure and the laminated armature core surface (see Fig. 1).

Windings (insulated copper conductors) are placed in the armature slots, and current is carried from the conductors through a commutator—copper conductor segments insulated from each other—to external circuits by means of brushes arranged at spacings equal to the spacing of pole pieces on the field structure. Some examples of typical armature windings are given in Figs. 2 and 3; there are many other variations.

A conductor on the rotating armature experiences a force f since it carries a current I_A in the presence of the magnetic field of density B produced by the stationary field structure. The induced voltage e and the force per conductor f, moving at a velocity u and having a

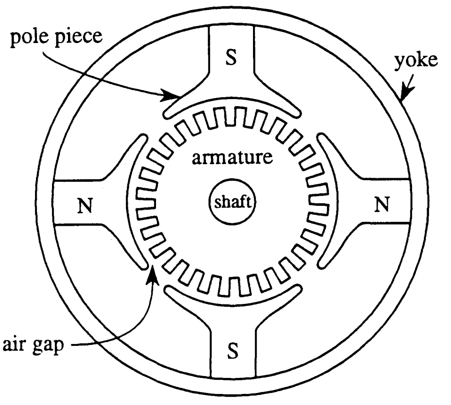

FIG. 1. dc motor. Commutator is mounted on shaft (not shown); see Fig. 2 for details of windings. Coils are placed on pole pieces to provide field excitation.

projected length l on the plane containing the **B** and **u** vectors, are given by [see Eqs. (7), (10)]

$$e=u\,B\,l \tag{11}$$

and

$$f=i\,l\,B. \tag{12}$$

More conveniently, the total generated voltage e_g for all the conductors in series between a pair of brushes is expressed by

$$e_g=K\phi\omega, \tag{13}$$

where ω is the radian velocity of the conductors (with $\omega R=u$, where R is the radius of the armature at the conductor position) and ϕ is the total air-gap flux per pole [$B\times$ (pole area)]; the coefficient K is determined by geometrical factors such as armature length, the number of turns, and their arrangement between brushes, etc., and is a constant for a given machine. $\omega/2\pi=n$ is the speed of rotation in revolutions per second, or rpm if multiplied by 60. e_g is also referred to as back or counter emf (in motors).

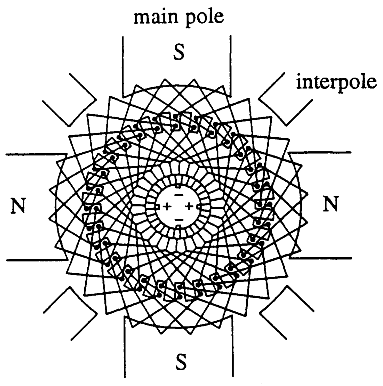

FIG. 2. dc motor with schematic of a lap armature winding shown.

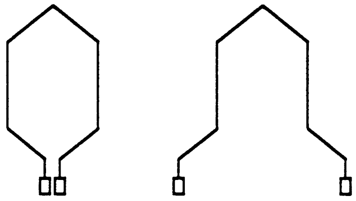

Coil for lap wound armature

Coil for wave wound armature

FIG. 3. Typical armature coil shapes.

The torque T_A produced by the interaction of the armature current with the field is similarly expressed as

$$T_A=K\phi I_a, \tag{14}$$

which gives the expected result

$$e_g I_A=T_A\omega \tag{15}$$

as required by energy conservation. T_A is the total torque, including friction and windage torques T_{loss} (shaft bearing friction and torques due to air motion produced by the rotating armature, often enhanced by fan blades to provide cooling). The net torque available at the shaft is $T_0=T_A-T_{\text{loss}}$.

Basic equivalent circuits for dc machines are given in Fig. 4. From the circuit equation and torque balance (in steady state)

$$V_0-R_A I_A=K\phi\omega, \tag{16}$$

$$T_0+T_{\text{loss}}=T_A=K\phi I_A, \tag{17}$$

speed–torque and voltage–current relations are readily obtained for a known value of ϕ. ϕ is determined by the field excitation. ϕ and, therefore, e_g depend on the field current I_f in the nonlinear fashion shown in Fig. 5. This nonlinearity is a consequence of the magnetization characteristics of iron. A machine is considered to be a motor if $T_0>0$ and a generator if $I_A<0$. In other words, energy flow from electrical energy to mechanical energy characterizes a motor, vice versa for a generator.

The magnetic flux ϕ due to the field excitation—different schemes are discussed

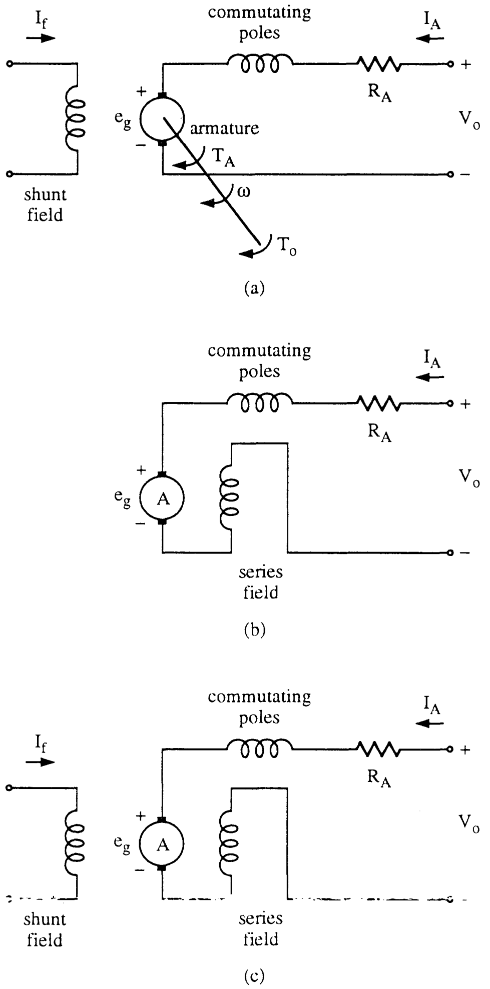

FIG. 4. Direct-current motor circuits: (a) dc shunt motor, (b) dc series motor, (c) dc compound motor.

below—can be readily obtained if the *B-H* characteristics and dimensions of each part of the magnetic path are known but are mostly determined by the air gap because of its higher reluctance (the effective permeability μ is much larger in the iron until it saturates). In practice, the experimental determination of e_g vs I_f is simple and convenient (and the results are readily adapted to all means of field excitation).

Currents flowing in the armature conductors produce an mmf that distorts the field produced by the poles. This effect is known as armature reaction. The armature current mmf essentially decreases the flux density in the trailing pole tip (in the case of a motor), and increases it in the leading pole tip. Because of saturation effects, the increase of flux density is smaller than the decrease, and the net effect of the armature reaction is to decrease the total available magnetic flux with increasing load.

Another factor that influences the operation and design of dc motors is commutation of currents as the commutator segments pass the brushes. Inductance effects cause sparking at the commutator brushes and, if not corrected, in all but the smallest motors or generators would lead to the destruction of the commutator. To counteract the effect, pole shoes (interpoles) are used in the space between the main poles (see Fig. 2), with windings connected in series with the armature in such a direction as to reduce the inductance of the armature coils under commutation to a small value. In very large machines, interpoles (also called commutating poles) do not suffice and a compensating winding, carrying armature current, is placed in slots on the main pole pieces, to oppose and hence reduce the net flux produced by the (commutating) armature conductors and avoid sparking at the commutator brushes.

3.2 Classification of dc Motors

Usually, dc motors are classified by the method used to obtain field excitation. Broadly speaking, one has to distinguish between *shunt excitation*, in which the field coils are supplied from constant or variable external dc voltage sources, and *series excitation*, in which the armature current flows through a set of field coils connected in series with the armature. Shunt coils are usually high-resistance, many-turn windings carrying a relatively small cur-

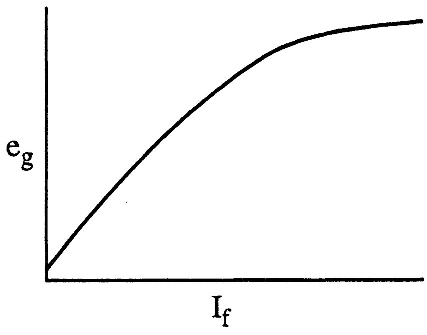

FIG. 5. Generated voltage e_g versus field current. Because of the remanent magnetic flux, e_g is not zero when I_f=0.

rent. On the other hand, series coils consist of few turns of wire, capable of carrying the total armature current at all loads.

A combination of shunt and series excitation is often used, with both a high-resistance shunt coil and a low-resistance series coil placed on each pole. Such a motor is called a *compound motor.* In a compound motor, the field excitation is given by the sum of the ampere turns of the shunt and series windings (or the difference in the case of a motor with negative compounding, which is rarely used). In Fig. 4 circuit diagrams are given for all the above.

dc motors may have fields provided by permanent magnets. Such motors behave like motors with shunt excitation, since a permanent magnet is, roughly speaking, equivalent to a winding carrying constant current.

3.3 Characteristics of dc Motors

The speed-torque characteristics of a dc motor depend on its mode of field excitation—shunt, series, or compound. Typical speed–torque curves are shown in Fig. 6.

3.3.1 Shunt Motors. As can be seen from Eq. (16),

$$\omega \approx (V_0/K\phi) \text{ if } R_A I_A \ll V_0,$$

as is usually the case. The effect of $R_A I_A$, at constant field excitation, is a small reduction in speed with increasing load. However, this effect is partly compensated by the decrease in flux ϕ due to armature reaction. A shunt motor provides, therefore, relatively constant speed; i.e., the slope of the speed–torque curve shown in Fig. 6 is very steep. Moreover, the motor speed level can be easily controlled by having the "shunt" field separately excited by means of a variable-voltage source (or a constant-voltage source with a variable series resistance or an electronic control; see Sec. 6). If the armature is also supplied from a variable-voltage source, then both V_0 and ϕ are independently controlled, resulting in a wide range of possible speeds. The easy speed control of dc shunt motors has been their traditional advantage over induction motors, offsetting their higher cost, though this advantage is now diminished by the advent of electronic control of induction motors.

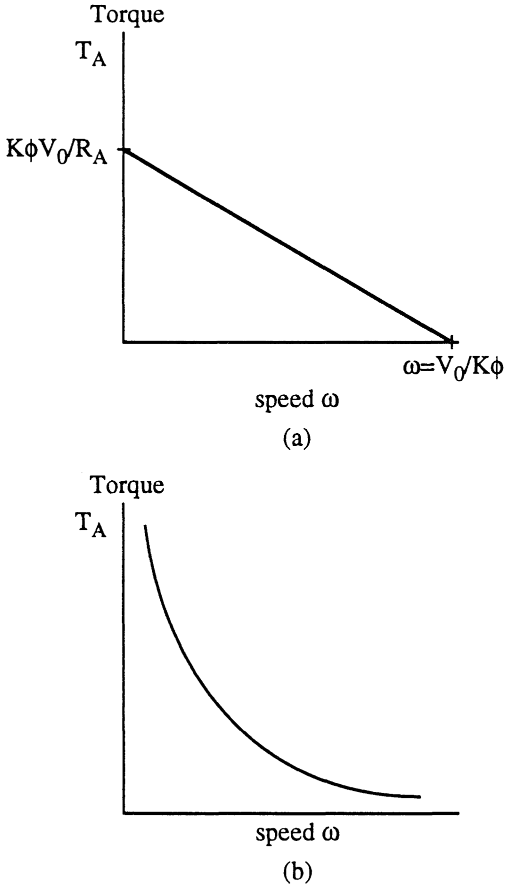

FIG. 6. Torque vs speed curves. (a) Shunt motor, (b) series motor.

3.3.2 Series Motors. When the field excitation is supplied by the armature current, ϕ becomes a function of I_A. If we neglect saturation effects, we have $\phi \propto I_A$, $T \approx K I_A^2$, and $\omega \approx (V_0/K I_A^2)$. Series motors exhibit very high torques at low speeds, at which armature current has to be limited to a safe value by means of external resistances (see Sec. 3.2.3). On the other hand, they have to be protected against excessive speeds at no load, since ϕ will drop almost to the remanent value, allowing excessive speeds. Series motors are used frequently in traction applications where the load is never removed and high starting torques are required.

The characteristics of a *compound motor* lie somewhere between those of shunt and series motors, depending on the amount of compounding (ampere turns of series winding relative to those on shunt winding, at a given load).

Operating points are readily found for any motor by plotting load-torque versus speed characteristics on the same graph as the motor torque-speed curves, and finding the intersection of the two curves, for each operating point (i.e., for each load condition and/or motor condition).

3.3.3 Starting of Motors. Transients in motors depend on mechanical and electrical time constants, with the mechanical time constants often much larger than the electrical time constants. For this reason, the starting currents of a dc motor have to be reduced by placing decreasing values of external resistance R_e in the armature circuit, as the speed ω gradually increases. I_A has to be limited to some safe value, a value that will not overheat the armature and series circuit during the starting period and will not allow excessive forces. R_e is usually decreased in steps so that I_A varies between an upper limit and the full-load value (or some similar value).

3.4 Direct-Current Generators

dc generators are essentially identical to dc motors, except that the power flow is reversed. Hence, the signs of T_A and I_A change (as well as the sign of T_0, of course). Then the applied torque T_0 must equal the sum of T_A and T_{loss}. Similarly, the output voltage V_0 is now given by the generated voltage $K\phi\omega$ minus the $R_A I_A$ voltage drop [see Eq. (16)].

Again, generators can be classified by their field connections. The separately excited generator has its field (with a variable series resistance for voltage adjustment) connected to a constant-voltage source. Hence the generated voltage $K\phi\omega$ is a constant for a given ω (actually, armature reaction will cause some decrease of ϕ at higher load currents). A self-excited machine has its shunt field connected across the armature terminals. The resulting operating point is readily determined from the magnetic characteristic e_g vs I_f of the machine, shown in Fig. 5, and its intersection with the field load line, i.e., Ohm's law applied to e_g and I_f: $e_g = R_f I_f$ where R_f is the total resistance of the shunt field circuit. The fact that there is usually some permanent magnetic flux plays an essential role in making a self-excited generator possible (as seen in Fig. 5, e_g is not equal to zero when I_f is zero). As the armature starts rotating the remanent flux will induce a voltage in the armature, causing some current to flow, allowing the flux, and hence, voltage to "bootstrap" up to the desired value if appropriate resistance values are chosen for the field circuit.

Compounding i.e., additional field windings carrying the armature current, can be added, producing a compound dc generator. The two windings usually are aiding—both produce magnetic fluxes in the same direction. Hence, a compound generator displays a flatter V_0 vs I_A characteristic, since the series winding increases the flux at larger armature current, thus compensating for the larger $R_A I_A$ voltage drop. Series generators are not often used, but their characteristics are readily derived from the principles given above. Typical curves for dc generator terminal voltage versus load current at a given speed are shown in Fig. 7 for various amounts of compounding.

4. ALTERNATING-CURRENT MACHINES

4.1 Rotating Field

A brief derivation of the rotating-field concept is given here, since it is the basis of most ac rotating machines. A three-phase arrangement will be considered, in which three separate sets of coils are supplied with three-phase power—three voltage sources with 120° time-phase difference between them.

We shall assume that each set of coils, arranged on the surface of a cylinder, pro-

duces a sinusoidally distributed flux at the cylindrical surface, described by

$$B=B(t)\cos(p/2)\theta \tag{18}$$

with

$$B(t)=B_m\cos(\omega t), \tag{19}$$

where p is the number of poles, determined by the winding pitch (i.e., the coil span; i.e., 180° for $p=2$, 90° for $p=4$, etc.) and placement of windings and θ defines the angular position on the cylinder. Obviously p has to be an even number. One period of the pole structure (i.e., "north pole" to nearest "north pole") spans $2\pi/(p/2)$ radians. The quantity $p\theta/2=\theta_e$ is referred to as "electrical degrees." In a typical three-phase machine, where the supply voltages differ in phase by 120°, the three identical sets of windings are displaced by $\theta_e=120°$ from each other.

The resultant field B at an angle θ and time t is given by the addition of the three components:

$$\begin{aligned}B&=B_m\cos\omega t\ \cos(p\theta/2)+B_m\cos(\omega t+2\pi/3)\\&\quad\times\cos(p\theta/2+2\pi/3)\\&\quad+B_m\cos(\omega t-2\pi/3)\\&\quad\times\cos(p\theta/2-2\pi/3)\\&=(B_m/2[\cos(\omega t+p\theta/2)+\cos(\omega t-p\theta/2)\\&\quad+\cos(\omega t+p\theta/2+4\pi/3)\\&\quad+\cos(\omega t-p\theta/2)\\&\quad+\cos(\omega t+p\theta/2-4\pi/3)\\&\quad+\cos(\omega t-p\theta/2)]\\&=\tfrac{3}{2}B_m\cos(\omega t-p\theta/2).\end{aligned} \tag{20}$$

Thus, the resultant field is a single field of constant amplitude $\frac{3}{2}B_m$ rotating at a speed

$$\frac{d\theta}{dt}=\omega/(p/2)=2\pi n_0, \tag{21a}$$

where n_0 is called the synchronous speed (in revolutions per second). Expressed in rpm,

$$\frac{d\theta}{dt}=\frac{\omega}{p/2}\,\frac{60}{2\pi}=(120f/p)\ \text{rpm}. \tag{21b}$$

Reversal of the connection to one of the three phases will reverse the direction of rotation. Note that each phase—each set of coils—produces an alternating field that can be resolved into two half-amplitude oppositely rotating fields. In this arrangement, the fields rotating in one direction have a vector sum of zero; those rotating in the opposite direction are exactly in phase and hence add to give a rotating field of amplitude $3B_m/2$. n-phase systems for $n\geqslant 3$ (n an integer), with coils displaced by $\theta_e=2\pi/n$ radians and supplied from sources with phase differences of $2\pi/n$ radians between adjacent phases, behave similarly. $n=2$ is a single-phase system with polarity reversal.

4.2 Induction Motors

An induction motor usually has a three-phase winding arranged in slots in the laminated stator structure, producing a rotating field in the air gap, that is, the space between the stator lamination surface and that of the cylindrical rotor. There are slots symmetrically placed around the rotor armature, into which copper or aluminum bars are inserted. These bars are shorted by solid metal (copper or aluminum) rings at each end. The conductor structure, if visualized without the iron (it is often cast as a unit on the rotor and not removable), looks like a cage; hence the name "squirrel cage" induction motor is used to describe this type of motor

In an induction machine the rotating field generated by the stator windings induces voltages and, hence, currents in the usually short-circuited rotor conductors. The field caused by the rotor currents interacts with the stator field and causes the rotor to start rotating. A simple explanation: the rotor field "chases" the stator field but never catches up—if it did, there would be no induced currents in the motor and, hence, no interaction [but supplying a dc current to the rotor conductors would cause the motor to "lock" in with the rotating stator field and become a synchronous motor, rotating at $(120f/p)$rpm].

4.2.1 Induction-Machine Equivalent Circuit and Characteristics. The equivalent circuit of the "locked rotor" (rotor not turning) ac motor is essentially that of a transformer (with an air gap). As the rotor starts turning, the voltage induced in the rotor windings decreases, and goes to zero if a speed of

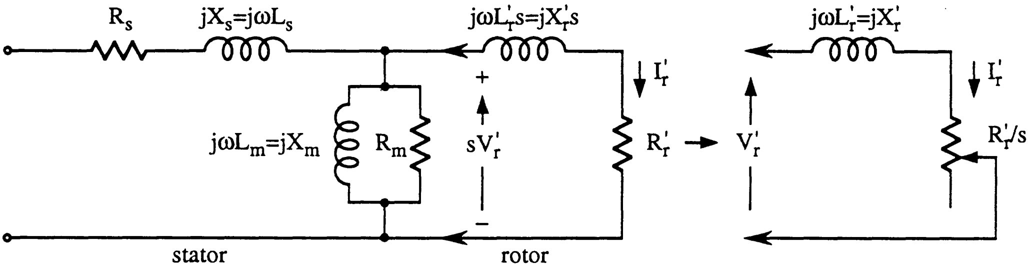

FIG. 8. Approximate equivalent circuit of induction motor showing evolution to modified rotor representation.

$2f/p=n_0$ rps is reached (i.e., the rotor moves at the speed of the rotating field). If we define slip as

$$s=(n_0-n)/n_0, \tag{22}$$

where n is the actual speed of rotation, the voltage induced in the rotor can be shown to be equal to sV_r, where V_r is the voltage induced in the "locked" rotor.

An equivalent circuit is shown in Fig. 8. It should be noted that the secondary (rotor) circuit has its values referred to the primary; hence the primed parameters (see TRANSFORMERS). As the speed of the rotor increases, and hence its speed relative to the rotating field decreases, the frequency of the voltage induced in the rotor decreases–it is always equal to $f(n_0-n)/n_0$, or sf, where f is the frequency of the stator ac supply.

It is convenient to "scale" rotor values by s, i.e.,

$$I'_r=sV_r/(R'_r+js\omega L'_r)=V'_r/(R'_r/s+j\omega L'_r) \tag{23}$$

without affecting the current (or the torques produced by these currents).

The evolution of the rotor circuit, referred to primary stator windings, is also shown in Fig. 8. Since $R'_r/s=R'_r+[(1-s)/s]R'_r$, Fig. 8 allows a simple interpretation of the power flow. I'_r and R'_r are the physical values of the parameters (actually R'_r may have to be adjusted for the change in the frequency of rotor currents because of skin-depth variations). The term $[(1-s)/s]R'_r$ is a fictitious resistance that models the power flow from the motor to the mechanical system via the rotating rotor shaft:

$$P=Tn_0(1-s)=I'^2_r[(1-s)/s]R'_r. \tag{24}$$

Since I'_r can be found from the equivalent circuit, torque versus speed curves for a fixed-voltage excitation of the stator are readily obtained from Eq. (24).

Typical speed–torque curves for an induction motor are shown in Fig. 9, for a series of values of rotor resistance R_r. Increasing the value of R_r shifts the point of maximum torque T_m to lower speeds, without affecting the value of maximum torque, as is readily derived from the above equations. Increasing the value of R_r consequently increases the starting torque. Squirrel-cage motors are often built to have a larger resistance upon starting than during normal operation. This is achieved by taking advantage of the fact that the depth of penetration of the currents varies with the speed: Cast aluminum or copper bars are placed in deep rotor slots, and a second winding with a higher resistance (usually cast aluminum) is placed at the top of the slots, near the air gap. As a result, the rotor resistance is higher near the surface where the currents concentrate at starting. At higher

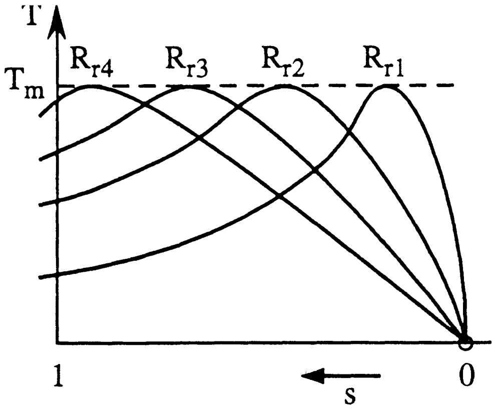

FIG. 9. Induction-motor torque-vs-slip curves for a number of values of rotor resistance R_r, with $R_{r_4}>R_{r_3}>R_{r_2}>R_{r_1}$. T_m is the maximum torque independent of value for R_r for constant voltage.

speeds, the frequency of the current decreases and, consequently, the current spreads deeper and a large portion of it is carried by the lower resistance copper bars.

As s reverses its sign (motor is driven above synchronous speed n_0) an induction motor becomes an induction alternator—it will convert mechanical energy to electrical energy. However, the stator has to be supplied by an ac source: this machine is not "self-excited" unless a bank of capacitors is connected to the terminals. Figure 10 shows torque and current versus s over a wide range of values of s defining different ranges of operation.

In some cases, instead of a squirrel-cage, separate three-phase windings are placed on the rotor and connected through slip rings to an outside circuit. This scheme allows a better control of the induction machine, but is becoming rare as more effective electronic means are being adopted to control the machine via the stator power supply.

4.2.2 Single-Phase ac Motors. The principle of operation of single-phase motors is readily explained by using an observation made in connection with the derivation of Eq. (20). Each phase produces an alternating field that can be resolved into two half-amplitude oppositely rotating fields. Superposing the torque speed curves of the two oppositely rotating fields, one finds that at the small value of slip at which induction motors operate, only the torque due to the appropriate component is significant. To get the motor started in the desired direction several schemes are used. The most common is the use of an auxiliary winding, displaced by 90° electrical from the main winding, and phase shifted by close to 90° by placing a large capacitor in series with it. A centrifugal switch may be used to disconnect this starting winding as the motor approaches the design speed. It should be noted that a single-phase motor is much noisier (pulsating rather than rotating field), larger, and less efficient than a three-phase motor of the same rating. Its main advantage is that it can be used where three-phase power is not available. A torque versus speed curve for a single-phase induction motor without an auxiliary starting winding is shown in Fig. 11.

In a *shaded-pole motor*, used for small single-phase motors with low starting torques, a short circuited copper strap is placed on a fraction of each pole (the "lagging" end of the pole). The induced currents provide a "lagging" field that, in turn, provides a small unidirectional torque, sufficient to start a fan motor, for instance.

4.3 Hysteresis Motors

Hysteresis motors (usually very small single-phase motors) derive their torque from the lagging flux produced by the motor magnetization, during subsynchronous operation. Special magnetic materials are used that are semihard (i.e., they are "permanent magnets" that can be cycled around their hysteresis loop by the stator currents). When the rotor reaches synchronous speed, the rotor flux no longer cycles and the permanent magnet rotor behaves as in a synchronous machine.

4.4 Universal Motors

Universal motors are series motors designed with relatively low field inductance, to allow them to function on either dc or ac supplies. Both stator and armature need to be laminated, and the design is usually more difficult since coils under commutation have voltages induced in them due to the ac fluxes (if used on an ac supply). Because of the higher ac impedance of a shunt field, as compared with its resistance, and because the high inductance of the shunt would lead to an undesirable phase difference between the stator and armature fields, universal motors are

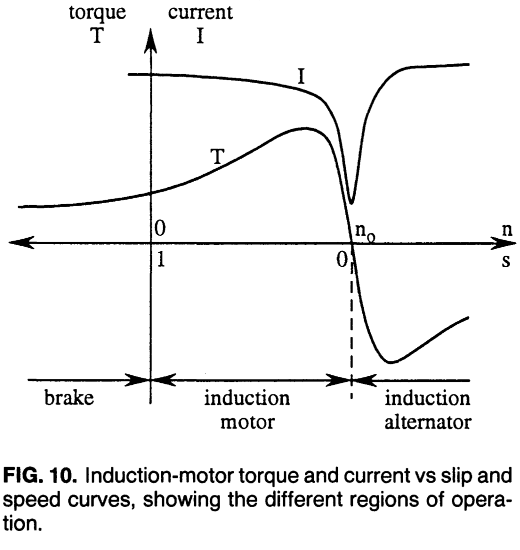

FIG. 10. Induction-motor torque and current vs slip and speed curves, showing the different regions of operation.

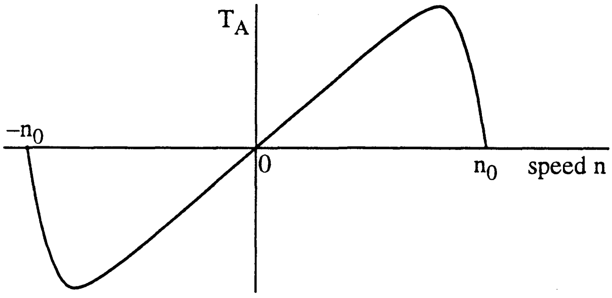

FIG. 11. Torque–speed curve for a single-phase induction motor without auxiliary starting winding.

not practical in a shunt-field configuration. Universal motors are commonly used in hand tools and similar applications.

4.5 Three-Phase Synchronous Machines

In synchronous machines, dc-excited poles rotate at a speed ω_s, where $\omega_s = 2\pi n_0/60$ rad/s, relative to stator windings similar to those described for an induction machine rotor. In a three-phase machine, there will be three windings displaced by 120° electrical from each other. The rotor may have a smooth cylindrical surface with slots to hold the dc windings (in large turbine alternators) or may consist of salient poles excited by windings, or the windings may be replaced altogether by permanent magnets. In this discussion we will explain the behavior of synchronous machines from a simple point of view without detailed considerations of harmonics—pure sine waves are only encountered in ideal machines—or of saturation effects. The reverse configuration (dc field on the stator and three-phase winding on the rotor) is possible, but rare, and can be described in a similar manner.

For symmetrical three-phase circuits, one needs to consider only one of the three phases—the other two will only differ by having their currents and voltages displaced by $+120°$ and $-120°$, respectively. For smooth-rotor (cylindrical rotor) synchronous machines, the reluctance of the magnetic paths will not depend on the position of the rotating member (if one neglects the effect of the slots, which will produce harmonics but will not directly affect the fundamental component in a major way).

An understanding of the principles of operation is most easily gained by considering the magnetic fluxes produced by the field current I_f and by the currents in the three-phase windings. Suppose the two fluxes are exactly in phase so that a rotor "south" pole faces a stator "north" pole. In this situation no torque can result. The two fluxes must be out of phase, and in fact the stator windings carrying the currents that produce the mmf will ideally be situated 90° (electrical) away from the center of the rotor pole, in a region of zero flux. For the rotor field to lead the stator field (the air-gap field), a torque, that is, power, needs to be applied to the rotor shaft; the synchronous machine, then, is an alternator. If, on the other hand, the rotor field lags behind the stator (air gap) field by some angle, then a torque is applied to the rotor by the field—it is "pulled along" by the air-gap field—and the machine becomes a synchronous motor. It can be shown that the torque T (or power flow $T\omega_s$, with ω_s a constant) is proportional to the product of the stator current I_s, the rotor field ϕ_f, and sin γ where γ is the electrical angle between the fields produced by the rotor and the stator current I_s, respectively. A very simple model results if one neglects stator resistance (reasonable for large machines), leakage reactance, and saturation so that one can assume that the total mmf produced relates linearly to the total voltage V_t at the terminals of the ideal machine. This voltage is the sum of E_f, the voltage generated by the rotor magnetic flux, plus the "armature reaction" voltage due to the stator current. $V_s = jX_sI_s$ where X_s is the magnetizing reactance of the stator and δ is the angle between E_f and V_t (between the direction of the rotor field and the resultant field, i.e., the rotating field in the air gap due to all mmfs. One obtains

$$(V_t - E_f)/jX_s = I_s. \qquad (25)$$

It follows from the above that the power P per phase of this ideal machine is

$$P = (V_t E_f \sin\delta)/X_s \tag{26}$$

with the sign of δ determining the direction of power flow. The same qualitative result was obtained from the physical reasoning above.

We can use this ideal model to understand the power flow, which has a maximum value of $V_t E_f/X_s$—if this is exceeded, the machine will fall out of synchronism (that is, the stator and rotor fields do not rotate at the same speed any more, and the average torque is zero). One can also study the use of the machine as a *synchronous condenser*, the operation when $P=0$ and hence $\delta=0$ (still neglecting losses) and V_t is fixed (supplied by a "bus," which is essentially a connection to a system that determines both V_t and the frequency f, and hence ω_s). For one value of field current I_f, $V_t=E_f$ and $I_s=0$. If I_f is increased, I_s has to increase in such a direction and phase that $\mathbf{E}_f+jX_s\mathbf{I}_s=\mathbf{V}_t$ for $E_f>V_t$ ($\delta=0$ since we are assuming a lossless, ideal machine). $\mathbf{I}_s$ has to lead $\mathbf{E}_f$ and $\mathbf{V}_t$ by 90°, i.e, $\mathbf{E}_f$ $E_f\angle 0°$ and $\mathbf{V}_t=V_t\angle 0°$ in phasor notation with $\mathbf{I}_s=I_s\angle 90°$. This machine behaves just like a capacitor, and hence this mode of operation is called that of a "synchronous condenser." A decrease in field current would cause a 90° lagging current to flow in the stator, a less desirable mode since a purely inductive load would lower the power factor of the system (assumed to be lagging), normally a poor option.

In a "real" machine, the terminal voltage V_t would be modified by additional voltage drops due to stator resistance and leakage reactance, conceptually similar to the transformer circuit model. Though complicating the circuit somewhat (see Fig. 12), the calculations needed to take account of the more realistic situation are straightforward.

Also, the nonlinear effects due to saturation in the iron have to be taken into account. The field excitation curve E_f vs I_f displays the effects of saturation—it is quite similar to that of a dc machine. Values of E_f have to be adjusted accordingly in regions of higher mmf and, hence, higher E_f values. With saturation, the value of X_s also decreases.

Experimental determination of cylindrical-rotor synchronous-machine parameters is similar to that of transformer parameters. E_f is determined by means of an open-circuit test, as a function of the field mmf. The short-circuit current is obtained, also as a function of the field mmf. The ratio of the open-circuit voltage divided by short-circuit current is the synchronous impedance at the value of the field mmf at which the ratio is taken. The synchronous impedance is the sum of the resistance plus the total reactance of the machine. The latter is also called synchronous reactance.

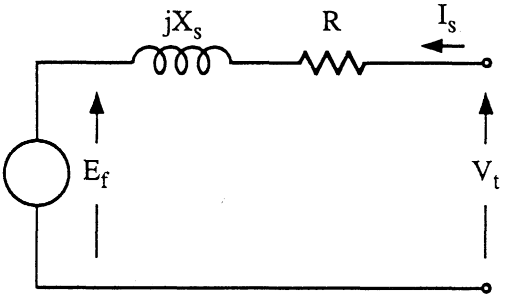

FIG. 12. Approximate equivalent circuit of a synchronous machine (per phase). X_s is the synchronous reactance and R is the total resistance of the stator circuit.

A salient-pole synchronous machine has separate pole pieces, with gaps between the poles. Hence, the reluctance of the magnetic path varies as the rotor rotates, with a complete period of the variation occurring as the rotor advances by 180° electrical. This situation is described most conveniently by defining two separate values of the stator reactance, the direct-axis synchronous reactance X_d for the position of the stator windings so that their mmf acts in the low-reluctance path, and a quadrature-axis synchronous reactance X_0, 90° electrical from the direct axis, when the reluctance is a maximum. The stator current is expressed in terms of its components, one in phase with the direct-axis position and the other (at 90° from the first) in phase with the quadrature-axis position of the rotor relative to the stator.

If the resistance and leakage reactance of the stator windings are neglected, one can write, approximately, for the salient-pole motor,

$$\begin{aligned} P = {} & (V_t E_f/X_d)\sin\delta + (V_t^2/2X_d X_q) \\ & \times (X_d - X_q)\sin 2\delta. \end{aligned} \tag{27}$$

As can be seen, the saliency adds a term called reluctance torque (or power when multiplied by ω_s) that only depends on the angle δ

between the center of the salient field structure and the peak of the air-gap flux variation of the fundamental term. Since the saliency introduces a 180° (electrical) periodicity, a "2δ" function appears.

4.5.1 Reluctance Motors. A *reluctance motor* is one that uses no dc field but relies entirely on the variation of reluctance of the structure to produce a torque. In principle, a *stepping motor* also is based on similar reluctance torques with the essential difference that, instead of three-phase excitation, two or three phase windings (arranged appropriately 90° or 120° electrical from each other) are excited successively by pulses, at a rate consistent with the speed at which the motor is to be "stepped" (and within a frequency range consistent with the capability of the system in terms of electrical and mechanical time constants).

4.5.2 Amortisseur or Damper Windings. Slots may be provided on the air-gap surface of the field structure (assumed to be the rotor here and in most of the previous discussion), and copper or aluminum bars placed in the slots and short-circuited at each end by means of a copper or aluminum ring, respectively, as in an induction (squirrel-cage) motor. The purpose is twofold. Currents are induced in these conductors when there is any "slip" between the rotating dc field structure and the synchronously rotating ac field, and will serve as a means of damping such motion. In a synchronous motor, this short-circuited winding will start the motor as an induction motor until it can be synchronized as the slip becomes small. Synchronization of synchronous machines is an important, practical topic beyond the scope of this article.

5.4.3 Transients in Synchronous Machines. These are a somewhat formidable subject. In the previous treatment, reactances have been discussed, but only for situations when all magnetic fluxes are stationary with respect to each other in a rotating frame of reference (expressed above by the term "synchronous speed"). In transients, this is no longer the case and additional "transient" and "subtransient" reactances have to be introduced, to account for the flux linkages between the dc field windings and the ac stator windings and damper windings, respectively. In salient-pole machines, direct- and quadrature-axis transients and subtransients have to be taken into account. The basic method used is based on the "conservation of flux linkages," in which one examines the rate of change of flux linkages in each circuit according to its time constant and uses the fact that flux linkages are conserved for times that are short compared to the time constant of the circuit considered.

4.6 Linear Motors

Linear motors are used to produce linear rather than rotational motion. Linear motors are built to operate as induction, synchronous, or reluctance motors. But instead of windings arranged in a cylindrical geometry, a planar geometry is used. The design may differ somewhat and larger air gaps are customary in traction devices. More sophisticated controls are needed. Only the windings in the region of the "moving part" of the motor (previously called rotor) are excited, and speed control, especially in synchronous motor design, is usually accomplished by means of variable-frequency excitation. One prospective application is the use of linear motors in high-speed transportation, with levitation integrated into the motor in some designs.

5. PERMANENT-MAGNET EXCITATION

Both dc machines and synchronous machines require a dc field structure. Conventionally, these fields were supplied by current-carrying coils placed on a pole structure (iron pole pieces) as explained above. However, with the advent of new permanent-magnet materials, and the availability of inexpensive ferrite magnets, dc fields can be supplied by substituting permanent magnets for the electromagnets in the field structure. In the automotive industry, ferrite permanent-magnet motors are commonly used in the dozens of small motors used in each automobile. Greater torque requirements are placed on some applications such as starting motors in a car or truck, so that neodymium-iron-boron permanent magnets, which provide much higher magnetic flux densities and have higher coercive forces, are used in these and other more demanding applications.

In modern practice, conventional dc motors are being replaced by so-called brushless dc motors (see Sec. 6.4.3). These are really synchronous motors with a permanent-magnet field structure. They are driven by variable ac polyphase sources, derived from solid-state supplies powered by a dc power source (or rectified ac sources). Total speed control over the entire range from starting to full speed is achieved by controlling the frequency.

6. ELECTRONIC CONTROL OF ELECTRICAL MACHINES

When supplied from conventional power sources, characterized by constant frequency and nearly constant voltage, electrical machines operate with their characteristic speed-torque curves. For all but series-connected dc machines (Sec. 4.2) and the ac equivalent, the universal motor, this results in very nearly constant-speed operation.

Adjustable-speed operation requires, as a minimum, the ability to control voltage. For efficient control of induction machines and for synchronous machines, coordinated voltage and frequency control is necessary. Because of the practical problems associated with control of frequency, traditional adjustable-speed drives utilized dc machines. However, advances in power electronics have made variable-frequency inverters quite feasible, and adjustable-speed ac drives are now readily available.

6.1 Electronic Power Converters for Electric Drives

The size and cost of all electronic power converters are strongly affected by both their continuous and short-time current capacities, which must therefore be carefully chosen and limited in the design process. An important characteristic of all electronic power converters is, therefore, very limited current capacity compared to conventional power sources. In all cases the controller must be designed to avoid the typical high inrush currents associated with normal "line starting" of motors. Current-limiting circuits and instantaneous electronic trip features are necessary to avoid damage to the electronic converter switching devices.

6.1.1 Controlled Rectifiers. Controlled rectifiers are used to provide variable dc voltage for motor control from a single-phase or three-phase ac supply. Thyristors (silicon-controlled rectifiers) are generally favored for higher power levels because of their high current and voltage ratings and low cost despite the attendant need for relatively complex timing and control circuits. Figure 13 shows a very good form of controlled bridge rectifier, called a dual bridge, capable of full four-quadrant operation. The circuit consists of two full bridges, one to handle forward (motor) current and one to handle reverse (regenerating) current. Avoiding having both bridges on simultaneously is imperative since this would result in a three-phase input fault. Reactors are often employed to limit fault current and allow recovery without shutdown. Because of control complexity and reliability considerations, the dual bridge is only used when necessitated by regeneration requirements. More typically only one bridge is used, and limited regeneration is allowed by employing a switched resistor on the dc bus. Other simplifications include semiconverters using three diodes in place of three of the thyristors, half-wave converters using only three thyristors, and single-phase versions of the various alternatives. There are also more sophisticated ac-to-dc converters (rectifiers) using gate turnoff devices such as transistors or GTOs (gate turnoff thyristors) to provide some control of the input ac wave form and power factor, but these are not currently widely used and will not be further described here.

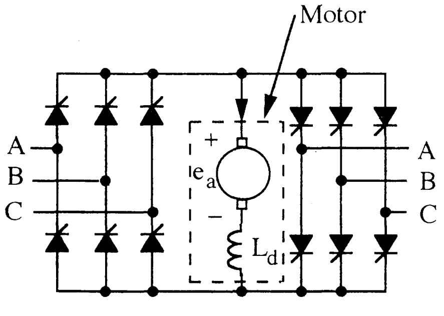

FIG. 13. Dual-bridge three-phase controlled rectifier.

When thyristors are used, the output voltage of a controlled rectifier is determined by the phase delay angle α of the thyristors. This angle is measured between the actual instant of initiation of conduction and the instant of conduction if the thyristor were replaced by a diode. Both positive and negative output voltage is available from a single bridge, and for the three-phase full bridge the voltage can be expressed as

$$V_{\mathrm{dc}}=(3\sqrt{6}/\pi)V_{\phi}\cos\alpha, \tag{28}$$

where V_{ϕ} is the rms phase voltage. There is also an equivalent resistance, related to the ac-side line inductance, which causes a reduction in output voltage dependent on the dc load current.

6.1.2 Choppers. Power converters used to convert a constant-amplitude dc source to variable amplitude are called choppers. The *H* bridge illustrated in Fig. 14 is a four-quadrant chopper. The switches are operated in pairs, 1 and 4 yielding a positive output, 2 and 3 a negative output, and 1 and 3 or 2 and 4 a zero output. The variable voltage output is obtained by pulse-width modulation (PWM) with the output wave form consisting of variable-width voltage pulses of the desired polarity separated by segments of zero voltage. There are simpler variants that do not offer four-quadrant operation. When combined with a simple diode rectifier, choppers offer an alternative to controlled rectifiers for ac to variable-voltage dc conversion.

6.1.3 Phase Control of ac Voltage. Variable ac voltage for motor control is accomplished by utilizing back-to-back connected thyristors or TRIACS, as is done in the dimmer control of lighting. Figure 15 illustrates the scheme and a typical wave form in a three-phase system. Voltage control is obtained by varying the phase delay angle much as in a phase-controlled rectifier.

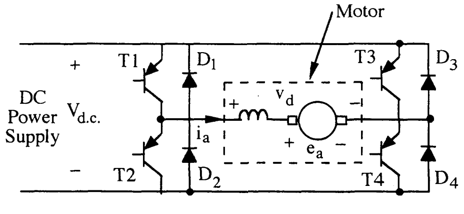

FIG. 14. Four-quadrant *H*-bridge chopper using transistors as the switching elements.

6.1.4 Inverters. Inverters are used to convert from dc to variable-frequency ac using either six-step operation (peak ac amplitude equal to the dc amplitude) or PWM operation (variable ac amplitude). At present, essentially all ac drives employ an inverter and hence require a dc supply. For ac drives operating from an ac power source, the resulting dc link system uses a simple rectifier (for PWM operation), or one of the various variable-voltage dc converters described previously, as the input converter. Figure 16 illustrates the two basic types of circuits in common use for three-phase systems.

The two circuits can be distinguished by the presence of the inverse connected diodes and the dc bus capacitor in the VSI and the dc link inductor in the CSI. Both switch blocks of the input dc to the output to create a three-phase output of rectangular wave form. The two systems differ in that the voltage source inverter (VSI) operates with three switches on at each instant and creates a direct instantaneous correspondence between dc voltage amplitude and the peak output ac voltage. In contrast, the current source inverter (CSI) only has two switches on at each instant and produces instantaneous correspondence between the dc current amplitude and the peak output ac current. The two systems are mathematical duals. Because of cost and certain technical limitations, the CSI is presently used only in very large sizes employing thyristors, and primarily with synchronous machines where leading power factor operation can be used to attain self-commutation. Some retrofit applications to large induction motors with added power factor correction capacitors also use thyristor-based CSIs.

The line-to-line output wave form of the VSI for six-step operation is a rectangular wave with two periods of zero voltage each of a duration of one-sixth of a cycle as shown in Fig. 17. The peak value is equal to the dc-side voltage resulting in a fundamental output voltage of

$$V_L=(\sqrt{6}/\pi)V_{\mathrm{dc}}, \tag{29}$$

where V_L is the fundamental rms line voltage. The line-to-neutral wave form for the six-step VSI has a peak amplitude of two-thirds of the

dc voltage amplitude as shown in Fig. 17 and has a fundamental component of

$$V_\phi = (\sqrt{2}/\pi)V_{dc}, \tag{30}$$

where V_ϕ is the fundamental rms phase voltage. The wave forms for the CSI are also shown in Fig. 17, and the values of the fundamental components of the line and phase currents (delta connection) are given by Eqs. (29) and (30) with I replacing V. These rectangular waves have only odd harmonics without any triple multiples of the fundamentals, and the harmonic amplitudes are inversely related to harmonic order. Only the fundamental produces useful output torque; the harmonics create torque pulsations and extra heating of the motor. Control of the output frequency is obtained by varying the stepping rate of the switches. The required voltage control can be accomplished by controlling the dc-side voltage or, now more commonly, by PWM operation of the switches as in the dc chopper. Both types of inverters are fully bilateral, allowing power flow in either direction. The VSI requires reversal of the dc current and thus requires a dual converter at the input to the dc link. In contrast the CSI regenerates by reversing the dc voltage and only requires one input-controlled rectifier bridge.

6.2 dc Drives

Solving Eq. (16) for the speed ω yields

$$\omega = (V_0 - R_A I_A)/K\phi, \tag{31}$$

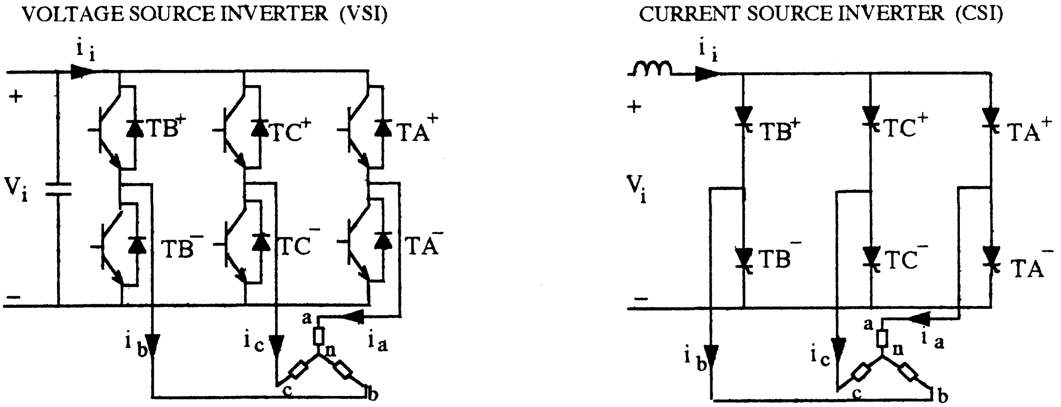

FIG. 16. Power-circuit configuration of VSI and CSI inverters.

which indicates that the dc-motor linear speed–torque characteristic can be controlled by

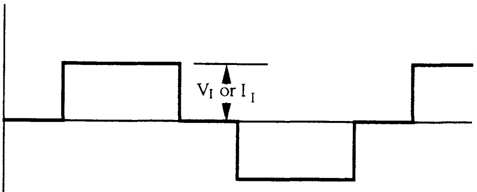
1. varying the armature voltage V_0, which controls the zero-speed intercept,
2. varying the armature resistance R_A, which controls the slope, or
3. varying the field flux ϕ, which controls both the slope and the zero-speed intercept.

Armature-resistance speed control is very inefficient and yields poor speed regulation and is therefore seldom used except in very small motors. Field flux control is the only way to attain operation above rated speed without exceeding rated voltage and is widely used in combination with other techniques to yield high-speed operation. It is also the only speed control method that does not require handling the full motor output power or current. It is, however, only useful at high speeds since it reduces the torque per ampere and thus the available output power unless the speed is high.

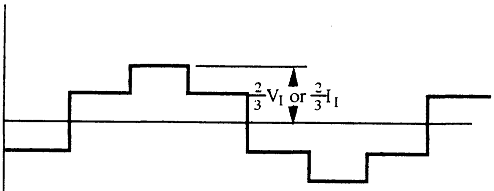
The simplest and most common electronic dc motor drive utilizes armature voltage control with a separate field supply (or permanent-magnet field). Before power electronic converters were available, the variable armature voltage was supplied by a dc generator with field control (Ward-Leonard system). Replacing the generator with an electronic converter provides much faster response and improved efficiency. However, the inherent regeneration capability of the dc generator requires a dual-bridge converter to provide equivalent performance. Also, the system isolation and input power-factor control provided by employing an ac synchronous motor to drive the dc generator are difficult to emulate in the electronic version of the system.

Power level, required control functions, and cost constraints are the primary factors that dictate selection of the type of converter used. Generally, high-power drives require thyristor-based converters and thus tend to be controlled-rectifier systems. Low-cost drives also are generally controlled-rectifier based using semiconverters or half-wave systems.

6.2.1 Capability Curves. The "capability curve" of a dc machine shows the available torque as a function of speed when the arma-



VSI Line Voltage or CSI Line Current



VSI Phase Voltage (Wye-Connection)
or
CSI Phase Current (Delta-Connection)

FIG. 17. Wave forms for six-step VSI and CSI inverters.

ture voltage V_0 and current I_A are limited to their rated values. As shown in Fig. 18, the total speed range is divided into two parts: the range from zero to the rated speed, where armature voltage control with full field current is employed, and the range from rated speed to the maximum allowable speed, where operation is with full-rated armature voltage and steadily reducing field current to keep the back emf e_g smaller than the terminal voltage V_0. The armature voltage control region below rated speed is called the "constant torque region" since the machine is *capable* of full-rated torque at any speed in this region. Above rated speed the torque *capability* is reduced since the field flux is smaller. This region is called the "constant (horse)power region" since with both the voltage and current held at their limit values, the power capability is constant. The term "field weakening region" is also used to describe this mode of operation at high speeds.

6.2.2 High-Dynamic-Performance dc Drives (Servo Drives). When fast response to speed or torque commands is required, a chopper-controlled system is employed except at very high power levels. This avoids the inherent dead time associated with controlled rectifiers. In high-power drives using controlled rectifiers this dead time can be reduced by employing multiple rectifier bridges phased to produce more pulses per input frequency cycle.

High-performance drives nearly always utilize an inner armature-current control loop to provide current regulation as shown in Fig. 19. With controlled current the dc motor becomes a controlled torque source since the torque and armature current are proportional when the field flux is constant. This makes the overall drive performance independent of the armature resistance, inductance, and back emf since these are all compensated by the action of the current loop.

There is an upper speed limit beyond which there is insufficient source voltage to overcome the back emf and maintain current control. Reducing the field flux (field weakening) reduces the back emf at any speed and thus extends the maximum available speed for the drive. Avoiding overcurrent in the converter is easily accomplished by simply limiting the command to the current regulator. This torque command signal is typically derived from the output of the outer loop regulator controlling speed, position, or other physical variables.

6.2.3 Open-Loop dc Drives. In applications where response time and/or precise control of speed are less important, the inner

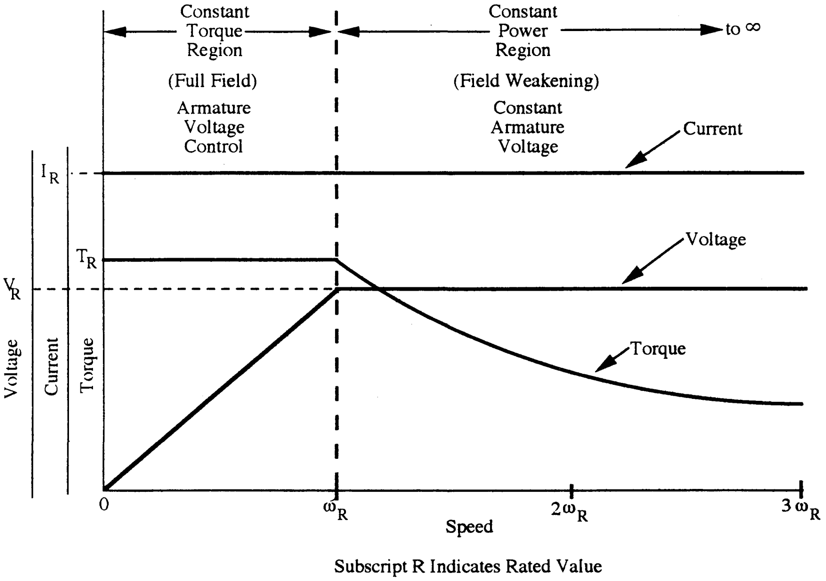


FIG. 18. Capability curves of a dc motor.

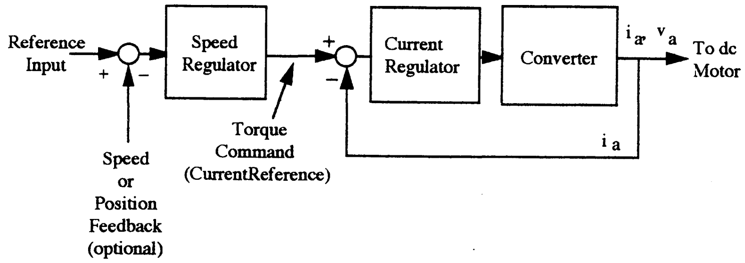

FIG. 19. High-Performance dc servo drive schematic block diagram.

current loop and sometimes even the outer speed feedback loop are eliminated. To avoid overcurrent resulting from the low dynamic impedance of the motor, an electronic current limit, as illustrated in Fig. 20, and, often, a slow ramping of the speed command that directly controls the converter output voltage are employed. The speed command can be the output of a regulator fed by speed error or simply an open-loop command. In this latter case, there is often an *IR*-drop compensator, which partially corrects for the speed droop caused by armature and converter resistance voltage drop. In most cases these simple, open-loop drives utilize some form of rectifier converter, often of the semiconverter of half-wave type.

6.3 Variable-Speed ac Drives

Unlike dc drives where there are only a few basic types, there are a large number of viable ac drive types. This variety stems from the many possible combinations of induction and synchronous machines, VSI and CSI inverters, and speed-control strategies. Only the most commonly used systems are described here.

6.3.1 Synchronous-Motor Speed Control. The only mechanism for speed control in synchronous machines is varying the frequency, which directly varies the speed of the rotating magnetic field [Eq. (21a)]. To avoid changing the flux density in the iron core, and particularly saturation, changes in frequency are typically accompanied by proportional changes in the applied voltage [Eq. (6)] leading to the term "constant-volts/hertz control" used to describe this mode of operation. When operated with constant volts/hertz and constant field current (and neglecting the armature resistance *R*; see Fig. 12), a synchronous machine develops the same torque at the same torque angle δ and the same armature current I_s at any frequency f. This very desirable result occurs because the voltage V_t, the induced voltage E_f, and the reactance drop I_sX_s in Fig. 12 are all linearly proportional to the frequency, and hence the phasor diagram relating the three quantities simply shrinks or grows as the frequency varies without altering the angle δ. Under these conditions the torque, given by the power divided by the speed, is [from Eq. (26)]

$$T=(V_tE_f/\omega X_s)\sin\delta \qquad (32)$$

and is constant. At low frequencies the armature resistance alters this simple relation and the torque is reduced unless the voltage V_t is increased above the constant-volts/hertz value (referred to as "voltage boost").

Above rated frequency the voltage is typically held constant at its rated value, and the flux is allowed to decrease [Eq. (6)]. The power capability can be maintained at the rated value for these higher frequencies if the

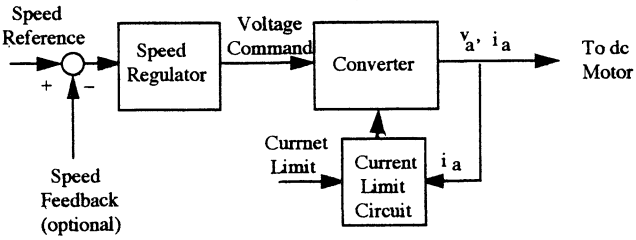

FIG. 20. Adjustable–speed dc drive schematic block diagram.

field current is appropriately reduced so as to maintain the power factor angle between V_t and I_s at a constant value. The synchronous machine thus has a "capability curve" identical to that of the dc machine illustrated in Fig. 18.

6.3.2 Induction-Motor Speed Control. Speed control in induction machines can be attained by varying the frequency and voltage as in the synchronous machine and, to a much more limited extent, by varying only the voltage.

6.3.2.1 Voltage-Controlled Induction-Motor Drives. Voltage variation alters the torque produced at any specific slip in proportion to the voltage squared and thus produces a family of torque–speed curves as illustrated in Fig. 21. Depending on the load torque–speed curve, the equilibrium point where motor torque and load torque are equal will vary with voltage, yielding speed control over a limited speed range. Since the synchronous speed is constant, speed control by voltage variation is really slip control, which results in high rotor I^2R loss as the speed is reduced.

Voltage control is therefore used only for speed control of small induction motors with fan loads in which the torque drops rapidly with speed (as speed squared). These drives are inherently inefficient since they require high-slip operation and are viable only because the rapid drop in torque makes the high percentage loss an acceptably small absolute number. Typically the voltage is controlled by varying the amount of phase delay in series connected TRIACS or back-to-back connected thyristors. This introduces additional losses as a result of the time harmonics in the voltage wave form. Phase control of voltage is also widely used in speed control of single-phase universal motors as in, for example, portable electric drills.

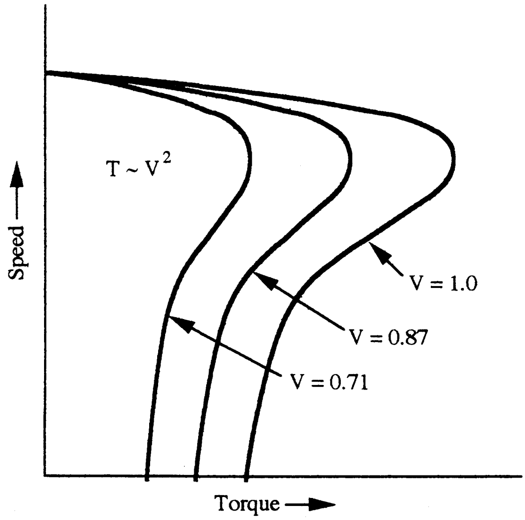

FIG. 21. Torque–speed curves of induction motor for voltage control.

Voltage control, typically via series-connected thyristors in which initiation of conduction is delayed by phase control of the gate voltage, is also used to limit starting current in induction and synchronous motors and for light-load loss reduction in motors subject to variable load cycles. This last application is limited to motors that operate at very light load for long periods, since the voltage controller creates its own loss at all loads and this must be overcome by the reduction of motor core losses at light loads.

6.3.2.2 Adjustable-Speed, Constant-Volts/Hertz Induction-Motor Drives. As in the case of synchronous-machine drives, the synchronous speed of an induction motor can be varied by varying the frequency. Maintaining constant motor flux density to avoid saturation is again accomplished by keeping the ratio of voltage and frequency (volts/hertz) constant. Under this condition the induction machine exhibits essentially the same speed–torque characteristic at all frequencies. This is readily shown by rewriting the resistance R_r'/s in Fig. 8 as $R_r'/s\omega$ times ω and observing that, except for R_s, for a fixed value of $s\omega$ (slip frequency) every element in the circuit is a linear function of ω. By making the voltage vary linearly with ω, the current and torque are independent of frequency for any fixed value of $s\omega$. At very low frequencies (below 5 Hz) the stator resistance becomes significant, and voltage boost (increased volts/hertz) is employed to maintain torque capability. The result is a family of torque–speed curves, as illustrated in Fig. 22, where the various curves are simply translated up or down as the frequency is varied. Operation above base frequency at constant output voltage (and increased values of $s\omega$) allows the flux to decrease and corresponds approximately to the constant-power, field-weakening region of dc drives as illustrated in Fig. 22. The most common system at low and moderate power levels employs a PWM VSI as the variable-

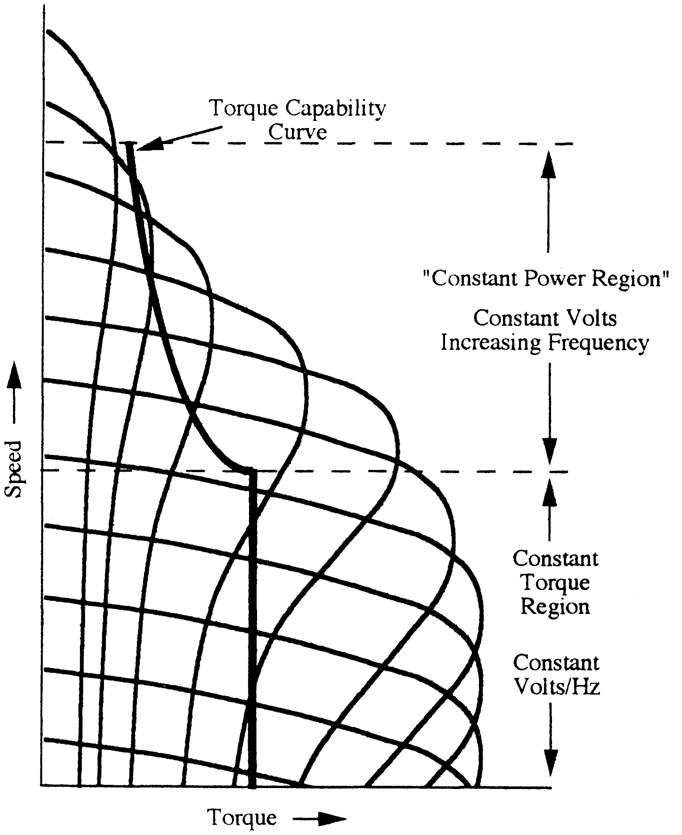

FIG. 22. Capability curves of induction motor for frequency control.

frequency supply. At higher power levels, six-step VSI or CSI inverters fed by controlled rectifiers are used. In the CSI case a voltage feedback loop is necessary to convert the CSI output to a controlled, constant-volts/hertz supply.

Motor starting is accomplished by initially applying a low frequency and slowly ramping up to the desired speed. This is necessary to keep the current within the converter rating. Unfortunately, the proper ramp rate and voltage boost depend on machine parameters and load characteristics, and effective converter utilization during starting is difficult to attain. A variety of control strategies utilizing internal converter variables such as output voltage or current, link dc current, or link power are used to assist under starting conditions or during load or speed changes. However, in the absence of feedback from the motor (speed or flux) these open-loop constant-volts/hertz drives have the fundamental problem of basically appearing as a voltage source to the machine and thus having to cope with the normal constant-voltage properties of the machine.

6.4 Adjustable-Torque, Vector-Controlled ac Drives

Torque control in ac motors is accomplished by emulating the regulated–armature-current dc motor drive (see Sec. 6.2.2). This requires controlling the spatial angle between field flux and armature mmf (leading to the name "field orientation"), which in turn requires control of both amplitude and phase of the ac excitation and leads to the name "vector control."

6.4.1 ac Current Regulators. Most torque controllers use an ac current regulator based on time-domain current feedback and a PWM inverter as shown in Fig. 23, although CSI inverters are also used at high power levels. A variety of schemes for generating the inverter voltage commands in the current regulator

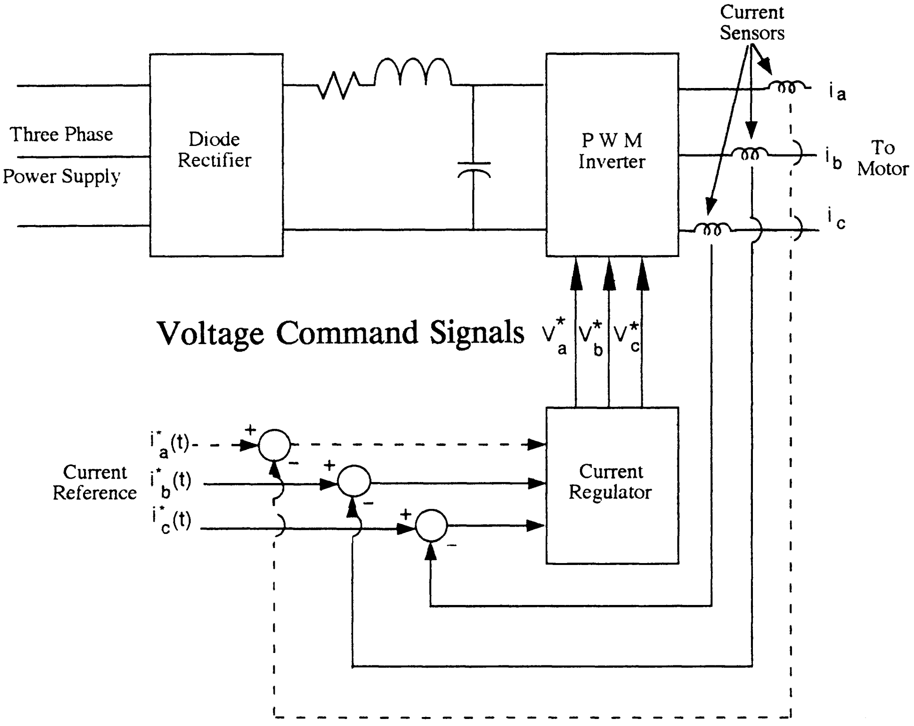

FIG. 23. Current-regulated PWM inverter for "vector control" of ac current.

block of Fig. 23 are employed, with simple on–off control with hysteresis and sine-triangle comparison (natural sampled PWM; see POWER ELECTRONICS) being the most common. The ac current-regulated inverter of Fig. 23 (or its CSI equivalent) allows positioning the machine armature (stator) mmf in space as well as eliminating the effects of armature (stator) resistance, inductance, and back emf as in the dc machine.

6.4.2 Field Orientation. The location of the field flux can be directly determined by measuring rotor position in a synchronous machine but must be estimated from indirect measurements in induction machines. The most common method in induction machines uses rotor position measurement and an estimate of slip frequency to estimate rotor flux position indirectly (indirect field orientation). As illustrated in Fig. 24, the slip estimation depends on the rotor time constant and hence is sensitive to operating conditions. The equation for the slip frequency used in the slip calculator block in Fig. 24 is

$$s\omega = \frac{R_r'}{L_r}\frac{I_T}{I_\phi} = \frac{1}{T_r}\frac{I_T}{I_\phi}, \tag{33}$$

where L_r is the total rotor self inductance, T_r the rotor (open circuit) time constant, I_T the torque command current, and I_ϕ the flux command current. Errors in the time constant cause steady-state flux and torque errors as well as noninstantaneous, usually oscillatory torque response. The sensitivity of the controller to errors in the time constant depends on the inductance-to-resistance ratio of the machine and is therefore more serious in large, high-efficiency machines. In small machines no adaptation to time-constant changes is usually necessary. For large machines a variety of adaptive controllers have been proposed, but the problem remains an area of active research.

For a synchronous machine the slip calculator in Fig. 24 is eliminated since rotor position and rotor flux position are identical (i.e., the slip frequency is zero). Direct field orientation in induction machines, in which the rotor flux position is estimated from flux

estimates obtained from flux coils or from armature (stator) voltage and current, is also used, but is much less common.

Torque-controlled ac drives based on field orientation are fully equivalent to torque-controlled dc servo drives. They offer the advantages of higher torque/inertia ratios, higher operating speed, and lower maintenance since there is no mechanical commutator. These drives can also be built in larger sizes than for dc machines by employing CSI inverters and synchronous motors (drives of several thousand horsepower are not uncommon) and for higher speeds since the limitations of a mechanical commutator are eliminated.

6.4.3 Brushless dc Machines. There are a large number of variants of the torque-controlled synchronous machine described in Sec. 6.4.2 and illustrated in Fig. 24 that are called brushless dc motors. They all follow the basic principle of controlling the spatial angle between flux and mmf, and all utilize some form of rotor position measurement. Most use permanent magnets for field excitation and some form of simplified position sensing using Hall-effect sensors or position estimation based on back emf. In some cases the motor back emf is intentionally caused to be trapezoidal in wave form to allow effective use of limited position-sensing accuracy and to increase the torque per ampere. The most common limitation of many of these machines is high torque ripple.

6.5 Other ac Drives

There are a number of other, less widely applied, ac drives utilizing special types of converters or special motors. For example, very high-power, low-speed applications sometimes employ cycloconverters for direct conversion of line frequency (50 or 60 Hz) to the low frequency needed to drive the machine without an intermediate dc link. Such systems are limited to frequencies below about one-third of the input frequency and utilize a large number of power-switching devices (usually thyristors) with 36 or more devices being common. Because of the complexity of controlling the switching of such systems, they are typically only used at power levels where other types of converters are unavailable because of power-switching–device limitations (for example, for large, high-voltage motors).

Another, somewhat more common, example is the use of a wound-rotor induction motor with a frequency converter feeding the rotor circuits in high-power applications requiring only a small speed-control range (20% to 40% variation). Here the motivation is to be able to use a lower power rating in the converter since it only needs to be rated to handle the slip power (i.e., 20% of the motor rating if only a ±20% speed range about synchronous speed is required), though this advantage must be balanced against the more expensive machine construction.

GLOSSARY

ac: Alternating current—a power source that alternates sinusoidally with time.

Alternator: A device to change mechanical energy to ac electrical energy.

Armature: The member of a machine in which the energy conversion takes place.

Brushless dc Motor: Synchronous motor operating on a dc supply which is converted to ac of variable frequency and voltage by means of electronic controls.

Commutator: Copper bars insulated from each other, mounted on the armature shaft, and connected to armature windings to carry currents, through brushes riding on the smooth cylindrical outer surface of the commutator, to external circuits.

Compound Motor or Generator: A dc motor or generator that has both shunt and series field coils.

Converter: A generic term for a device that alters the nature of electrical energy (for example, changes the frequency).

Diode: A power-switching device which allows current to pass in only one direction.

dc: Direct current—a power source that has a constant polarity of voltage (or current).

Four-quadrant drive: A drive capable of operating the driven machine both as a motor and as a generator and in either direction.

Generator: A device to change mechanical to electrical energy.

Hall-Effect Sensor: A magnetic-field–sensitive semiconductor device used to sense rotor position in electric drives.

Induction Motor: An ac motor in which rotor currents are set up by magnetic induction (often in a squirrel-cage conductor arrangement).

Inverter: A device for converting dc to ac.

Linear Motor: An electric motor providing linear motion rather than rotation.

Motor: A device to change electrical energy to mechanical energy.

Rectifier: A device for converting ac to dc.

Rotor: The rotating member of an ac machine.

Semiconverter: A controlled rectifier in which half of the thyristors are replaced with diodes.

Series Motor or Generator: A dc motor or generator that has the field coils connected in series with the armature.

Shunt Motor or Generator: A dc motor or generator which has the field coils connected in parallel with the armature.

Synchronous Motor or Alternator: An ac motor or alternator that runs at a constant speed dictated by the frequency of the power supply and the number of pole pairs of the machine.

Thyristor: A power-switching device which can be turned on with a small control signal but must have its voltage reversed to be turned off.

TRIAC: A bidirectional device equivalent to two thyristors connected in inverse parallel.

Universal Motor: A motor that will operate on ac or dc.

Volts/Hertz Control: A control strategy that maintains approximately constant magnetic flux in ac machines.

Wound-Rotor Induction Motor: An induction motor in which the rotor circuits are windings as in the stator and are made accessible by slip rings.

INTRODUCTION

Iron ferrite or magnetite was "lodestone" to the ancients. Its magnetic properties were known to the thirteenth-century Chinese, as was its property of pointing to the north (Bai Shouyi, 1982). The stone was ground and shaped into a needle, kept aloft inside a bowl of water by a floating wick, and used for guidance. The resulting compass (see Fig. 1) is the first example of a magnetic device. The torque exerted on the compass needle is the result of the action of the Earth's magnetic field on the ferrite. It exemplifies the two elements that define a "magnetic device": an element using the measurement of the intensity or direction of a magnetic field, or an element using a magnetic material.

This article is organized in the following way. The principles of operation of magnetic field-measuring devices, such as magnetoresistors, Hall generators, magnetodiodes, and magnetotransistors, are described, as well as some integrated circuits that use them. Also described are pickup coils, and fluxgates that are used in compasses. A special paragraph is included in which the performance of the different sensors is compared. A second section is devoted to applications of magnetometers. Magnetic field-measuring devices are used in compasses and attitude detectors, in magnetic recording heads (see also MAGNETIC STORAGE OF INFORMATION), in position and speed sensors, in rotary encoders, in contactless potentiometers, in dc current measurements, and in scientific instrumentation.

Microwave devices, such as filters, phase shifters, isolators, and circulators, use ferrimagnetic resonances in ferrites and garnets. Other ferromagnetic or ferrimagnetic materi-

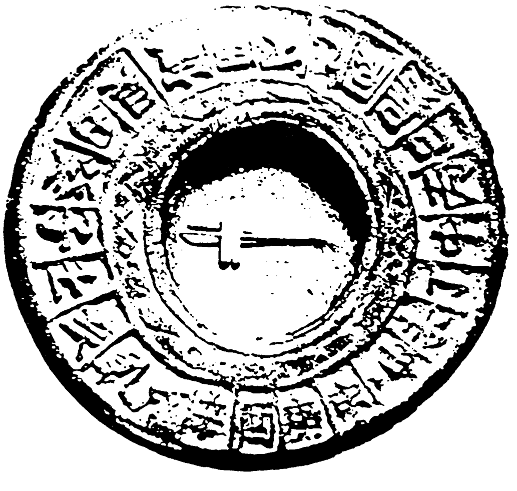

FIG. 1. A Song dynasty compass in the collection of the Museum of Chinese History, Beijing (from Bai Shouyi, 1982).

als are used in antenna cores, inductors, or even simple electromagnets. These devices are described.

Magnetic materials are also used in electrical machinery (see MACHINES, ELECTRICAL), transformers and inductors, thermometry (see MAGNETOTHERMAL DEVICES), and magnetic lenses (see MAGNETOELECTRICAL DEVICES). The reader is referred to the appropriate articles.

Recent developments in microelectronic technology have revolutionized the fabrication techniques of magnetic devices and broadened the range of useful applications. Even pickup coils can be made using thin-film technology. Magnetic field sensors with on-chip integrated amplifiers and signal conditioners are sensitive, reliable, and inexpensive, and have made magnetic position detection a practical reality. Microwave circuit elements, including gallium arsenide (GaAs) amplifiers, are integrated on semiconductor chips called monolithic microwave integrated circuits (MMICs). Soon magnetic circuit elements will be integrated (Prinz, 1990) directly in MMICs, thus lowering their cost and opening new fields of applications.

I have attempted to describe the physical principles of operation of the devices by using simplified schematic outlines. The reader can find more detailed descriptions and mathematical formulation in the references.

1. MAGNETIC FIELD SENSORS

1.1 Galvanomagnetic Effects in Semiconductors

The fundamental principles of galvanomagnetic effects are discussed in the articles ELECTRONIC TRANSPORT IN SOLIDS and TRANSPORT PHENOMENA. In this section I point out the difference between the intrinsic magnetoresistance that many electrically conductive materials exhibit and the geometrical magnetoresistance effects that are the basis of magnetoresistive sensing elements (Heremans, 1993).

Electrons or holes moving under an electric field **E** and a transverse magnetic field **H** are subject to the Lorentz force **F** proportional to the velocity **v** of the carrier and the magnetic induction **B**:

$$\mathbf{F}=\pm e(\mathbf{v}\times\mathbf{B}), \tag{1}$$

where $e=1.6\times10^{-19}$ Coulomb; the + sign is used if the carriers are holes, and the − sign if they are electrons. The Lorentz force is exerted at right angles to both **v** and **B**. As a consequence, the path of these charge carriers, or the current density vector **j**, is not collinear with the applied electric field. The angle θ between **j** and **E** is the Hall angle. Consider the case of a slab of semiconductor, of length l, width W, and thickness t along the x, y, and z directions, respectively, as shown in plan view in Fig. 2. An applied voltage V_{xx} forces a current I through the slab. A magnetic field **H** is applied normal to the plane of the slab, and the induction is **B**. The Lorentz force will distort the current lines close to the injecting contacts. Some distance along the x axis into the slab, there is an accumulation of charge carriers to one side of the slab. This results in the generation of a transverse voltage, the Hall voltage, V_{xy} in Fig. 2. In a slab of arbitrary length and width, the current lines follow the paths shown in Fig. 2. Conformal mapping techniques are used to calculate these lines (Lippmann and Kuhrt, 1958). If the slab is long enough, the transverse, or Hall, electric field balances the Lorentz force, and the current lines become parallel to the side of the sample along the x axis. In an infinitely long slab (not shown in Fig. 2) the electric fields associated with V_{xx} and V_{xy} are

$$E_x=V_{xx}/l, \tag{2}$$

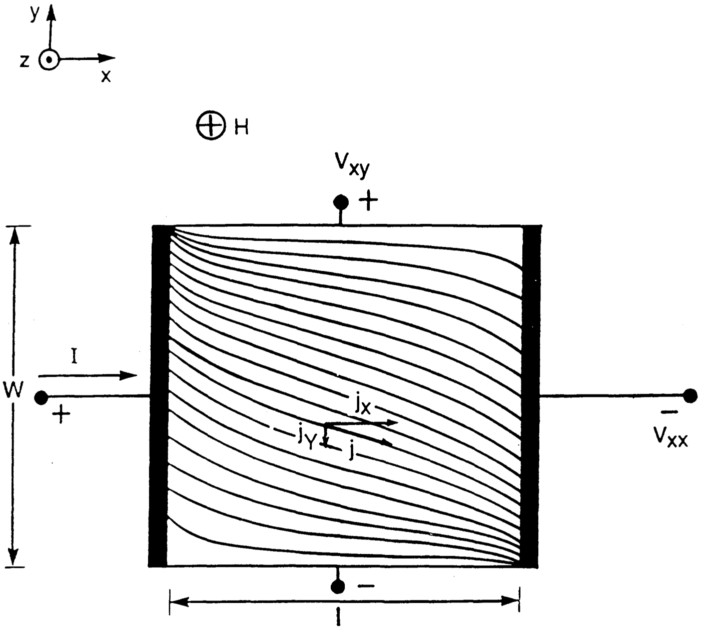

FIG. 2. Projection of a slab of semiconductor with current density (j) lines flowing between the two current electrodes (dark regions) in the presence of a magnetic field H pointing into the plane of the slab. The total current flowing is I, V_{xx} is the longitudinal voltage, and V_{xy} is the transverse, or Hall, voltage.

$$E_y = V_{xy}/W, \tag{3}$$

and the current density is mostly parallel to x:

$$j \simeq j_x \simeq I/Wt. \tag{4}$$

This geometry is commonly used to make resistivity and Hall effect measurements on materials, since these intrinsic material properties are then easily defined. The resistivity is

$$\rho_{xx} = E_x/j = (V_{xx}/I)(Wt/l). \tag{5}$$

The Hall resistivity is

$$\rho_{xy} = E_y/j = (V_{xy}/I)t \tag{6}$$

and the Hall coefficient is

$$R_{\mathrm{H}} = \rho_{xy}/B. \tag{7}$$

In a homogeneous, nonmagnetic material, with a single type of charge carrier, R_{H} is a constant related to the density n of these carriers by

$$R_{\mathrm{H}} = \pm 1/ne, \tag{8}$$

where the + sign is used if the carriers are holes, and the − sign if they are electrons. The resistivity ρ_{xx} is then given by

$$\rho_{xx} = 1/ne\mu, \tag{9}$$

where μ is the carrier mobility. The Hall angle is then θ, where

$$\tan\theta = \mu B. \tag{10}$$

If, furthermore, the carrier's Fermi surface is isotropic, the resistivity ρ_{xx} is independent of B. All the conditions needed for this are almost never met, and most materials have a dependence of ρ_{xx} on B that contains information about the physics of the electrical transport in that material. This is the *intrinsic magnetoresistance* and has a different origin than the geometrical magnetoresistance used in sensors.

The Hall angle can become large even in moderate magnetic fields if the mobility of a semiconductor is very large. In a rectangularly shaped slab of semiconductor, shown in Fig. 3, with $l \ll W$, there is not much length available for the current lines to become parallel to the x axis, and the current lines are similar to what they are near the contacts in Fig. 2. The current path in such a short, wide sample is considerably longer than in the same sample at zero magnetic field. This leads to a large increase in resistance $R = V_{xx}/I$. It is the *geometrical magnetoresistance* effect. The Hall voltage is not fully developed and does not counteract the Lorentz force effectively. The Corbino disk (Fig. 3) is another geometry in which the Hall voltage is shorted out and a large geometrical magnetoresistance is observed. Conformal mapping techniques can show that the Corbino disk is equivalent to an

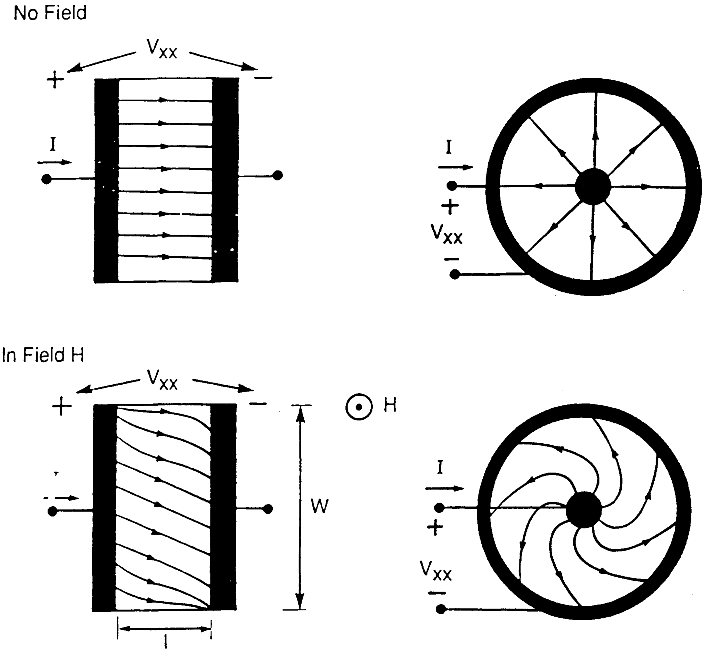

FIG. 3. Elements showing the geometrical magnetoresistance effect. A short, wide rectangle, at left, can be viewed as consisting only of the regions close to the contacts in Fig. 2. In absence of an applied magnetic field *H*, the current lines are normal to the contacts, but in presence of the field, they distort as shown, leading to an increase in current path length and resistance. In the Corbino disk at right, the current lines are radial in the absence of field, but lengthen as shown in the presence of field.

infinitely wide or short rectangular element, in which the Hall voltage is totally shorted out, and the geometrical magnetoresistance is maximal. The resistance of the device is then

$$R(B)=R(B{=}0)\,[1+(\rho_{xy}/\rho_{xx})^2]\times[\rho_{xx}(B)/\rho_{xx}(0)].$$

In practical devices, Corbino disks are not used, because they have a low resistance, which leads to a large power dissipation. Most devices are made from rectangular elements such as shown in Fig. 3 (left). The response of such elements is then given by

$$R(B)=R(B{=}0)\,[1+g(W/l)(\rho_{xy}/\rho_{xx})^2]\times[\rho_{xx}(B)/\rho_{xx}(0)] \tag{11}$$

or, under the conditions under which Eqs. (8) and (9) hold, and for small Hall angles $\theta<\frac{1}{8}\pi$, or $\rho_{xy}/\rho_{xx}<0.2$,

$$R(B)=R(B{=}0)\,[1+g(W/l)\mu^2B^2]\times[\rho_{xx}(B)/\rho_{xx}(0)]. \tag{12}$$

In these equations, the factor $\rho_{xx}(B)/\rho_{xx}(0)$ accounts for the intrinsic magnetoresistance, while the factor $g(W/l)$ accounts for the geometrical influence of the width-to-length ratio and is given in Fig. 4.

1.2 Semiconductor Magnetoresistors

Practical magnetoresistive devices are made out of high-mobility semiconductors, such as *n*-type InSb or InAs, because the device sensitivity is essentially a quadratic function of mobility [see Eq. (12)]. Unfortunately, these are also narrow-gap semiconductors, in which the carrier density is a strong function of temperature at room temperature. To compensate for this, manufacturers dope the semiconductors *n*-type. This technique has two disadvantages:

1. In most semiconductors, the mobility de-

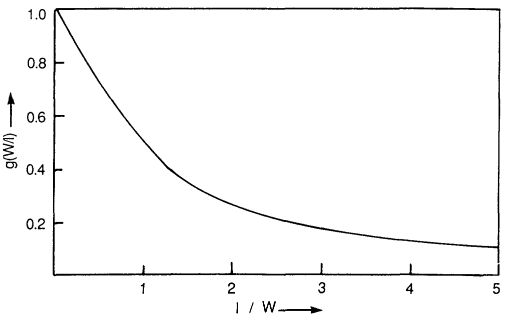

FIG. 4. The geometrical coefficient *g*(*W*/*l*) that relates the geometrical magnetoresistance to the length/width (*l*/*W*) ratio of a rectangular element (Lippmann and Kuhrt, 1958).

creases as the doping level is increased, because of scattering of electrons by ionized impurities, and

2. when both the electron density and the electron mobility are high, the electrical conductivity is also high.

In order to keep current consumption and heat dissipation low, the ideal resistance of a magnetoresistor is in the 500- to 10 000-Ω range. Given the high conductivity of the active semiconductor used, obtaining such high device resistances requires the use of very thin slabs or films of semiconductor. Recent breakthroughs in growing thin InSb and InAs films epitaxially on insulating III-V substrates, by molecular-beam epitaxy and metal-organic chemical vapor deposition (Partin and Heremans, 1992), have made thin-film magnetoresistors very practical. Devices are made by connecting multiple rectangular elements in series (Fig. 5) to increase the resistance. The magnetoresistor shown in Fig. 5 was described by Heremans *et al.* (1993); its resistance is shown in Fig. 6 as a function of applied magnetic field at different temperatures.

The recent use of two-dimensional electron gases (see HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR) in magnetoresistors has made it possible to achieve the best compromise between high electron density and high mobility, while maintaining a reasonably large resistance per device (Heremans *et al.*, 1990). Devices based on two-dimensional electron gases have so far been limited to InAs, and work is under way to extend this to InSb-based magnetoresistors.

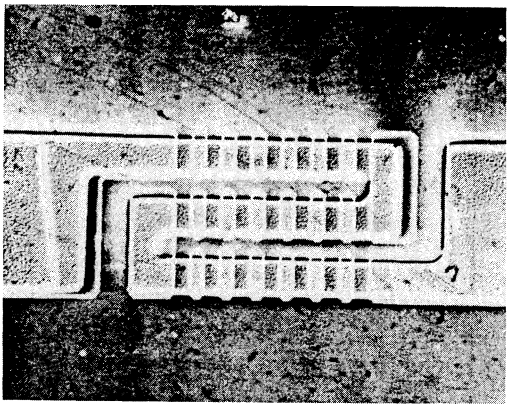

FIG. 5. A multielement magnetoresistor made from an InSb mesa etched from an epitaxial film of InSb on InP. Each rectangular element not covered by the contact metal behaves as one element described in Fig. 3.

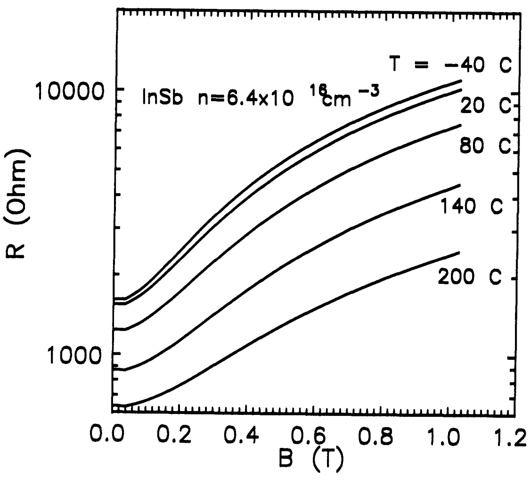

FIG. 6. The resistance of a magnetoresistor made from *n*-type InSb doped at 6.4×10^{16} cm^{-3}, as a function of applied magnetic field at the different temperatures indicated (Heremans *et al.*, 1993).

Siemens AG uses a different manufacturing process based on InSb boules that contain needlelike precipitates of metallic NiSb. The metallic needles serve the same purpose as the lateral contact stripes in the device shown in Fig. 5: they short out the Hall voltage, so that a large magnetoresistance appears. Devices are made from the boules by slicing wafers and lapping them to the desired thickness (Göpel *et al.*, 1989).

1.3 Hall Generators

The Hall voltage itself is commonly used to measure the magnetic field. Hall generators are often made in the geometry shown in Fig. 2. The Hall resistance for an infinitely long slab is defined by

$$R_{xy} = V_{xy}/I = \rho_{xy}/t. \tag{13}$$

The Hall resistance of a generator made from a material for which Eq. (7) holds is

$$R_{xy} = B/net. \tag{14}$$

A four-terminal device analysis (Heremans, 1993) of a Hall device (Fig. 2) shows that the ratio of the power output ($V_{xy}I_{\text{out}}$, where I_{out} is the current drawn from the Hall electrodes) to the power input ($V_{xx}I$) is almost proportional to the mobility of the semiconductor. Equation (14) shows that the output of a Hall generator is linear in the applied magnetic field, and that the most sensitive devices are made from thin, lightly doped slabs of material. Again, the best compromise between sensitivity, temperature stability, and moderate current consumption is obtained when Hall generators are made from thin doped slabs of high-mobility semiconductors. Two-dimensional electron gases are very well suited, but not widely used yet.

Silicon Hall generators (Popovic, 1991) can be made using an inversion layer in a metal-oxide-semiconductor (MOS) structure. Hall devices also can be made by ion-implanting of an *n*-type doped region of the desired geometry into *p*-type or semi-insulating GaAs, or *p*-type Si. Sometimes, *n*-type epitaxial Si, GaAs, or InAs grown on *p*-type or semi-insulating substrates is used. A mesa of the desired geometry is etched into it and equipped with current and voltage contacts. Thin lapped layers of InAs or InSb are sometimes used. Silicon is the preferred semiconductor for room-temperature applications that are very cost sensitive and do not require operation above 10 kHz, because amplifying and signal-processing electronics can be integrated on the same chip as the Hall sensor. *n*-type channels or implanted regions are preferred, since the electron mobility is larger than the hole mobility in Si. In applications in which a substantial current is to be drawn from the sensor's output, InAs- or even InSb-based sensors are used, because of their better power efficiency. InAs and InSb Hall sensors are also preferred in metrology applications or when high signal-to-noise ratios are desired. GaAs is used in some high-temperature applications. Figure 7 shows the output of an ion-implanted GaAs Hall generator (Siemens KSY-10). The ordinate is the Hall resistance, i.e., V_{xy}/I, the ratio of the output voltage to the input current. This device is quite stable with respect to temperature in the range from −40 to 160 °C. GaAs integrated Hall sensors for high-temperature applications are also being developed (Itakura *et al.*, 1989).

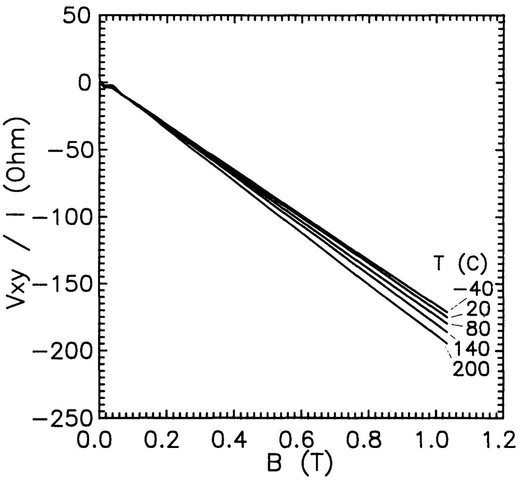

FIG. 7. Ratio of the Hall voltage to the input current, for a GaAs Hall sensor (Siemens KSY-10) made by ion implantation, shown as a function of magnetic field and temperature (after Heremans, 1993).

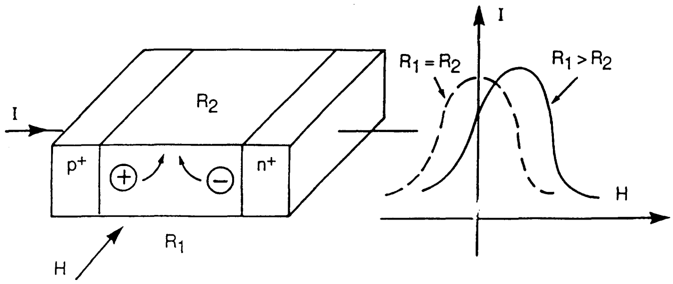

FIG. 8. A magnetodiode, made from a slab of lightly doped semiconductor sandwiched between heavily doped *n* and *p* regions. The surfaces of the lightly doped region have different recombination rates R_1 and R_2. The longitudinal voltage applied to the diode in forward biasing injects both electrons and holes in the lightly doped region. In presence of a magnetic field, the Lorentz force pushes both types of carriers in the same direction. The magnetic field *H* can push the carriers either toward the high-recombination-rate surface, in which case the current decreases, or toward the low-recombination-rate surface, and then the current is increased. The current versus field relation under a given bias is schematically given at right (after Cristoloveanu *et al.*, 1983).

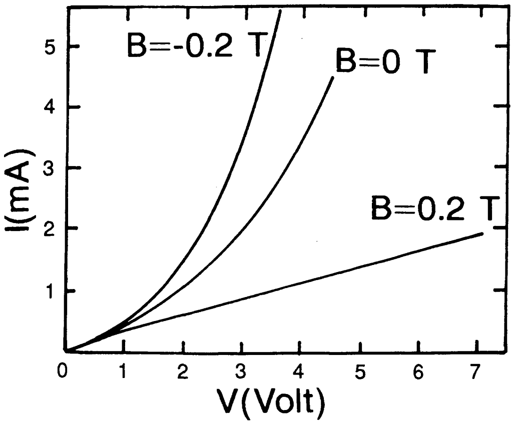

FIG. 9. Magnetic field dependence of the current-voltage characteristics of a Ge magnetodiode (after Yamada, 1968).

1.4 Magnetodiodes

Magnetodiodes (Cristoloveanu *et al.*, 1983) are *p-i-n* diodes, schematically represented in Fig. 8. They consist of an intrinsic region, contacted to a heavily *n*-type region on one side and a heavily *p*-type region on the other. The magnetodiode differs from a simple *p-i-n* diode because one of its lateral faces has been treated to form a surface at which electrons and holes have a high recombination rate R_1. This treatment can be mechanical abrasion or damaging by ion implantation. Some magnetodiodes exploit the high recombination rates at the silicon/sapphire interface. The other face is made as nearly perfect as possible, by etching for instance, to keep the recombination rate R_2 low. When the diode is forward biased, and a current I flows as shown in Fig. 8, electrons are injected from the n^+ electrode into the intrinsic region, and holes from the p^+ region. In the presence of a magnetic field H oriented as shown, the Lorentz force acting on both types of carriers pushes them in the same direction, because the Lorentz force is sensitive to the sign of the charge of the carrier; see Eq. (1). If the carriers are deflected by the magnetic field toward the face with a high recombination rate R_1, they recombine there, and the current flow is impeded. If they are deflected toward the other face, much less recombination takes place and more current flows. Current-voltage characteristics of a Ge-based *p-i-n* diode at room temperature at different field values are shown in Fig. 9. Sensitivities can be up to 1000 times higher than those of Hall generators made from similar materials. Discrete magnetodiodes have been made from Ge, Si, GaAs, silicon-on-sapphire, and CMOS technology (Baltes and Popovic, 1986).

1.5 Magnetotransistors

Many geometries have been used to exploit the influence of the Lorentz force on the flow of charge carriers in transistors. For a more complete review, the reader is referred to Baltes and Popovic (1986). Magnetotransistors can be made as FET transistors with two drains, or as bipolar transistors with two collectors. The applied magnetic field distorts the current lines and favors current flow into one of the two collectors or drains.

A dual-drain Si magnetic FET is shown in Fig. 10. A magnetic field normal to the chip plane causes a deflection of the current lines toward one of the two drains, as is shown in Fig. 11. Complementary magnetic FETs can be made using CMOS technology, and consist of a dual-drain *n*-channel device and a dual-drain *p*-channel device. The gate electrode voltage does not need to be varied during

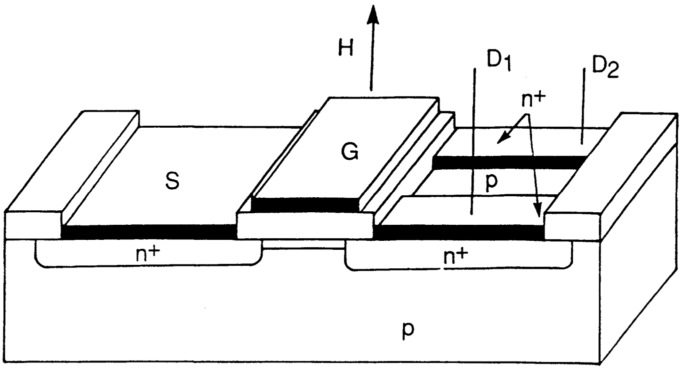

FIG. 10. Two-drain (D_1 and D_2) magnetic FET transistor. A magnetic field H exerts a Lorentz force that pushes the electrons from the source (S) preferentially toward one of the drains. The resulting current imbalance is a measure of the field H. The gate is labeled G (after Baltes and Popovic, 1986).

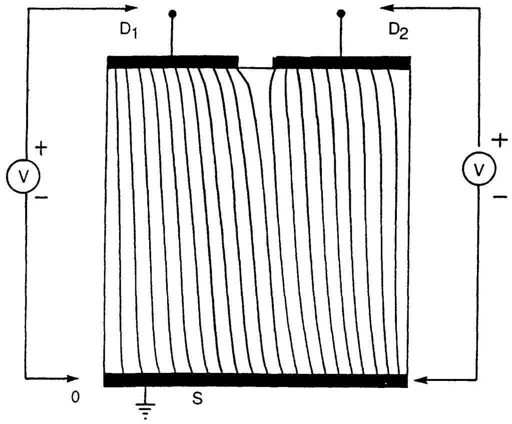

FIG. 11. Current density lines in a two-drain magnetotransistor as shown in Fig. 10 (after Baltes and Popovic, 1986).

operation; its only purpose is to create a channel of the desired surface density. In that sense, these devices are not strictly transistors. InAs tends to have a natural accumulation layer of electrons at its interface with air. Three-terminal magnetic field sensors with geometries similar to those in Fig. 10 can be etched as mesas into epitaxial layers of InAs grown on insulating GaAs, and no gate electrode is necessary (Heremans *et al.*, 1992). Similarly, GaAs/AlAs interfaces with active two-dimensional electron gases have been used by Nathan *et al.* (1990). In dual-drain magnetic FETs, the useful output voltage is measured as a voltage drop between load resistors connected to the drains; see Fig. 12.

Bipolar transistors can be designed to be sensitive to magnetic fields in different ways: some transistors have field-dependent current gains; others are designed with dual collectors. They can be made vertically or horizontally. The magnetic field can be designed to act in three different ways:

1. The Lorentz force can act on the minority carriers in the base region, or in the base-collector depletion layer, or in the low-doped collector region itself.
2. The Hall voltage can be designed to deflect the majority carriers in the base region.
3. The Lorentz force can act on both types of carriers, which then will adjust their concentration to maintain space-charge neutrality at each point.

In general, all three effects coexist to some degree. A *pnp* double-collector magnetotransistor with large sensitivity was described by Popovic and Baltes (1983). A schematic of the device is shown in Fig. 13. The output voltage is the differential voltage obtained between two load resistors connected to the two bases; see Fig. 12. The device in Fig. 13 has an emitter purposely designed with a low efficiency. The magnetic field operates on the majority-carrier current in the base (effect **2**), yielding a larger Hall field than if the Lorentz force were operating on the minority carriers alone. The base region is surrounded by a deep diffusion ring, which confines the base current to a thin slab perpendicular to the direction of the magnetic field.

Magnetotransistors can achieve sensitivities $(dI_C/dB)/I_C$ (I_C is the collector current in Fig. 12) as high as 4 T^{-1}. This seems superior to those of Si-based Hall plates, but such bipolar magnetotransistors require high base currents. When the sensitivities of existing magnetotransistors, bipolar or FET-like, are calculated including the sum of all currents, they are similar to those of Hall generators. Given the large variety of effects involved in

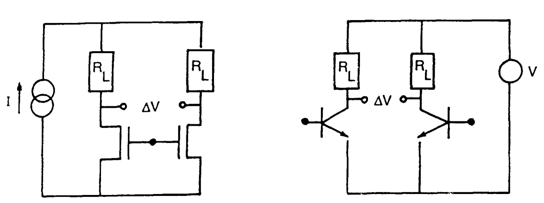

FIG. 12. The output of dual-drain FETs (left) and of bipolar magnetotransistors (right) is a current imbalance, which translates as a voltage ΔV across load resistors R_L in these diagrams.

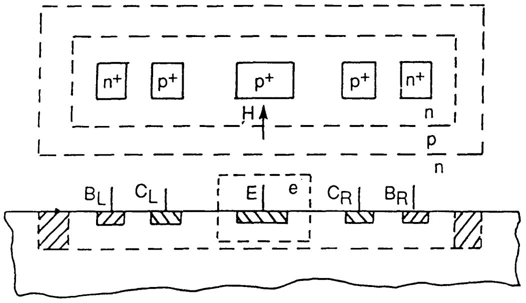

FIG. 13. Double-collector magnetotransistor. The magnetic field *H* modulates the ratio of the currents between the emitter (*E*) and each of the collectors (C_L at left and C_R at right). A diffusion ring (dashed line) confines the current. The base contacts are B_L and B_R (after Popovic and Baltes, 1983).

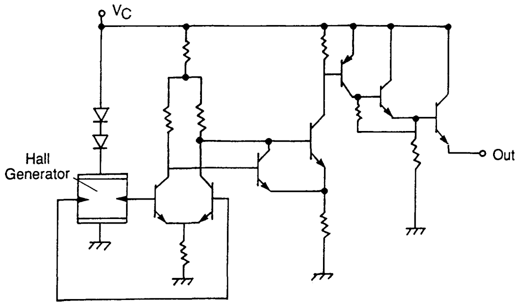

FIG. 14. Schematic diagram for an integrated silicon Hall element with amplifier (after Nakamura and Maenaka, 1990).

magnetodiode and magnetotransistor operation, these devices still have a large potential for optimization (Nathan *et al.*, 1989).

1.6 Integrated Semiconductor Magnetic Field Sensors

Silicon Hall generators are mostly used with on-chip amplification and signal-conditioning electronics. A simple circuit, used in solid-state keyboards (Nakamura and Maenaka, 1990), is shown in Fig. 14. Most integrated magnetic field sensors are rather simple combinations of the sensor with an amplifier and, when hysteresis is desired, with a latching circuit. The voltage output of a Si-based Hall generator is usually low, especially when small current consumption is also a design requirement. This implies that high-gain amplifiers must be used, with limited bandwidth. Hall generators also give a differential output, which often has to be converted to a single-ended output. For high-temperature applications, such as many automotive ones, GaAs sensors with integrated electronics are being developed (Itakura *et al.*, 1989).

InAs- or InSb-based magnetoresistors grown on an insulating GaAs substrate, in which the amplifiers and signal conditioners can be integrated, become very competitive with GaAs Hall generators, because they generate ten times higher output voltage in moderate magnetic fields (see Sec. 1.11, Comparison of Magnetic Field Sensors). Magnetoresistors give a single-ended output voltage with an offset bias.

Magnetotransistors can readily be integrated. Complementary pairs of magnetic FETs can be incorporated into a configuration reminiscent of a CMOS differential amplifier, shown in Fig. 15. Each of the usual two complementary MOS transistor pairs is replaced by the corresponding magnetic FET. Their drains are cross-coupled. When a magnetic field is applied perpendicularly to the plane of the devices, the current in one drain of one transistor increases, while the current in the drain of the other transistor connected to it decreases. The gain built into the circuit is such that small imbalances in the drain currents lead to large output-voltage variations. This circuit converts the differential output of the magnetic FET into a single-ended, amplified signal. The bipolar dual-collector magnetotransistor shown in Fig. 13 can be integrated using standard analog bipolar technology (Maenaka *et al.*, 1990).

1.7 Ferromagnetic Metal Film Magnetoresistors

The electrical resistance of certain ferromagnetic alloys is anisotropic in a magnetic field (see MAGNETIC ORDERING IN SOLIDS; MAGNETIC MATERIALS). The theoretical background

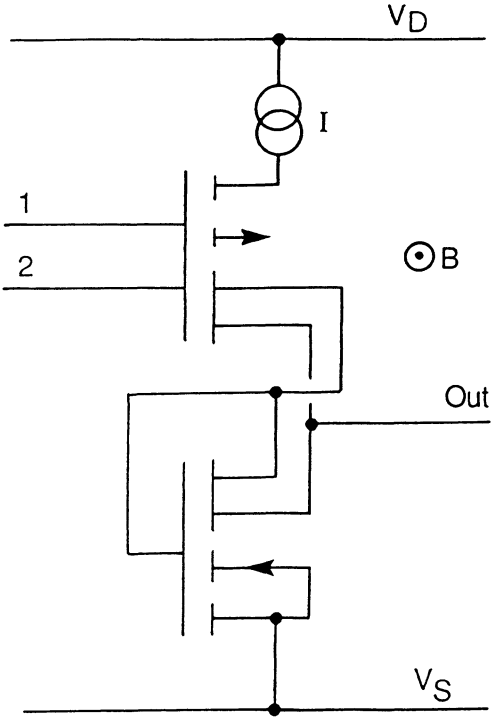

FIG. 15. Two complementary dual-drain magnetic-field effect transistors integrated with a conventional CMOS differential amplifier (after Baltes and Popovic, 1986).

for this effect is summarized by McGuire and Potter (1975). In a film of a ferromagnetic metal thin enough to be single-domain, the magnetic moment vector tends to lie in the plane because of the large demagnetization factor. The electrical resistivity measured when the current-density vector is parallel to the magnetic moment, $\rho_{\parallel}$, is different from the resistivity measured with the current perpendicular to the moment, $\rho_{\perp}$; see Fig. 16. This experimental fact has been explained by an anisotropy in the scattering of the electrons (Campbell *et al.*, 1970).

The anisotropy in the magnetoresistance of Permalloys ($Ni_{1-x}Fe_x$, $x \sim 0.2$) is used to make magnetoresistors (Dibbern, 1986). These devices are made from thin films because the electrical resistance of thin-film devices is higher than that of bulk samples, which keeps the current consumption low. A thin layer can also be made to behave like a single magnetic domain. Its magnetization with no external field applied has one single, well-defined direction in the plane, called the easy axis, also introduced during manufacture. A conceptual diagram of a device is shown in Fig. 17. There is an angle θ between the direction of current flow and the direction of the magnetization **M** along the easy axis. As an external magnetic field **H** is applied to the sample, the direction of the magnetization **M** is rotated away from the easy axis, and the angle θ changes. Since the resistivity along the magnetization direction is $\rho_{\parallel}$, different from that perpendicular to **M**, $\rho_{\perp}$, the total resistance of the film becomes a function $R(H)$ of the applied field H, via the dependence of $\theta(H)$ and $\rho_{\perp}$ on H:

$$R(H) = (l/Wt)[\rho_{\perp} + (\rho_{\parallel} - \rho_{\perp})\cos^2\theta]. \qquad (15)$$

Several techniques exist to linearize the output of these sensors; see Dibbern (1986). Ferromagnetic magnetoresistor sensors are best suited to the measurement of low fields, because they are not sensitive at fields above the saturation field of the layer.

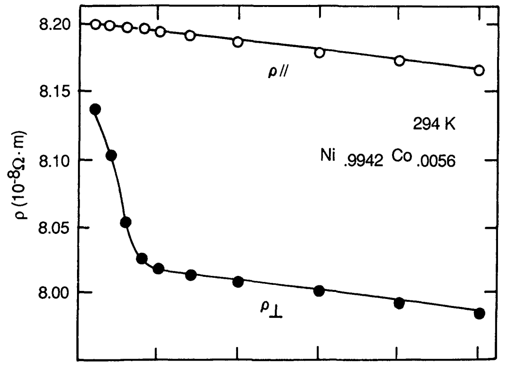

FIG. 16. Magnetoresistivity of Ni-Co at room temperature as a function of field, applied parallel ($\rho_{\parallel}$) or perpendicular ($\rho_{\perp}$) to the easy axis of magnetization (after McGuire and Potter, 1975).

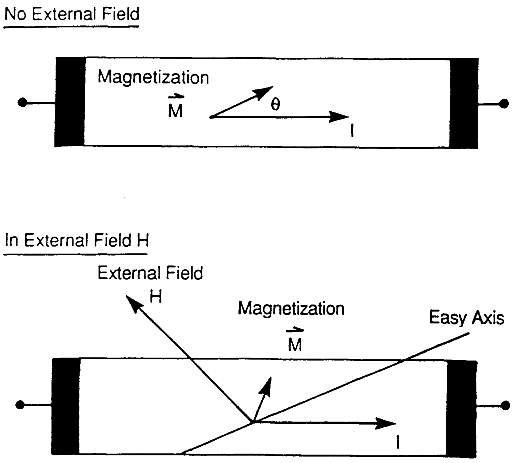

FIG. 17. Magnetoresistor made from a thin film of Permalloy. In the absence of field (top), the current makes an angle θ with respect to the magnetization **M**, which lies along the easy axis. An in-plane applied field **H** (bottom) rotates the magnetization **M**. The anisotropy in the magnetoresistivity shown in Fig. 16, and the fact that the angle between current *I* and moment **M** is influenced by the field, lead to a change in resistance of the strip (adapted from Lenz, 1990).

A recent development, which may force a reassessment of the previous statement, is the discovery of giant negative magnetoresistance in Fe/Cr superlattices (Baibich *et al.*, 1988) consisting of alternating layers of magnetic and nonmagnetic metals. The magnetic moments of adjacent magnetic layers can be spontaneously aligned either ferromagnetically or antiferromagnetically, depending on the thickness of the layers. When the magnetic layers are aligned antiferromagnetically, the resistance of the structure is greater than when they are aligned ferromagnetically, because of the interplay between the spin dependence of the scattering and the magnetic orientation in the structure. An external magnetic field can change the magnetic orientation of the layers with respect to one another, and thus change the resistance of the multilayers (Barthelemy and Fert, 1991). Relative changes in resistance of 50% at applied fields of 2 T have been reported, and are shown in Fig. 18. To date, no publications have appeared describing the use of this effect in sensors, but that is likely to change. The large saturation field H_S for the Fe/Cr system is a disadvantage for sensor applications, but other systems, such as Co/Cu (Mosca *et al.*, 1991), offer better sensitivity. Also recently discovered are giant magnetoresistive effects in metal multilayers that are not magnetically coupled (Dieny *et al.*, 1991), and these too may lead to future devices.

1.8 Variable-Reluctance Sensors

This type of sensor is based on the measurement of the current induced in a coiled conductor, which is proportional to the rate of change of the magnetic flux through the coil (Göpel *et al.*, 1989, Chap. 6). A core of high-permeability magnetic material can be inserted in the coil to gather the surrounding magnetic flux. An example of such a sensor, implemented with thin-film technologies and used in a magnetic recording head, is shown in Fig. 19. The simplest output of such a device is a voltage or a current appearing between the coil end contacts as the magnetic flux through the coil is varied with time. In the example of Fig. 19, a magnetic recording medium passes over the gap (see the next section), and closes the magnetic loop that is coupled to the search coil. The sensitivity of such sensors depends on the permeability of the core material, the area of the coil, the number of turns, and the rate of change of the magnetic flux through the coil. The core material's desired properties include a high permeability for optimal sensitivity, but also a large saturation field, so that large fields can be used in the gap. A small coercivity, low hysteresis losses, and a low magnetostriction are desired to minimize noise. The core material should also have a small but nonzero uniaxial anisotropy so that the domain structure is controllable, and a high electrical resistivity to minimize eddy-current losses. The most used materials are Permalloys (Ni-rich NiFe alloys), and newer materials are being developed such as FeAlSi, Fe/C or Ni/Fe superlattices, and other materials described by Jagielinski (1990). The frequency response of search-coil sensors is limited by the ratio of the coil's inductance to its resistance, though the capacitance between the windings also can be a limiting factor. Their useful range is typically from 1 Hz to 1 MHz. The low-frequency limit implies that variable-reluctance sensors cannot be used as steady-

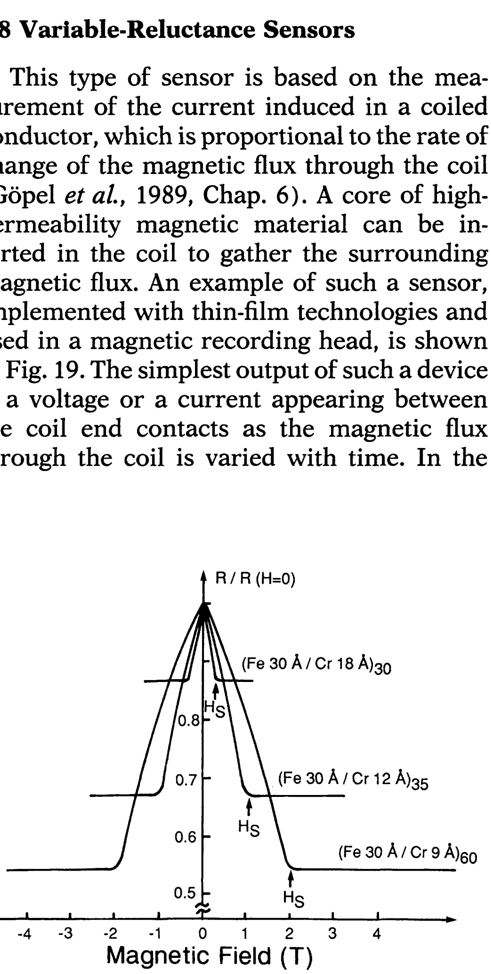

FIG. 18. Relative change in resistance of Fe/Cr multilayers as a function of magnetic field, at 4.2 K. The thicknesses of the individual layers (in Å) are given in the figure, along with the number of layers. The magnetoresistance saturates at a field H_S, but the effect persists to room temperature (after Baibich *et al.*, 1988).

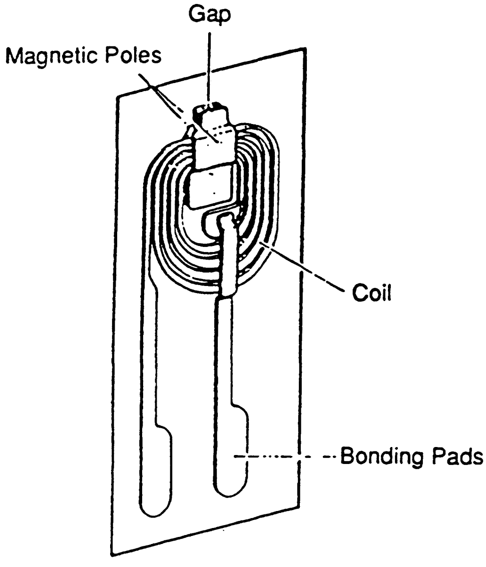

FIG. 19. Inductive head for magnetic recording/readout, made using thin-film technology (after Jagielinski, 1990).

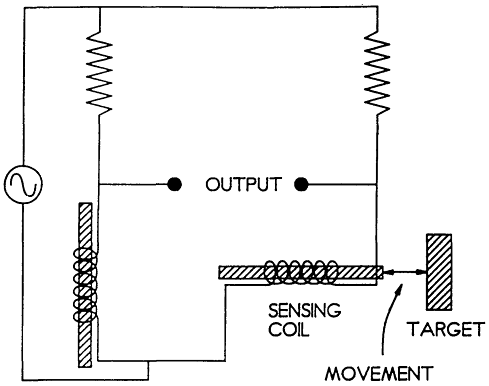

FIG. 20. Search-coil magnetometer in an inductive bridge. Movement of the ferromagnetic target changes the inductance of the coil at right, and unbalances the bridge.

state magnetometers, or in position- sensing applications. They can, however, detect field changes as small as 10^{-10} T.

Another possible way to obtain a readout from a search-coil magnetometer is to measure the coil's inductance, which will change as the magnetic circuit around the coil is changed, for instance by the proximity of a target made from ferromagnetic metal (see Fig. 20). There are two typical readout circuits used to do that. In the circuit shown in Fig. 20, the coil is one leg of a balanced inductive bridge, and the output voltage of the bridge measures the change of inductance of the coil. The coil also can be incorporated in an oscillating circuit, in such a way that a change in inductance results in a change in resonant frequency of the oscillator. These "active" search coils can be used in true position sensors.

1.9 Fluxgates

Fluxgates are often used in compasses. They exploit the magnetic hysteresis exhibited by ferromagnetic materials. They typically consist of cores of a high-permeability ferromagnet, such as Permalloy, each equipped with two coils (Geyger, 1954). There are many types of possible configurations, but only one will be described here (see Fig. 21), built around two rods of a ferromagnetic material. The long thin geometry of the rods is designed to concentrate the flux Φ from the external magnetic field **H**, which is the quantity to be measured. A sinusoidal ac current is applied to the primary windings W'_p and W''_p, which are connected in series but generate magnetic fluxes of opposing polarity in the rods. There are two secondary windings W'_s and W''_s, connected in series as shown. A third coil can eventually be added to supply a dc current I_{dc}. The primary coils are driven so that the core is saturated at each half-cycle of the current. Figure 22 shows very schematically how the voltages induced in W'_s and W''_s are not sinusoidal at frequency f, but clipped. With no external flux Φ or dc current I_{dc}, the voltages V'_s and V''_s induced in W'_s and W''_s cancel each other identically. When an external dc flux Φ or a dc current I_{dc} is applied, the voltages induced in the secondary coils become asymmetrical. A voltage consisting largely of even harmonics of f appears at the output of the two secondary coils. The voltage $V'_s + V''_s$ can be detected by an amplifier locked in at a frequency $2f$. The output can be used as a measurement of Φ, and is sensitive to the polarity of Φ. The dc coil can eventually be used to balance the external field, and the fluxgate is then used as a null detector. The

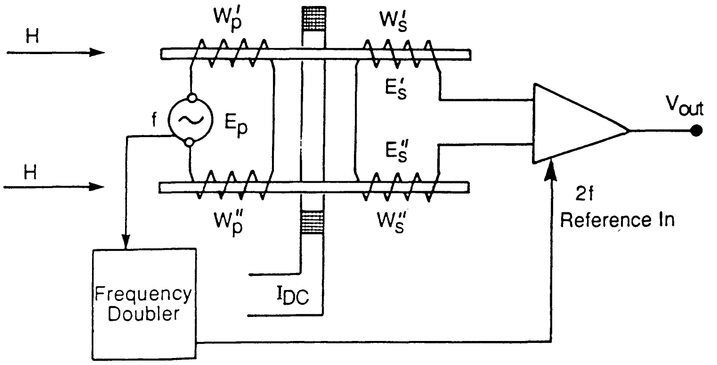

FIG. 21. A fluxgate magnetometer (after Geyger, 1954).

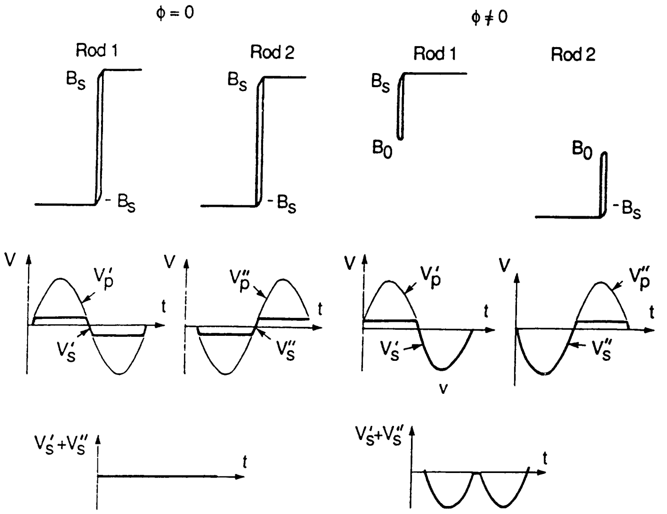

FIG. 22. Principle of operation of the fluxgate. The top figures show which part of the hysteresis curve of the core material is swept in each of the two rods at zero external flux Φ (left), and when flux Φ is present (right). The bottom shows schematically the time dependence of the voltages across the primary (V'_p and V''_p) and secondary (V'_s and V''_s) coils, again without (left) and with (right) flux Φ. The voltage at the input of the amplifier, $V'_s + V''_s$, is shown on the last line. In presence of Φ, $V'_s + V''_s$ has a large component at double the excitation frequency.

sensitivity of fluxgate magnetometers depends on the shape of the hysteresis curves, which should ideally be square. The use of a core material with low coercivity and saturation field values minimizes the power consumption of the device. Sensitivities range from 10^{-10} to 10^{-2} T, but the operation frequency is limited to about 10 kHz, because of the need to have an excitation source at a higher frequency. The power consumption of fluxgate magnetometers can be decreased by operating them on a minor hysteresis loop, because then the core does not have to be driven from saturation to saturation. Flux gates based on thin-film technology have been described by Seitz (1990).

Magnetic amplifiers are devices similar to fluxgates, in which a magnetically controlled saturation of the core of a winding is used to modulate the amount of power delivered from a source to a load. The reader is referred to descriptions by Geyger (1954) and Shea (1968).

1.10 Other Magnetometers

The devices described above are mostly small solid-state type devices. Many complex magnetometer systems exist. Scientific magnetometer systems used in the measurement of magnetic properties of materials have been reviewed by Foner (1981).

Superconductive quantum interference devices (SQUIDs) are the most sensitive instruments for measuring magnetic fields. SQUIDs are described in a separate article in this encyclopedia, and the reader is referred thence.

Optical magnetometers are based on the Zeeman effect in gases such as helium or cesium vapor; they are typically large devices with a high power consumption (Lenz, 1990). There are nuclear precession magnetometers, based on the precession of proton magnetic moments around an applied magnetic field. This type of sensor makes use of hydrocarbon fluids or ^{3}He, and the precession is sensed by a pickup coil. These magnetometers are potentially very sensitive (Lenz, 1990). Magnetooptical sensors are based on Faraday rotation of polarized light traveling through a magnetic material, for instance a terbium gallium garnet (Lenz, 1990). Unfortunately, the Faraday effect is rather small in moderate fields, except in ferromagnets. Dandridge *et al.* (1980) describe a magnetic field sensor based on a conventional single-mode optical fiber coated with a magnetostrictive layer. Under an applied field, the magnetically induced strain changes the optical path length, which can be monitored by interferometry.

1.11 Comparison of Magnetic Field Sensors

The magnetic field range to be detected determines the choice of sensor. The relative sensitivity of the sensor in its field range is the primary factor that must be considered, but other factors are the operating temperature range, the power consumption, the size, the linearity of the sensor, and whether or not sensitivity to the polarity of the field is needed.

Solid-state sensors, such as magnetoresistors, Hall generators, magnetodiodes, and magnetoresistors, have the great advantage of being integratable with amplification and signal-processing circuits, resulting in very cost-competitive systems. In Fig. 23, the sensitivity of a number of solid-state sensors is shown at 20 °C as a function of applied magnetic field. These sensors are a thin-film InSb-based magnetoresistor [n-doped at 6×10^{16} cm^{-3} (Partin *et al.*, 1992)], a thin-film Permalloy-based magnetoresistor (Nippondenso 076100-0202), an ion-implanted GaAs Hall generator (Siemens KSY-10), and a Si-based Hall generator with integrated on-chip amplification (Allegro 3501). In order to make a meaningful comparison, the "sensitivity" of each sensor is defined as the difference between the output voltage of the sensor at the field given in the abscissa and at zero field divided by the supply current (Heremans *et al.*, 1992). At the lowest fields, magnetoresistors based on Permalloy are most sensitive, but their sensitivity saturates at fields around 5×10^{-3} T. Hall generators give an almost linear response to field, while InSb-based magnetoresistors give a quadratic one. As a result, Hall generators are always more sensitive than magnetoresistors at low fields, and the opposite is true at high fields. The crossover field depends on the technology used: unamplified InSb-based magnetoresistors are more sensitive than the Si-based Hall generator shown with integrated amplifier above 0.03 T. The latter sensor has a cutoff frequency (3 dB) of 25 kHz, because of the large-gain amplifier used on the chip. Many other ways of conditioning the output signal can be integrated with the Si Hall generator, such as trigger circuits, latching circuits, or circuits that linearize the output and compensate for temperature over a limited range. Similar functions could be integrated on the GaAs substrates used in the InSb- or GaAs-based sensors. To summarize, Permalloy-based magnetoresistors are preferred for sensing magnetic fields below about 0.005 T, Si Hall sensors with integrated amplification for fields between 0.005 and 0.03 T, if the frequency cutoff is not a problem, and InSb-based magnetoresistors for fields above 0.03 T. These are only crude guidelines. When high-temperature (above 170 to 200 °C) operation is required, such as in automotive applications, GaAs Hall sensors can be considered along with heavily doped InSb or InAs magnetoresistors, but magnetoresistors are more sensitive.

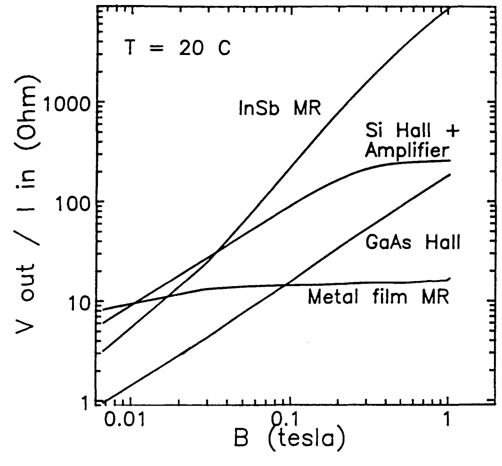

FIG. 23. Comparison of the sensitivities of different solid-state magnetometers at room temperature. The sensitivity is defined as the change in output voltage, divided by the input current, when the applied magnetic field is changed from zero to the value shown in abscissa. At very low fields, the magnetic metal film magnetoresistance (MR) is the most sensitive. It is instructive to note that when field changes above 0.03 T have to be detected, unamplified InSb-based magnetoresistors are more sensitive than Si Hall sensors with integrated amplifiers. The gain of such amplifiers is limited by the signal-to-noise ratio and the bandwidth (Heremans *et al.*, 1993).

2. APPLICATIONS OF MAGNETIC FIELD SENSORS

2.1 Magnetic Recording Heads

Magnetic recording is described elsewhere (see MAGNETIC STORAGE OF INFORMATION). In short, thin layers of magnetic recording media can be magnetized in the direction perpendicular to the film, or in the plane of the film ("longitudinal recording"). Recording heads can use search coils, magnetoresistors, or Hall generators. Figure 24 shows an example of a magnetic circuit that uses a Hall sensor to read codes magnetized into a magnetic data carrier (Siemens, 1989). Magnetoresistive heads operate on much the same principle, but use the more sensitive metal magnetoresistors (Sec. 1.7). A review of biasing methods is given by Markham and Jeffers

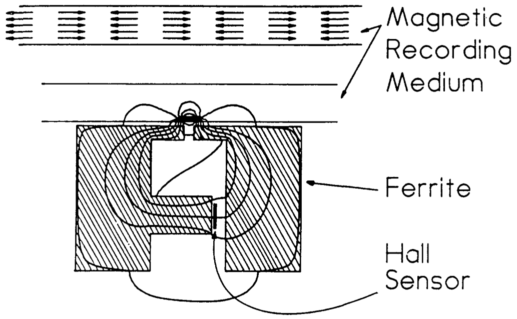

FIG. 24. Data can be encoded in a medium, the top foil, by magnetizing regions of the foil in the longitudinal direction (top). The reading head (bottom) consists of a closed ferrite flux path with two gaps: one for the magnetometer (a Hall sensor) and one close to the medium. The magnetized area (dark rectangle) in the medium generates the flux lines shown.

(1990). Inductive heads are also used, and Jagielinski (1990) shows an example of the parallel readout of ten recording tracks, using thin-film pickup devices such as shown in Fig. 19. Current technology trends are toward multitrack devices, response frequencies up to 100 MHz, and head-media spacings less than 50 nm. In longitudinal recording an increase in linear information density requires a corresponding decrease in gap width, and a higher magnetic field in the gap.

2.2 Position and Speed Sensors

With the widespread use of microprocessors in cars and airplanes, sensors that translate mechanical movement into an electrical signal are becoming very common. The simplest device that does this is the potentiometer; but the friction involved in conventional potentiometers makes them less reliable than frictionless methods. Optical techniques (a light-emitting diode and a photodetector, with or without fiber optics, for instance) are sensitive to contamination, and their applications are limited to protected environments. Magnetic position sensors are the technology of choice when reliability is a critical issue. They are based on the use of a permanent magnet whose position is changed with respect of that of a magnetic field sensor. Alternatively, the magnetic field sensor can be mounted on the magnet, and a ferromagnetic metal part moved with respect to that assembly. In either design, the mechanical movement is translated into a change in the flux through the magnetic field sensor. An example of the design of a rotary contactless potentiometer is shown in Fig. 25. Linear position sensors using a sliding magnet moving with respect to a magnetoresistor or a Hall sensor can be designed. Proximity sensors based on similar designs are also common, for instance to verify door and hatch closures (Lenz, 1990).

2.3 Rotary Shaft Encoders

Magnetoresistors or Hall sensors are widely used in rotary shaft encoders when the speed and the position of the shaft have to be detected. Pickup coils can be used when the information is not needed at zero rotation speed. A typical magnetic circuit used for sensing the position of gear teeth machined into an iron or steel wheel is shown in Fig. 26.

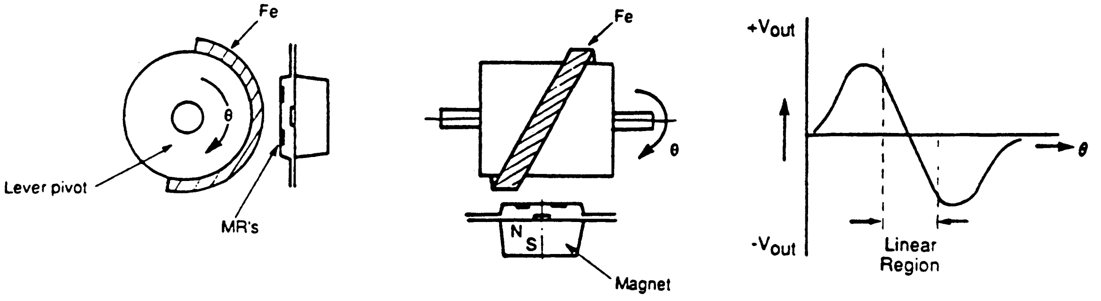

FIG. 25. A contactless potentiometer using an iron film on a mandrel, and two magnetoresistors (MRs) mounted on a biasing magnet. The angular position θ of the mandrel determines the amount of flux through each magnetoresistor. When the two magnetoresistors are connected in series, the voltage V_{out} of the midpoint varies with θ as shown. In the region in which V_{out} varies linearly with θ, the device can be used as a potentiometer (adapted from Siemens, 1989).

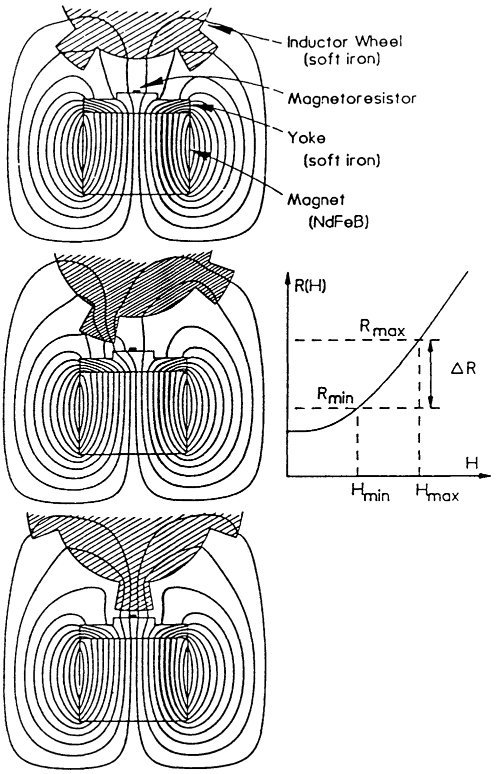

FIG. 26. Rotary shaft position sensor using a magnetoresistor mounted on an iron yoke on a bias magnet, and a cogged inductor wheel. The flux lines are shown at left, for different positions of the inductor wheel. The magnetic induction *H* at the sensor location changes with the inductor wheel angle, and so does the electrical resistance *R*(*H*) of the magnetoresistor.

The size and distance of the teeth can be used to encode absolute position sensing. This type of sensor is widely used to measure the position of the crankshaft and camshaft in a gasoline engine (see Fig. 27). Its information is fed into the engine control computer, which then determines which cylinder fires and when it does so. The ignition system shown in Fig. 27 now replaces the mechanical switches and "points" used in older car engines.

2.4 Brushless Motors

Figure 28 shows a schematic diagram of a brushless dc electric motor. The rotor is a permanent magnet (labels indicate the north and south poles). The position of the rotor is monitored by Hall sensors H_1 and H_2. These control the base currents into the bipolar transistors that control the current flow through the stator windings. Such motors have easy starting characteristics. The absence of brushes results in better reliability and the elimination of the electrical noise due to sparking. They find applications in video recorders, disk drives, turbopumps, and automotive motors. The control of the absolute rotor position can be done by a microprocessor chip, and complicated rotation patterns can be programmed in a flexible manner.

2.5 Shuntless dc Current Measurements

Shuntless dc ammeters can be made as follows: A primary coil is wound on a soft iron core that contains an air gap. The current to be measured, I_{in}, passes through this winding. The resulting flux generates a field that can be detected by the Hall sensor located in the air gap. The output of the Hall sensor is a measurement of the current I_{in}. For more precision and wider dynamic range, a secondary coil is wound around the core. A current can be made to flow through this secondary, so as to cancel the field in the gap. The Hall sensor is then used as a null detector, and the current through the secondary coil is a measure of the current through the primary.

3. HIGH-FREQUENCY DEVICES

3.1 General Aspects

The magnetic component of an electromagnetic wave couples readily to magnetic materials. Ferrites and powdered ferromagnetic materials are used as magnetic field concentrators in antenna cores, inductors and transformers. Devices operating in the microwave-frequency range also use the ferromagnetic (or ferrimagnetic) resonance. In ferromagnetic solids, the adjacent magnetic moments of the atoms interact very strongly and align parallel to each other, as long as the solid is below a critical temperature, the Curie temperature T_C. In ferrimagnetic materials, the spins are aligned antiparallel, as in antiferromagnets, but there are more spins pointing in one direction than in the other. The material thus has a net magnetic moment, but smaller than it would have if all spins were parallel. Their critical ordering temperature is called the Néel temperature, T_N. Unfortunately for device applications, solids that are strictly

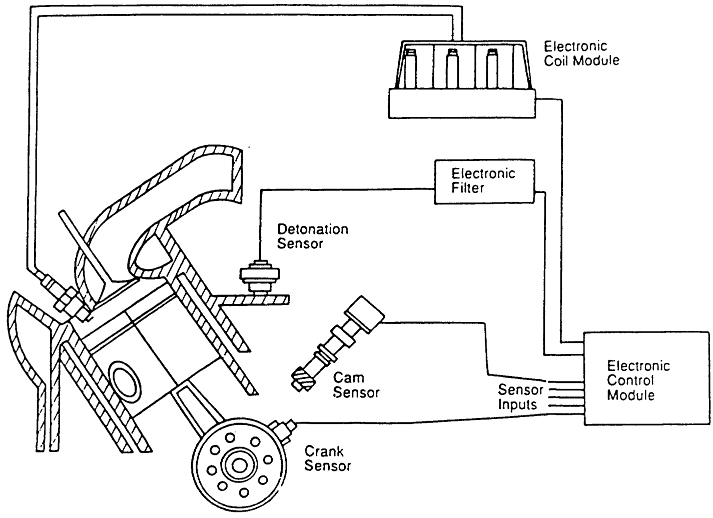

FIG. 27. Ignition system of a Buick engine. Magnetic position systems such as shown in Fig. 26 measure the position of crankshaft and camshaft, and transmit the information to a microprocessor (the electronic control module). The microprocessor, which also receives data on the air flow into the engine, the coolant temperature, the knock sensor, and the transmission, determines the spark timing and sequence. At the proper time, it switches low-voltage current to one of three coils. The secondary windings of each of these coils are connected to two spark plugs. When the current to a given coil is interrupted, both sparks fire, one in an empty cylinder, and one in a fully fueled cylinder. Such ignition systems avoid the mechanical commutation of high voltage.

ferromagnetic and with Curie temperatures above room temperature are metals. Eddy currents are generated in these electrically conducting materials at high frequencies. This leads to unacceptable energy dissipation. Magnetic materials with a high electrical resistivity, such as powdered metals, ferrites, and garnets, are preferred for high-frequency devices.

Powdered ferromagnetic materials, compacted with an insulating binder, can have reasonably low eddy-current losses. The reduction in losses in these materials usually comes at the expense of the permeability of the compact. Powdered cores are made using Permalloy, pure iron, or Sendust powder. Some properties of these powders are summarized in Table 1.

Ferrites (Smit and Wijn, 1959) are ferrimagnetic. The general chemical composition of soft ferrites is $(MO) \cdot (Fe_2O_3)$, where M is a divalent metal such as Fe, Ni, Co, Mn, Mg, Zn, Cd, or Cu. The simplest member of this class is thus iron ferrite, Fe_3O_4, or magnetite, mentioned in Fig. 1. Ferrites have high resistivities because the constituent atoms have no free 3s or 4s electrons available for conduction. Ferrites are selected on the basis of a number of properties, such as a high permeability at low field, or low losses at high frequency, or a square hysteresis loop. Impurities tend to decrease the permeability. The properties of some ferrites are given in Table 1.

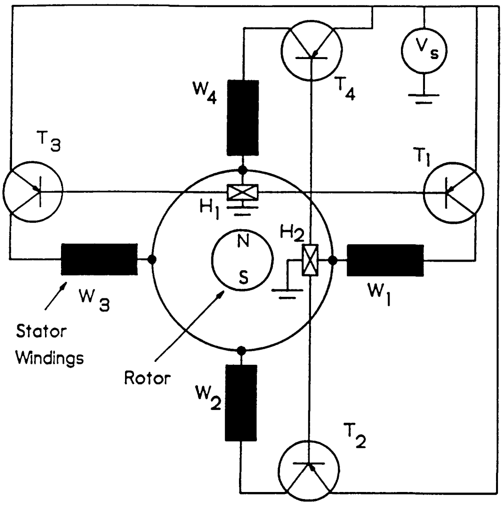

FIG. 28. Brushless electrical motor, with a permanent-magnet rotor and Hall sensors. The control currents are provided by the Hall sensors H_1 and H_2 to the transistors T which supply the windings W (adapted from Siemens, 1989).

Table 1. Magnetic properties of ferrites and pressed powders used in magnetic cores (Chikazumi, 1964). The balance for composition in the powders is Fe.

Material	Composition	Permeability, μ	Saturation magnetization (G)	Curie or Néel temp. (°C)
Pressed powders				T_C
Iron	Carbonyl Fe	20	1240	770
Mo-Permalloy	2 Mo, 81 Ni	125	560	480
Sendust	5 Al, 10 Si	80	360	500
Ferrites				T_N
Mn-Zn	50 Mn, 50 Zn	2000	200	110
Cu-Zn	40 Cu, 60 Zn	1100	—	90
Cu-Mn	40 Cu, 60 Mn	—	230	—
Ni-Zn	30 Ni, 70 Zn	80	320	130
Mg-Zn	50 Mg, 50 Zn	500	207	120
Mg-Mn	50 Mg, 50 Mn	1400	215	130

Other materials commonly used are rare-earth garnets, mostly yttrium iron garnet (YIG) or gallium-substituted YIG (GaYIG). Their general chemical formula is $(5Fe_2O_3) \cdot (3M_2O_3)$, where M represents Y or a rare-earth ion (Sm to Lu). Materials used in practice can deviate from these simple formulas. Both polycrystalline and single-crystal materials are used.

Microwave applications use the ferromagnetic resonance, whereby the spin system absorbs energy from the electromagnetic wave at a specific, resonant energy. Figure 29 shows schematically a sphere of YIG in a vertical dc field H_0. Ferromagnetic resonance can be viewed as the tendency for the spins in the garnet to precess about the vertical field H_0. For a YIG sphere, the resonance frequency of the precession is empirically given by $f_R = (28\ \mathrm{GHz/T})H_0$. The spin precession results in a rotating magnetic dipole **m** shown in Fig. 29(a). A circularly polarized microwave (rf) radiation with a magnetic vector $\mathbf{h}^+$ shown in Fig. 29(b) can excite that precession, if the radiation is at or near the frequency f_R. rf magnetic fields will build up about the sphere in the same way as the magnetic field builds up in the inductance of an *L-C* tuned circuit at resonance. Circularly polarized rf radiation with a magnetic component in the direction $\mathbf{h}^-$ shown in Fig. 29(c) does not couple to the sphere, even if the radiation is at the resonant frequency. The device is thus not "reciprocal," and will be selective with regard to the direction of propagation of a traveling rf wave. Linearly polarized fields may be constructed as the sum of two circularly polarized fields of equal strengths rotating in opposite directions. When the sphere is subjected to a linearly polarized field, it will respond to only one of the two circularly polarized components, and therefore emit only that circularly polarized field at resonance.

Some relevant properties of a few single-crystal materials used in practice are given in Table 2. The saturation magnetization limits the range of dc magnetic field available for tuning the resonance frequency. The linewidth of the resonance can be expressed as the range of dc magnetic fields ΔH over which the resonator responds (within 3 dB) at frequency f_R. This quantity depends on material parameters, and also on the shape and surface finish of the device. The resonant frequency is a function of the shape of the resonator (via the demagnetization factor; see MAGNETOSTATICS), the crystalline anisotropy (in single crystals), and interactions of the ferrite or garnet with currents in the metallic walls surrounding the device. Details are given by Soohoo (1985) and Matthaei *et al.* (1980).

3.2 Microwave Devices

3.2.1 Filters. Figure 30 shows a resonator filter built around a ferrite sphere. The incoming and outgoing waves are coupled through two loops, slightly elliptical in shape so that they can be nested perpendicularly to each other. The ferrimagnetic resonator is located in the center. The biasing dc magnetic field H_0 is parallel to the plane of both loops.

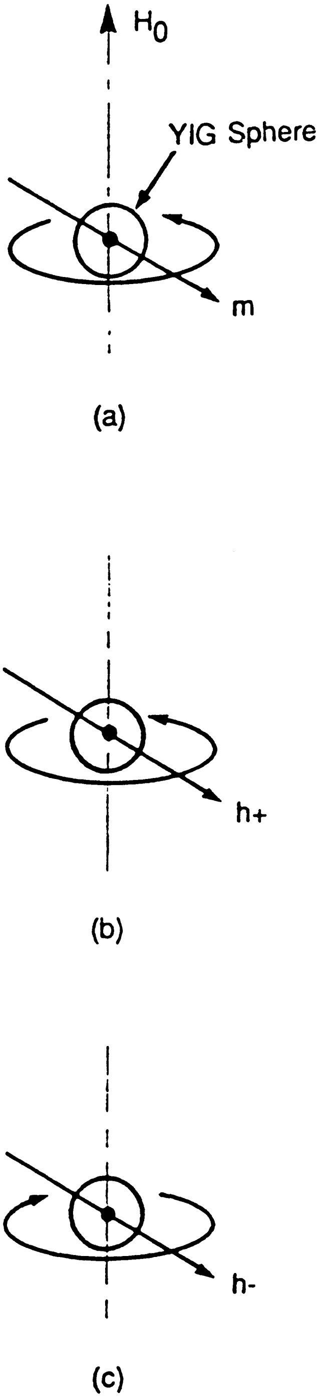

FIG. 29. (a) A YIG sphere with a circularly polarized ac moment **m**. (b) External ac fields at the resonant frequency of the sphere and circularly polarized magnetic field component $\mathbf{h}^+$ couple to the sphere. (c) If the polarization of the external field is in the wrong direction, $\mathbf{h}^-$, the wave does not couple to the YIG sphere. (After Matthaei *et al.*, 1980.)

When an rf magnetic field h_x at the resonant frequency f_R is generated by the x loop, the ferrite emits an rf moment m with components m_x and m_y. The m_y component couples to the y loop, and the wave propagates into the termination R_y. At frequencies other than f_R, no wave propagates. The frequency f_R can be tuned by changing the biasing field H_0. Such loop-coupled filters are easy to understand, but in practice there is considerable stray coupling between the loops, and the rf fields generated are not very uniform, which tends to excite higher-order modes. A much more practical, waveguide-based, device is shown in Fig. 31. Two ferrimagnetic resonating spheres are placed near the walls in the waveguide at locations such that the spheres see a strong rf magnetic field. The spheres are coupled to one another through a slot parallel to the waveguide axis; the geometry of the slot is designed to minimize coupling between the waveguides except when the spheres are excited into resonance. The spheres are placed in reduced-height waveguides to obtain adequate coupling between them and the waveguide. This also reduces the air gap for the dc biasing magnet. The steps in the waveguide height form a Tchebyscheff transformer, designed to provide impedance matching between the normal waveguide and the reduced-height portion (Matthaei *et al.*, 1980). This filter, tunable via variations of H_0, has the same attenuation and phase characteristics for both directions of transmission. Similar structures can be designed in strip-line technology. Filters can also be designed that induce a phase shift in the propagating wave, or that have different transmission coefficients for waves propagating in different directions (Matthaei *et al.*, 1980).

3.2.2 Isolators. Isolators are devices that allow wave propagation in one direction, but not in the opposite one. They are particularly useful to isolate a microwave source from the waves reflected from a load that perturbs the amplitude or frequency stability of the source. A waveguide-based ferrite isolator is shown in Fig. 32. In an empty rectangular waveguide, Fig. 32(a), the components of the rf magnetic field for the TE_{10} mode are h_x and h_z, shown in

Table 2. Properties of single-crystal ferrimagnetic materials used in microwave devices (Matthaei *et al.*, 1980).

Material	Néel temp., T_N (°C)	Saturation magnetization, $4\pi M_s$ (G)	Linewidth, ΔH (Oe)
Yttrium iron garnet (YIG)	292	1750	0.22 (@ 4 GHz)
Gallium-substituted YIGs	—	50–1750	—
(GaYIGs)	160	600	—
	206	950±50	0.7–2 (@ 4.4 GHz)
Lithium ferrite[a]	—	3550±40	3 (@ 5 GHz)
Planar ferrite, $Ba_{12}Zn_2Fe_{12}O_{22}$	—	2850	16 (8–12 GHz)

[a] Nielsen *et al.* (1962)

Fig. 32(b) as functions of x for $y=0$. Since h_x and h_z are in space and time quadrature, circular polarization is obtained at the locations where $|h_x| = |h_z|$, i.e., the points x_1 and $a-x_1$ in Fig. 32. The value of x_1 is calculated by Soohoo (1985). An isolator can be made by applying a ferrimagnetic layer as shown in Fig. 38(c) at those points, and biasing them with opposing dc magnetic fields H_0 as shown. The nonreciprocity of this structure arises from the fact that each ferrite layer couples to only one direction of polarization of the rf magnetic field, as shown in Fig. 29. Not all four strips of ferrite need to be present to make an isolator. As described, the device in Fig. 32 is an efficient isolator, giving a large attenuation for waves traveling backward (backward attenuation), and a low attenuation for forward propagating waves (low forward attenuation, or insertion loss) only at the resonant frequency. If the bias magnetic field H_0 is far away from resonance, one can obtain a phase shift at low attenuation. Such devices are "phase shifters." A phase shifter with reciprocal action can be made if the H_0 values applied to the strips at x_1 and $a-x_1$ are of the same polarity. If the bias magnets produce H_0 values of opposite polarity, as shown in Fig. 32, the phase shift is nonreciprocal.

Both the bandwidth and the reverse-to-forward absorption ratio of the isolator can be increased by adding a strip of dielectric in the waveguide, next to the ferrite strip and on the inside of it. This technique makes the fields inside the waveguide more circularly polarized throughout the cross section and over a broader wavelength range. It is described by Soohoo (1985).

3.2.3 Circulators. A circulator is a microwave-circuit component with three or more ports. In a circulator, microwave energy can propagate from one port to another only in

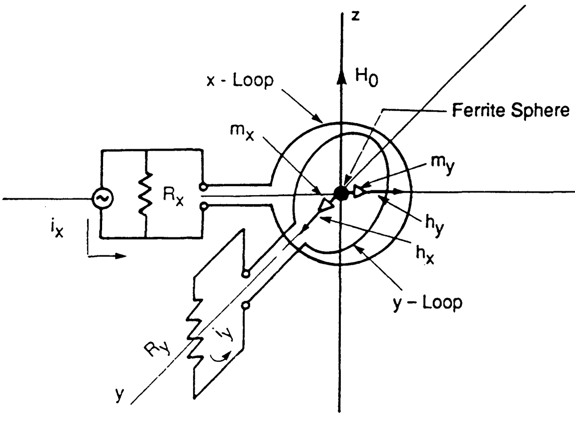

FIG. 30. A magnetically tunable filter using a single ferrite resonator in a dc biasing field H_0, and loops x and y for coupling the waves (after Matthaei *et al.*, 1980).

one direction. In the three-port circulator shown in Fig. 33, with the dc field H_0 applied in one direction, energy can go from port 1 to port 2, from 2 to 3, and from 3 to 1, but not from 1 to 3, 3 to 2, or 2 to 1. A pedagogical example of the use of these devices is an elementary radar: attach a source to port 1, an antenna to port 2, and a detector to port 3. The wave generated at 1 propagates out through port 2 and out of the antenna. The wave reflected back from the target is received by the antenna and propagates from port 2 to port 3, where it can be detected. A Doppler radar can be made by mixing a small amount of source radiation with the wave reflected from the target. The carrier-wave frequency is filtered out at port 3 and the detector is made sensitive only to the difference frequency. This frequency is then a measure of the relative velocity of the target with respect to the radar. The circulator itself can be built as shown in Fig. 33 (top). The ferrite is attached to the top or bottom plate of the cavity at the location where the wave is circularly polarized, as in the design of the isolator, Fig. 32. A dc biasing magnetic field H_0 is applied normal to the plane of Fig. 33. Depending on the polarity of H_0, circulation is made possible either in the clockwise direction, $1 \rightarrow 2 \rightarrow 3$, or in the counterclockwise direction. This circulator is strictly a resonant device again. Dielectrics can be used, as in the design of isolators, to broaden the device's bandwidth (Fig. 33, bottom). There are many other circulator designs possible, and the reader is referred to Matthaei *et al.* (1980), Nielsen *et al.* (1962), and the article on MICROWAVE CIRCUITS.

3.2.4 Strip-Line, MMIC, and Thin-Film Technologies. The microwave-circuit elements described above used waveguide technology, for pedagogical reasons. The component elements described above are copied in strip-line technology, using ferrite or YIG thin films, and even thin-film magnets (Stancil, 1989). Ferromagnetic metals can be considered in thin-film devices, because the eddy currents are much reduced when the rf magnetic field is applied in the plane. This allows for the design of novel devices, such as the strip-line notch filter shown in Fig. 34. This filter is based on the ferromagnetic resonance in iron. The iron film shown has a resonance at $f_R \simeq 10$ GHz without external biasing. In Fig. 34, the radiation is polarized with the ac electric and magnetic fields **e** and **h** as shown. It propagates from left to right. In the iron film, which has a magnetization vector **M** as shown, radiation at the resonant frequency f_R is absorbed by the iron. Radiation at other frequencies is transmitted through the strip with much less attenuation, so that the strip serves as a notch filter.

Modern thin-film techniques can combine device-grade semiconductors with ferromagnetic films. This opens fascinating new device opportunities in monolithic microwave integrated circuits (MMICs) (Prinz, 1990).

3.3 Other Magnetic Devices

3.3.1 Antenna, Inductor, and Transformer Cores. A winding distributed about the length of a rod of high-permeability material forms an antenna in broadcast radio receivers. The core concentrates the ac magnetic flux into the antenna. Similarly, inductors and

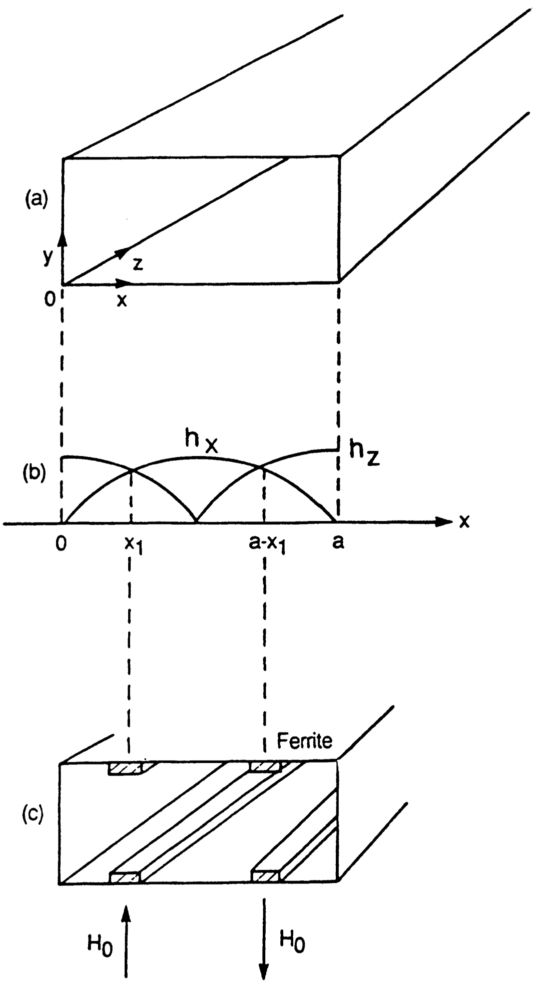

FIG. 32. A waveguide-based ferrite isolator. (a), (b) The magnetic field distribution of the TE$_{10}$ mode in a rectangular waveguide. (c) The ferrite strips are inserted at the location where the wave is circularly polarized, i.e., $|h_z| = h_x$. The dc biasing field is H_0. (After Soohoo, 1985.)

transformers are wound around magnetic material cores. Adjustable inductors are used in many circuits. The most common form of adjustment involves changing the position of the high-permeability core material with respect to the windings. Conventional variable capacitors are difficult to seal with respect to ambient humidity; this is much less a problem in tuned inductors. The windings can easily be sealed, and moisture has little effect on the behavior of the core. Designs of antennas, inductors, and transformers use a compromise between high permeability and low losses at the intended frequency of operation. Powdered magnets and ferrites are used for cores at the higher end of the frequency spectrum. Ferromagnetic metals, such as the Ni-Fe alloys, Mumetal, Permalloy, Perminvar, and thin metglasses can be used at lower frequencies. Tape-wound cores from these alloys are available. Fe-Co, Fe-Si, Fe-Al, and pure Fe are sometimes also used in electromagnet and relay cores, since these are nearly dc applications (Fink and McKenzie, 1975).

3.3.2 Magnetic Memories. Magnetic materials are used in memories, and this type of devices is the subject of a separate article (MEMORIES). The synergistic effects of new film-growth techniques of both semiconductors and magnetic materials, already mentioned in the section on microwave thin-film techniques, also influences this field. For in-

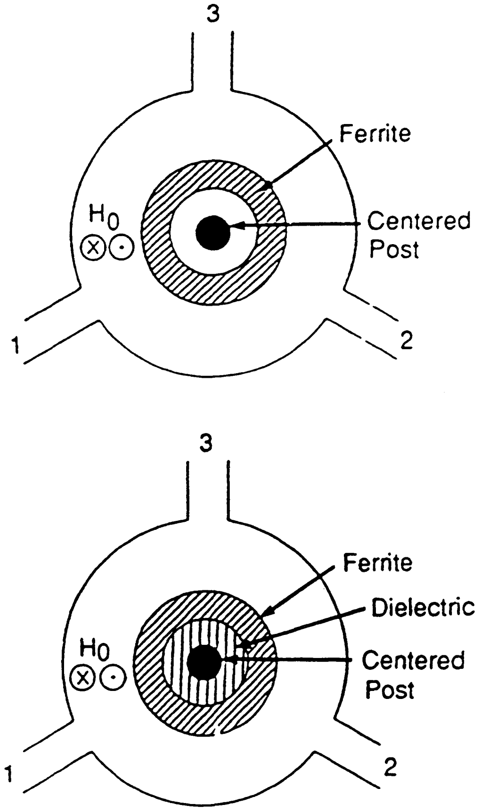

FIG. 33. (top) A waveguide circulator with three ports, 1, 2, and 3. Microwave energy can go from 1 to 2, 2 to 3, and 3 to 1, but not vice versa. The circulator is made by inserting a ferrite at the location where the wave is circularly polarized. (bottom) Dielectric loading of the circulator increases the bandwidth. (After Soohoo, 1985.)

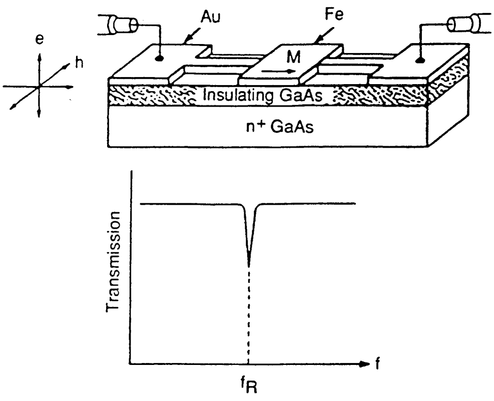

FIG. 34. Strip-line microwave notch filter, using an epitaxial iron film as resonator (after Prinz, 1990).

stance, an integrated magnetic memory element was proposed by Prinz (1990), and is shown in Fig. 35. It is the thin-film analog of the ferrite core. The element can be made from epitaxial magnetic metal deposited on a semiconductor substrate, such as Fe on Si or GaAs. In the example chosen, the iron film is patterned so that the magnetic moments align with the magnetically easy axes of Fe, here the ⟨100⟩ axes. The film can be magnetized with the moments aligned clockwise or counterclockwise, representing the 0 or 1 states of the bit. The readout of the magnetic state of the memory element can be integrated in the semiconductor, for instance as a Hall element. The magnetic loop is closed, and very little leakage flux and cross-talk are expected. The down-scaling of this memory element is only limited by semiconductor technology, because the magnetic properties of Fe are independent of size, down to maybe 200 Å.

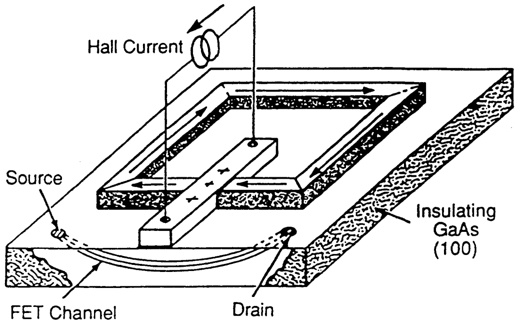

FIG. 35. Picture-frame memory element made from a thin epitaxial iron film on GaAs with a readout Hall sensor integrated in the substrate (after Prinz, 1990).

Another intergrated magnetic storage technology that uses magnetoresistors has been described by Daughton (1992), and a bipolar spin switch is described by Johnson (1993).

4. CONCLUSION

Magnetic effects and materials are widely used in electrical machines, but also in the conversion of mechanical movement into an electrical signal (position sensors) and in electronics. Magnetic device technology parallels semiconductor technology, and the synergism between the two will continue to lead to yet new devices. The ultimate synergism would be in the field of magnetic semiconductors, which were not discussed here. Only "dilute" magnetic semiconductors have been studied recently (see SEMICONDUCTORS, DILUTE MAGNETIC), and their applications are limited, because their magnetic properties are not very pronounced, especially at room temperature. Optical isolators, which perform in the visible light range the same function as their microwave equivalents described in Sec. 3.2.2, and are needed in high-data-rate optical communication systems, could be made from such materials (Furdyna *et al.*, 1991).

Acknowledgments

I want to acknowledge the help of Dr. J. Herbst and Dr. S. Foner in reading the manuscript, Dr. D. L. Partin for frequent discussions, and Mr. R. C. Dinsmore, from Dinsmore Instruments Company, for reviewing the section on fluxgates.

GLOSSARY

Circulator: Microwave device having three or more ports, labeled 1, 2, 3, etc. Microwave radiation can only propagate from port 1 to 2, 2 to 3, etc., in that order, and cannot propagate in the reverse order.

Corbino Disk: Circularly shaped slab of semiconductor, with two electrodes, one in the middle of the circle, the other on the periphery. The current lines in this element flow radially through the semiconductor. This geometry gives the largest geometrical magnetoresistance. (Can also be made from semimetals and metals.)

Fluxgate: Sensitive magnetometer using a core of magnetic material driven close to saturation, and often used in compasses.

Garnet: Ferrimagnetic mixed oxide of iron and rare-earth elements or yttrium, electrically insulating. Used as magnetic material for high-frequency applications, in which eddy-current losses have to be minimal.

Geometrical Magnetoresistance: Magnetoresistance induced in a semiconductor resistive element by choosing the geometry of the element in such a way that an applied magnetic field lengthens the current paths of the charge carriers.

Hall Generator: Device exploiting the Hall effect to generate a voltage that is used to measure the magnetic field.

Isolator (microwave or optical): Device that lets an electromagnetic wave propagate only in one direction. It is commonly placed between a source (microwave generator or laser) and its load to prevent energy reflected from the load from perturbing the source.

Magnetic Amplifier: Transformerlike device that modulates the amount of power that can be delivered from a source to a load by saturating the core of the transformer using a separate dc control current.

Magnetodiode: *p-i-n* diode in which an external applied magnetic field controls the amount of recombination in the intrinsic region.

Magnetoresistor: Resistor having a resistance that is a strong function of magnetic field, used in magnetometers. It exploits either the geometrical magnetoresistance in semiconductors, or the magnetoresistance anisotropy in magnetic metals.

Phase Shifter: Microwave device that shifts the phase of a wave propagating through it. Nonreciprocal phase shifters give different amounts of shift for waves propagating in opposing directions.

INTRODUCTION

Magnetic materials are widely used in industrial societies: they are essential for the generation and transmission of electric power, for electric motors, for recording and playback of sound, pictures, and numerical data, and for a great many other purposes. This article reviews the basic phenomena of magnetism, including units and terminology, with emphasis on the quantities that are important for applications. No treatment of the basic physics of magnetism is attempted (see MAGNETOSTATICS; MAGNETS). The magnetic materials of greatest usefulness for magnetic purposes are described, and some representative properties are given.

1. CLASSES OF MAGNETIC MATERIALS

1.1 Paramagnets and Diamagnets

All materials may be classified according to their magnetic behavior as paramagnetic, diamagnetic, or ferromagnetic. Paramagnetic and diamagnetic materials are only weakly magnetic; they are not obviously attracted to or repelled by a permanent magnet, and sensitive instruments are required to detect their magnetization. Paramagnets show positive magnetization in a positive field; diamagnets show negative magnetization in a positive field; that is, they become (very slightly) magnetized in a direction op-

posite to that of the applied field. The magnetic behavior of paramagnets and diamagnets provides information about the electronic structure and bonding of the constituent atoms, but these materials have few if any practical uses based on their magnetic properties except when strongly magnetic behavior must be avoided. *Superconductors*, however, are strongly diamagnetic.

1.2 Ferromagnets, Antiferromagnets, and Ferrimagnets

This article will concentrate on strongly magnetic materials, which show *ferromagnetic* behavior. Some of these materials belong to a subcategory known as *ferrimagnets*, as explained later. These strongly magnetic materials are used for a very wide range of applications—most notably the production and transmission of electric power in generators and transformers; the conversion of electric power to mechanical motion in motors, relays, and loudspeakers; and the recording of audio, video, and digital information on magnetic tapes and disks.

In visualizing and understanding the behavior of strongly magnetic materials, it is useful to regard each "magnetic" atom as carrying a fixed magnetic dipole moment. That is, each magnetic atom acts like a tiny permanent magnet, with a north and a south pole, or alternatively as a tiny loop carrying a constant electric current. These atomic moments are conventionally represented by arrows, as shown in Fig. 1.

In ferromagnetic materials (iron, Latin *ferrum*, is the prototype), the atomic moments are held in parallel alignment by a coupling energy known as the exchange energy. Figure 2 illustrates this arrangement. A positive value of the exchange energy corresponds to parallel alignment of the atomic moments. Only three elements are ferromagnetic at room temperature: iron, nickel, and cobalt. The rare-earth metal gadolinium becomes ferromagnetic just below room temperature, and several other rare-earth elements are ferromagnetic at lower temperatures (often with more complex spin structures). It is also possible to have a ferromagnetic arrangement of magnetic atoms in a compound where some of the atoms have no moment, as shown schematically in Fig. 3. The best-known example is chromium dioxide, CrO_2, which can be used as a video magnetic recording material.

The exchange energy can be negative, leading to antiparallel coupling between magnetic atoms. This occurs most commonly in oxides and other compounds, and is shown schematically in Fig. 4. These materials are called *antiferromagnets*; their magnetic be-

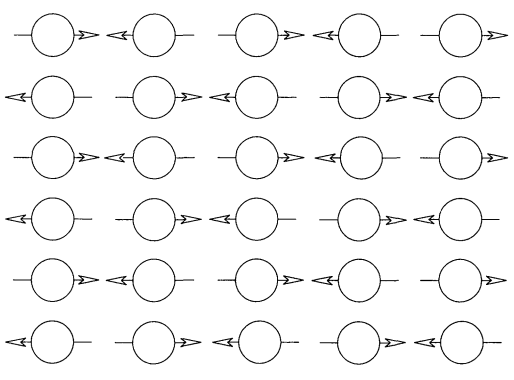

FIG. 4. Arrangement of moments in an antiferromagnetic compound (schematic).

havior is generally similar to that of paramagnets, although with a different temperature dependence (discussed in more detail later). Antiferromagnets are of little importance in applications, but a special case of antiferromagnetism, known as *ferrimagnetism,* has great practical utility. If two different magnetic atoms, each with a different value of the atomic moment, are arranged antiparallel, the net or resultant moment is not zero. This case is shown schematically in Fig. 5.

Practical ferrimagnets are oxides. The most important group of ferrimagnets are called ferrites; they are oxides having the spinel structure, with the general formula $M\mathrm{O} \cdot \mathrm{Fe_2O_3}$. The simplest example is $\mathrm{FeO} \cdot \mathrm{Fe_2O_3}$ or $\mathrm{Fe_3O_4}$ (magnetite). In this case the two different magnetic atoms are $\mathrm{Fe^{2+}}$ and $\mathrm{Fe^{3+}}$. A second class of useful ferrimagnets comprises the garnets, which have the general formula $\mathrm{RE_3Fe_5O_{12}}$, where RE represents a rare-earth metal, and which are used in microwave devices. Oxide ferrimagnets are electrical insulators, whereas most ferromagnets are metals, and hence are electrical conductors. For high-frequency applications, non-conductors have overwhelming advantages. For more detailed consideration of ferromagnets, antiferromagnets, and ferrimagnets, see the article MAGNETIC ORDERING IN SOLIDS.

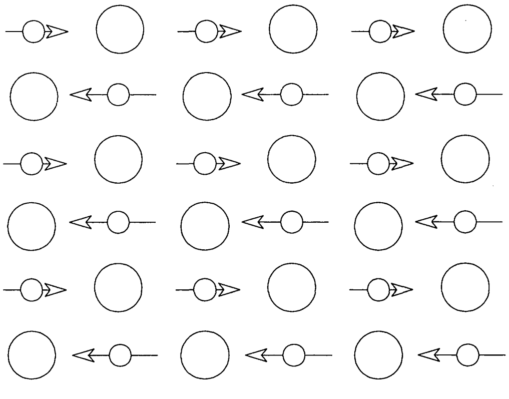

FIG. 5. Arrangement of moments in a ferrimagnetic compound; net magnetic moment is not zero (schematic).

2. FUNDAMENTAL MAGNETIC PROPERTIES

2.1 Saturation Magnetization

When a ferromagnet or ferrimagnet is subjected to a strong magnetic field, the net magnetization aligns parallel to the field and the material is said to be magnetically saturated. The macroscopic saturation magnetization is simply the vector sum of the atomic moments divided by the volume of the sample:

$$\mathbf{M}_s = (\Sigma \mathbf{m})V^{-1}. \tag{1}$$

Here $\mathbf{m}$ is an atomic moment, V is the sample volume, and $\mathbf{M}_s$ is the saturation magnetization. In SI units, energy moment is measured in $\mathrm{A \cdot m^2}$, reflecting the fact that a magnetic moment is equivalent to a current flowing in a circular loop. Magnetization is then moment/volume, $\mathrm{A \cdot m^2/m^3}$ or A/m. In cgs units, still widely used in applied magnetism, the magnetic moment is defined by the work done in rotating the moment in a fixed magnetic field. The electromagnetic unit of magnetic moment is then the erg/Oe (the oersted, abbreviated Oe, is the cgs unit of magnetic field strength), commonly called the emu (electromagnetic unit of moment). Magnetization in cgs units is therefore in emu/$\mathrm{cm^3}$, or (less commonly) erg/$\mathrm{Oe \cdot cm^3}$.

It is sometimes useful, especially when considering changes in magnetization with temperature, to eliminate thermal expansion effects by defining magnetization per unit mass, σ. The SI units are $\mathrm{A \cdot m^2/kg}$, and the cgs units are emu/g.

Physicists commonly express the moment of a single atom in a unit called the *Bohr* *magneton*, corresponding to the moment of a single unpaired electron spin. The Bohr magneton is 0.927×10^{-20} emu, or 0.927×10^{-23} $\mathrm{A \cdot m^2}$.

2.2 Magnetic Field

A magnetic field is produced by a current-carrying conductor. The field at the center of a long solenoid of length l, containing N turns of wire, and carrying a current i, is

$$H = Ni/l \quad \text{A/m [SI]} \quad \text{or}$$

$$H = (4\pi/10)Ni/l \quad \text{Oe [cgs]},$$

where SI length is in meters and cgs length is in centimeters, and current in both cases is in amperes.

2.3 Magnetic Induction

The quantity called magnetic induction or magnetic flux density (symbol B) is the vector sum of the magnetization and the field:

$$B = \mu_0(H + M) \text{ tesla [SI]},$$

$$B = H + 4\pi M \text{ gauss [cgs]}.$$

The quantity μ_0 is the magnetic constant or the permeability of free space. Its value is $4\pi \times 10^{-7}$ H/m or V s/A. The quantity B is necessary and useful primarily because changes in B generate a voltage in a surrounding wire, according to Faraday's law: $E = -k(dB/dt)$. This equation is the basis for the operation of generators and transformers.

2.4 Curie Temperature; Néel Temperature

As the temperature of a ferromagnet increases, the measured saturation magnetization decreases. The decrease is slow at first, but then increasingly rapid until at a temperature called the *Curie temperature* or *Curie point*, the magnetization disappears (Fig. 6). The thermal energy kT tends to randomize the direction of the atomic moments, while the exchange energy acts to keep the moments parallel. When the effect of thermal energy exceeds the exchange energy, the atomic moments are no longer aligned, and the material behaves as a paramagnet with a strongly temperature-dependent magnetization.

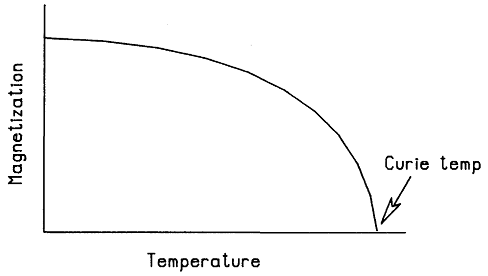

FIG. 6. Variation of magnetization with temperature in a ferromagnet, showing the Curie temperature.

The ideal curve of Fig. 6 is rather more complicated in practice; there is an increasingly strong field dependence of the magnetization at temperatures near the Curie point. This leads to experimental difficulty in measuring the Curie point with an accuracy better than a few K. Various methods have been proposed and used, but there is no generally accepted standard method. However, for practical purposes an uncertainty of a few K is seldom a major problem.

The disordering temperature for an antiferromagnetic is called the *Néel temperature*; experimentally it is evident as a maximum in the magnetic susceptibility $\chi = M/H$. In ferrimagnets, the two magnetic sublattices can each have a different temperature dependence of the magnetization, and so the curve of saturation magnetization versus temperature can take various forms, including the appearance of a compensation point (Fig. 7) where the magnetization goes to zero but then increases again before disappearing at the Curie point. The magnetization is very sensitive to both field and temperature near the compensation point, and this behavior can be used in some techniques for magnetic recording.

2.5 Anisotropy

The magnetic properties of a material may vary with the direction of measurement in the sample. This anisotropy may arise for several reasons. One source of anisotropy is magnetostatic or shape anisotropy: the magnetization prefers to lie parallel to a plane surface and parallel to the long axis of an elongated sample such as a wire or ribbon. This effect arises because surface magnetic charges or free magnetic poles exist wherever the mag-

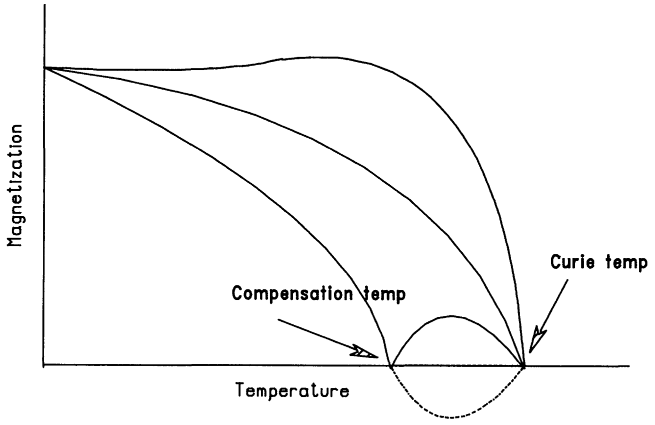

FIG. 7. Possible variations of net magnetization with temperature in ferrimagnets. Curves for three different materials, normalized at 0 K. The different behavior is due to different temperature variation of the moment of two oppositely-directed magnetic sublattices. The lowest curve shows a compensation point at which the net magnetization is zero; the thin line indicates that the net moment of the sample changes sign at the compensation point, although this will not be directly observed (thick line).

netization has a component normal to the sample surface. These free poles create magnetic fields in space, known sometimes as stray fields and sometimes as demagnetizing fields. The energy density of these fields is minimized when magnetization is parallel to the sample surface and when the free poles are as far apart as possible, which is why magnetization in the "long" direction is favored.

The demagnetizing field acting on a magnetized sample as a result of the free poles at its ends is given by

$$\mathbf{H}_d = N\mathbf{M}, \tag{2}$$

where N is a number called the demagnetizing factor. The value of N depends on the sample geometry. The demagnetizing factor has its maximum value (unity in SI; 4π in cgs) when the magnetization is normal to an infinite thin plate, and is zero in a rod or ribbon of infinite length. In real samples, the demagnetizing field is often comparable to or larger than the measuring field, and so must be corrected for in making measurements.

Most magnetic materials are crystalline, and in general the magnetization has a preferred crystallographic direction. This phenomenon is called the magnetocrystalline anisotropy, or just the crystal anisotropy. It can be measured by observing the torque exerted on a single crystal sample by a magnetic field, or from the difference in resonance fields in different crystallographic directions in a ferromagnetic resonance experiment (see NUCLEAR MAGNETIC RESONANCE, DETERMINATION OF STRUCTURE BY). If a polycrystalline material has its constituent crystals, or grains, oriented at random, there will be no macroscopic crystal anisotropy in the sample. Often, however, there is a preferred orientation, or texture, in the crystals, which is reflected in the macroscopic directional properties. A preferred orientation is beneficial in some cases, and may be deliberately induced.

The crystal anisotropy energy is expressed in a power series reflecting the symmetry of the crystal structure. In a uniaxial structure (hexagonal, tetragonal), the leading term has the form

$$E = K \sin^2\theta, \tag{3}$$

where θ is the angle between the magnetization and the uniaxial axis. In a cubic structure, the anisotropy is given by

$$E = K(\alpha_1^2\alpha_2^2 + \alpha_2^2\alpha_3^2 + \alpha_3^2\alpha_1^2), \tag{4}$$

where the α's are the direction cosines of the magnetization with respect to the three crystal axes. In both equations, E is the energy of the system as it depends on the direction of magnetization. The higher-order terms are usually not significant.

A third source of anisotropy arises from the interaction of mechanical stresses and the magnetostriction (see the next section).

2.6 Magnetostriction

When a magnetic material is cooled through its Curie temperature, it undergoes an elastic distortion (usually very slight) whose symmetry axis corresponds to the local direction of magnetization. If the direction of magnetization is changed, as by an external field, the distortion follows the magnetization, and the sample undergoes a macroscopic change in dimensions. This change in dimensions with the state and direction of magnetization is called *magnetostriction*. The measured strain (change in length per unit length, $\Delta l/l$), depends both on the direction of magnetization in the crystal and on the direction in which the strain is measured. In a cubic system, the simplest expression is

$$\begin{aligned}\Delta l/l &= \lambda_s\\ &= \tfrac{3}{2}\lambda_{100}(\alpha_1^2\beta_1^2 + \alpha_2^2\beta_2^2 + \alpha_3^2\beta_3^2 - \tfrac{1}{3})\\ &\quad + 3\lambda_{111}(\alpha_1\alpha_2\beta_1\beta_2 + \alpha_2\alpha_3\beta_2\beta_3\\ &\quad + \alpha_3\alpha_1\beta_3\beta_1),\end{aligned} \tag{5}$$

where the α's are the direction cosines of the magnetization and the β's are the direction cosines of the direction of the strain. The constants λ_{100} and λ_{111} are called the magnetostriction constants or magnetostriction coefficients. In the case of an isotropic material, such as a random polycrystal, a much simpler expression holds:

$$\Delta l/l = \tfrac{3}{2}\lambda_s(\cos^2\Theta - \tfrac{1}{3}), \tag{6}$$

where Θ is the angle between the magnetization and the strain axis.

These equations are based on an assumed demagnetized state in which the magnetization is completely random; the actual measured change in length depends strongly on the initial magnetic state of the sample, and may be much less than the value predicted by Eqs. (5) and (6).

In most magnetic materials the magnetostrictive strains are small, of the order of 10^{-5}, although there are materials where the strains can approach 10^{-2}. The dimensional changes can produce acoustical noise (generally unwanted) when magnetic materials are magnetized with ac fields; the magnetostriction also can make the properties of a material sensitive to applied stress. In particular, the interaction of an applied elastic stress with the magnetostriction creates another source of magnetic anisotropy, given (in the isotropic case) by

$$E = \tfrac{3}{2}\lambda_s\sigma\cos^2\Theta, \tag{7}$$

where σ is the applied stress and Θ is the angle between the magnetization and the stress axis.

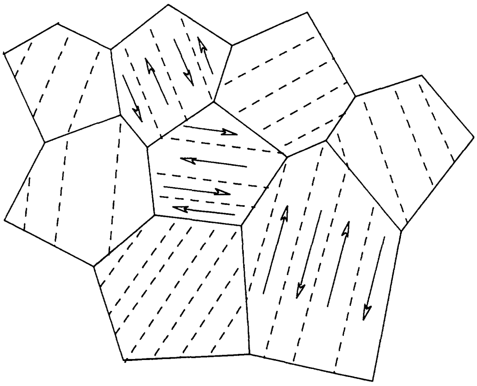

FIG. 8. Polycrystalline material containing multiple magnetic domains (schematic).

2.7 Magnetic Domains

According to Fig. 2, in a ferromagnetic material all the atomic moments are aligned parallel, so that one would expect the material to be magnetically saturated at all times. The demagnetized, or partially magnetized, state is achieved by the material being subdivided into small regions, called *domains*, each magnetized locally to saturation but adding vectorially to a lower value, or to zero. Figure 8 indicates schematically how domains may subdivide the crystals of a polycrystal; Fig. 9 shows how the motion of domain walls changes the magnetization.

A domain wall is a region in which the lo-

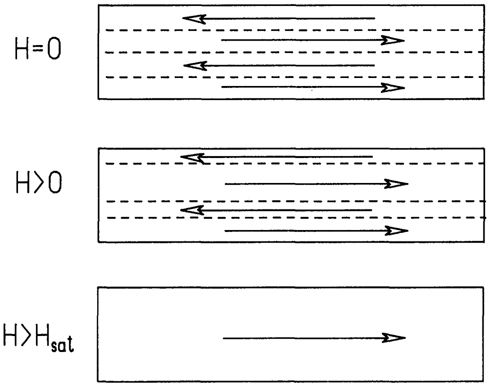

FIG. 9. Change in magnetization caused by domain wall motion (schematic).

cal magnetization rotates from one easy direction to another. In a cubic material with $K > 0$, the easy directions are either 90° or 180° apart, and the domain walls are classified as 90° or 180° walls. Figure 10 shows the structure of a 180° wall. In most ferromagnetic and ferrimagnetic materials, the domain-wall thickness is several hundred atomic spacings. This means that there is little interaction between a domain wall and a single impurity atom or a lattice vacancy or an isolated dislocation. There is, however, a strong interaction with a second-phase particle whose magnetization is different from that of the matrix, or with a region of local elastic strain.

The magnetization process at low fields consists primarily of the motion of domain walls. In general, the walls do not move smoothly and continuously, but in a series of local displacements called Barkhausen jumps, resulting from local pinning of the walls by magnetostatic and magnetoelastic forces. In an electrically conducting material, domain-wall motion is further limited by the fact that wall motion causes a local change in magnetic induction, and this change in induction generates local voltages (by Maxwell's equations) which in turn drive local *eddy currents*. These eddy currents dissipate energy by generating heat, and act to retard domain-wall motion. In electrically insulating materials, this effect is practically absent, although at higher frequencies there are energy losses associated with the rapid change in the direction of magnetization.

At high fields, as the magnetization approaches saturation, the magnetization process consists primarily of the slow rotation of the local magnetization away from the local easy direction toward the direction of the applied field. This is a basically reversible process, which causes very little energy loss.

3. TECHNICAL MAGNETIC PROPERTIES

3.1 Remanence

The curve of magnetization versus field of a ferromagnet or ferrimagnet is not only nonlinear (Fig. 11) but also irreversible (Fig. 12). When a magnetic material is saturated, and the field is then removed, some magnetization remains when the field is zero. The remaining magnetization is called the remanence M_r; it is often expressed as the remanence ratio M_r/M_s. In permanent magnets and in magnetic recording materials, high remanence is desirable; in materials for ac applications such as motors and transformers, low remanence is usually wanted.

3.2 Coercive Field (Coercive Force)

Since the magnetization is not zero when the field is zero (Fig. 12), it is necessary to apply a negative or reverse field in order to make the magnetization zero. The negative field required to reduce the magnetization to zero is called the coercive field or coercive force H_c (regarded as a positive number).

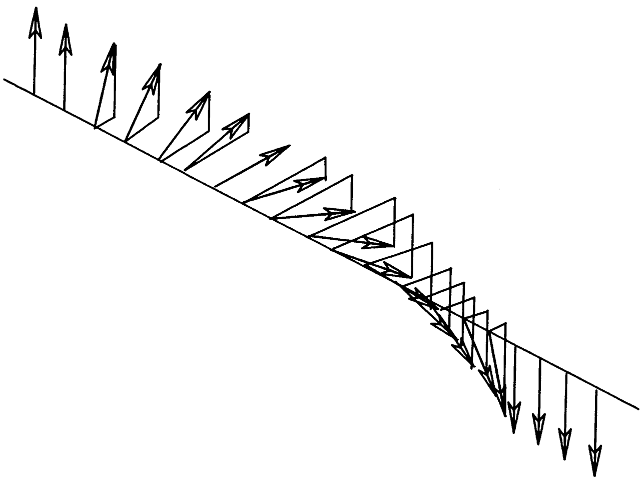

FIG. 10. Arrangement of atomic moments through a 180° domain wall.

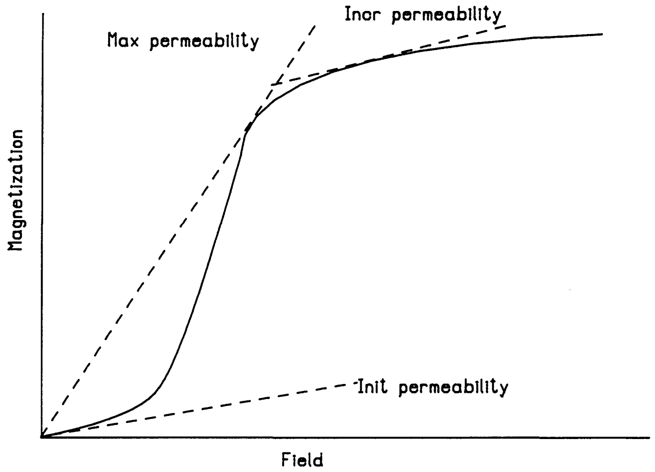

FIG. 11. Magnetization curve (B vs H) showing initial permeability, maximum permeability, and incremental permeability.

Strictly, this quantity is the intrinsic coercive field H_{ci} or H_c^i. The ordinary or normal coercive field H_c is the field required to reduce the magnetic induction $B = H + M$ to zero. (We ignore the complexities of magnetic units here.) Except in permanent-magnet materials, H is generally small compared to M, and the distinction between H_c and H_{ci} is unimportant. In permanent magnets, however, H can be comparable to or larger than M, and H_c and H_{ci} can be very different. H_{ci} is always larger than H_c.

3.3 Permeability

If a magnetic field is applied to a demagnetized sample (that is, a sample whose net magnetization is zero), the resulting curve of B vs H is known as the magnetization curve. There is a small field region over which the induction varies nearly linearly and reversibly with field. The slope of this region is known as the initial permeability, μ_0 (note that this is not the magnetic constant, for which the same symbol is used). With increasing field, the magnetization rises rapidly and irreversibly. The maximum slope of a line joining the origin and the magnetization curve is the maximum permeability $\mu_{\max}$, sometimes called simply the permeability. This is the quantity often used as a measure of magnetic quality for soft magnetic materials, although it is seldom directly useful in design. At any point on the magnetization curve, a small ac field may be applied, and the slope of the resulting minor loop is the

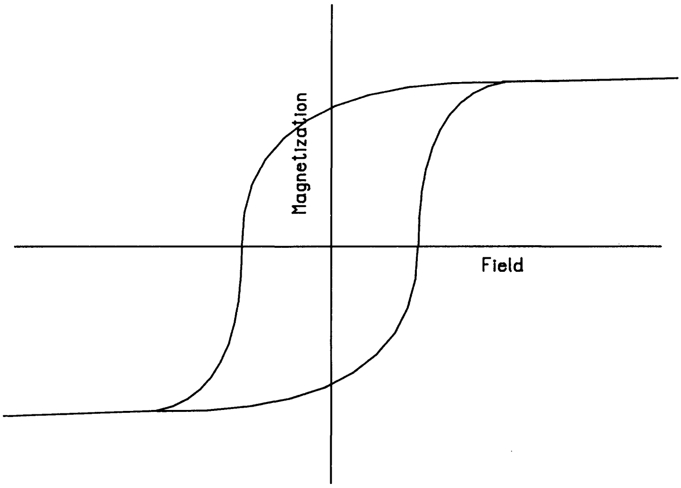

FIG. 12. Hysteresis loop of a ferromagnetic or ferrimagnetic material.

incremental or reversible permeability, μ_i. These quantities are shown in Fig. 11.

3.4 Hysteresis Loop and Power Loss

Work must be done in order to magnetize or demagnetize a magnetic material. The area enclosed by the hysteresis loop (Fig. 12) is proportional to the energy lost as heat when the material is magnetized to saturation alternately in the positive and negative directions. This energy loss is of primary importance in many ac applications of magnetic materials. The energy lost as heat reduces the efficiency of the device, and the heat may cause a local rise in temperature that is damaging.

The hysteresis loop is usually measured slowly, giving what is called a dc loop, but it may be measured at any desired frequency. The loop changes shape as the frequency is increased, notably by an increase in the coercive field and consequently of the enclosed area. This effect is especially marked in electrically conducting materials, because the energy lost to eddy currents increases as the frequency increases.

Most of the useful information about the magnetic properties of a ferromagnetic or ferrimagnetic material is contained in the hysteresis loop. The fact that the magnetization is both nonlinear and irreversible makes the behavior of magnetic materials difficult to handle mathematically, either analytically or by computer approximation.

3.5 Energy Product

A useful and widely used figure of merit for permanent-magnet materials is the maximum energy product $(BH)_{\max}$. It is defined as the area of the largest rectangle under the B vs H hysteresis loop in the second quadrant ($M > 0, H < 0$). The second quadrant is important because permanent magnets are always used to create a magnetic field in space, and therefore always operate in the presence of their own demagnetizing field. The maximum energy product defines the amount of magnetic material needed to create a given field in a given volume of space. Higher energy product means less material is required.

4. ENGINEERING MAGNETIC MATERIALS

4.1 Soft Magnetic Materials

This class of materials is used where the magnetization is required to change frequently in magnitude and/or direction; these uses are broadly considered ac applications. Examples are transformers, motors, generators, tape recorder heads, microwave equipment, and many other items. The name "soft" derives from the fact that the original material for this class of use was a mechanically soft, relatively pure iron, as opposed to the first permanent magnets, which were hardened steel. The terminology is no longer correct in its original sense, because there are mechanically hard materials that are magnetically soft, and also moderately soft and ductile materials that are magnetically hard.

A soft magnetic material has a low coercive field, and so it can be magnetized and demagnetized easily. This naturally leads to a hysteresis loop with small enclosed area, which means a small loss of energy in the form of heat during each magnetization cycle. The desired value of remanence may be large or small depending on the application. These requirements are met when the domain walls can move as freely as possible. This is accomplished by making the material of high purity and large crystal or grain size, and avoiding mechanical stresses or plastic strain. If the material has nonzero crystalline anisotropy, the use of a preferred anisotropy, or crystal texture, is desirable; in such a material, the individual crystals are not oriented at random, but the magnetic easy directions are preferentially aligned in the direction of the desired magnetization when the material is in use. This is not always easy or practical, but is done on a large scale in the production of high-quality transformer steel, consisting of Fe plus about 3 wt. % silicon.

It is also desirable to have the electrical resistivity as high as possible. This reduces the power losses due to circulating electric eddy currents. Metallic materials for ac use are always in the form of electrically insulated sheets or laminations, arranged with the sheets parallel to the direction of magnetization. Since the eddy currents flow perpendicular to the direction of magnetization, the layered structure interrupts the current path and reduces the eddy-current loss. Electrically insulating magnetic materials, known generically as ferrites, do not need to be laminated and are used as solid blocks.

Table 1 gives typical values for saturation induction (flux density) and coercive field for several common soft magnetic materials.

4.1.1 Iron and Steel The cheapest soft magnetic material is commercially pure iron, or very low-carbon steel. It is used when cost is a major consideration, or when efficiency is not important. The latter condition may apply, for example, in very small motors or in motors that operate only occasionally (like vacuum cleaners for home use). Higher-quality grades of magnetic steel contain added silicon, to increase the electrical resistivity; the upper limit of silicon content (about 3%) is set by the increasing brittleness of the steel as silicon is added. The best grades of magnetic steel are treated in a fairly elaborate series of rolling and annealing treatments to develop a preferred crystallographic orientation; this material is known as grain-oriented steel. The usual production processes for this material result in a very large grain or crystal size in the sheet; this is undesirable because it leads to a large magnetic domain size, and increases the alternating-current losses. This can be overcome by "laser scribing," which consists of rastering a fine laser beam over the sheet, creating a series of fine lines on the surface of each grain that act as nucleation sites for domains.

4.1.2 Nickel-Iron Alloys (Permalloys) Better soft magnetic properties are obtained in the nickel-iron alloys, known by their original trade name of Permalloy. There are two families of permalloys, one containing approximately equal amounts of iron and nickel, the other containing about 75%Fe-25%Ni. Both may contain small amounts of additional elements, to increase resistivity or control chemical ordering. The magnetic properties of these alloys depend quite sensitively on the details of their heat treatment, and they are mechanically soft and easily damaged by bending or other deformation.

Table 1. Soft magnetic materials (representative values).

Material	B_{sat}(T)	H_c (A/m)
Iron (commercial purity)	2.17	80
Steel (low carbon)	2.17	100
3% silicon steel (unoriented)	2.0	40
3% silicon steel (oriented)	2.0	8
Permalloy (79% Ni, 17% Fe, 4% Mo)	0.8	1
MnZn ferrite	0.4	5
NiZn ferrite (high electrical resistivity)	0.3	80
Amorphous $Fe_{81}B_{13.5}Si_{3.5}C_2$ (Allied Corp Metglas 2605SC)	1.6	3

4.1.3 Glassy Metals or Amorphous Alloys A relatively small number of metallic alloy compositions may be made in the form of noncrystalline, or amorphous, material. These are solids in which the atoms are not arranged in a regular crystal structure, but are densely packed in a random structure; these materials are also known as glassy metals. A number of these alloys containing large fractions of Fe or Co are ferromagnetic, and have useful magnetic properties. They have the general composition $(TM)_xM_{1-x}$, where TM represents one or more of the transition-metal elements, and M represents one or more of the metalloid or glass-forming elements, such as B, Si, C, or P. The value of x is in the range of 75 to 85 at. %. A widely used composition is $Fe_{78}Si_{10}B_{12}$, which combines relatively high magnetization with low losses, and is used in power transformers. The composition $(Co_{93}Fe_7)_{80}(SiB)_{20}$ has lower magnetization but near zero magnetostriction, and is superior for some applications.

These materials are made by rapid solidification: a pool of liquid alloy is cooled by a rapidly rotating cold metal wheel, which carries with it a thin layer of solid alloy. The resulting strip is about 25 μm thick and may be 10 cm or more in width. The electrical resistivity is many times higher than that of iron. Since these materials have no crystal structure, they have no crystal anisotropy, although they do develop a small but significant anisotropy when annealed in a magnetic field. The combination of high electrical resistivity and small thickness leads to very low power losses under ac excitation. They are, however, relatively costly and tend to be brittle after annealing; also the small thickness makes them difficult to use in some conventional manufacturing operations.

4.1.4 Ferrites The ferrimagnetic spinels known as ferrites have relatively low magnetization, but are electrical insulators. They are used exclusively for high-frequency applications where the power losses in metallic materials would be intolerable. These are ceramic materials, prepared by pressing powders into the desired shape and then sintering at high temperature to bond the particles together by solid-state atomic diffusion. By long experience, a relatively small number of compositions have emerged as standard, although variations in preparation conditions can influence the magnetic properties in useful ways.

4.2 Hard Magnetic Materials

Table 2 lists representative values of magnetic properties of some well-known hard magnetic materials. They are discussed in more detail in the following sections.

4.2.1 Alnico The first widely used permanent magnets (aside from naturally occurring magnetite lodestones) were hardened steels of various compositions. They were bulky and not very stable in their magnetic properties, and were quickly replaced when better materials became available.

The first of these better materials emerged in the 1930s from experiments on Fe-Ni-Al alloys intended as high-temperature structural materials. Eventually there resulted a family of materials known as the Alnicos, containing iron plus aluminum, nickel, and cobalt (AlNiCo), plus often other elements such as Ti or Zr. These are brittle multiphase alloys, made usually by casting but sometimes by powder compaction and sintering. They are much superior to steel in their permanent-magnet properties, but have now largely been replaced by newer materials except (because of their relatively high Curie temperatures) in applications where the magnetic properties must be maintained at temperatures above room temperature.

4.2.2 Hard Ferrites The most widely-used permanent-magnet materials are a family of ferrimagnetic oxides with hexagonal crystal structure and the general composition $MFe_{12}O_{19}$ (M = Ba or Sr), known generically as hard ferrites. They have high coercive fields, but relatively low magnetization, and they are low in cost. They are used in most loudspeakers, small motors, holding magnets, etc., unless the special properties of more expensive materials are required.

4.2.3 Rare-Earth Compounds The rare-earth elements became available in industrial quantities as a result of research carried out during World War II, and it was quickly established that many of these elements are strongly magnetic with large anisotropy. Their Curie temperatures are all below room temperature, and so they are not useful as magnetic materials in pure form. However, there are numerous binary and ternary intermetallic compounds of the rare earths with transition metals and other elements, some of which are ferromagnetic with Curie temperatures substantially above room temperature. Of these, a few have large positive crystal anisotropy, and can make excellent permanent magnets. There are three major families of rare-earth permanent magnets, based on the compounds $SmCo_5$, Sm_2Co_{17}, and $Nd_2Fe_{14}B$ (Sm is samarium and Nd is neodymium).

All three of these materials are magnetically superior to any of the previously available permanent magnets. Their only serious disadvantage, aside from cost, is their relatively low Curie temperature. This means that

Table 2. Hard magnetic materials (representative values).

Material	B_r (T)	H_c (kA/m)	$(BH)_{max}$ (kJ/m^3)
Cobalt steel	1.0	12.5	6
Alnico (isotropic)	0.6–0.8	60–100	40–60
Alnico (anisotropic)	1.1–1.4	60–120	50–70
Ba or Sr ferrite	0.43	180–240	35
$SmCo_5$	0.85	650	150
Sm_2Co_{17} [$Sm_2(Co_{.68}Cu_{.10}Fe_{.21}Zr_{.01})_{14.8}$]	1.1	525	250
$Nd_2Fe_{14}B$	1.25	900	300

their magnetic properties are fairly sensitive to temperature, degrading as the temperature rises. This problem is the most serious with $Nd_2Fe_{14}B$, which is otherwise the best and cheapest of the rare-earth magnets. The Curie temperature can be raised by replacing Fe with Co, but this unfortunately lowers the coercive field. NdFeB magnets are also susceptible to corrosion in humid atmospheres, but various protective schemes can be used to minimize this problem.

These materials are produced by pressing and sintering (heating below the melting point) small particles at high temperatures. The particles may be produced in various ways, but commonly are mechanically ground from bulk materials. The NdFeB magnets may also be made from flake material made by a rapid-quenching process (see Sec. 4.1.3).

4.2.4 Bonded Magnets All of the common permanent-magnet materials are mechanically hard and brittle. Simple shapes can be made by pressing and sintering (or by casting in the case of Alnico), but complex shapes can only be made by abrasive cutting and grinding. This is slow and expensive, and so in cases where the highest magnetic properties are not required, either ferrite or rare-earth permanent magnets may be ground into coarse powders and embedded in a matrix of a rigid or flexible polymer. These bonded magnets are easily molded by standard polymer equipment, and are furthermore not subject to breakage. Bonded magnets can also be made by embedding magnetic particles in a metal matrix.

4.3 Information Storage Materials

Conventional magnetic recording, as used in audio and video cassettes and in hard and floppy computer disks, employs a highly localized magnetic field produced by a *recording head* to magnetize a small region on a magnetically coated tape or disk. When the magnetized region is moved past a *playback head*, the local magnetization induces a voltage in a coil on the head, which is amplified to recreate the recorded signal. The same basic system is used for both analog and digital recording. The recording and playback heads (sometimes both functions are combined in a single head) must be magnetically soft materials with good wear resistance: ferrites, Permalloys, and amorphous alloys have been used. The recording material must have a low enough coercive field to be magnetized by the field from the recording head, and a high enough coercive field to retain its magnetization in the presence of negative fields (from the surroundings, or from neighboring magnetized regions). Thus properties intermediate between the usual soft magnetic and hard magnetic materials are required.

4.3.1 Particulate Media The commonest material for both audio and digital recording is an assembly of small particles of γ-Fe_2O_3, a metastable oxide prepared by a complex series of chemical steps. The particles are irregular elongated single crystals, about 100 nm long and 20 nm in diameter. They are embedded in a polymer matrix on a flexible or rigid substrate to make recording tape, floppy disks, or rigid (hard) disks. For increased coercivity, the particles may be given a surface coating containing Co ions.

Particles of other compositions are sometimes used, including chromium dioxide (CrO_2) and metallic Fe or FeCo. For high-density digital recording, particles of the hard magnetic oxide barium ferrite can be used. The recording characteristics of the various materials are different, so that they cannot be used interchangeably.

4.3.2 Continuous Media In order to obtain higher recording densities (more information in less space), continuous metal films, produced by vapor deposition in a vacuum chamber, may also be used for video and digital recording. Alloys of Co and Cr are usually employed for video tape, and Co-P or CoNi-P alloys for digital recording.

4.3.3 Magneto-optical Materials The demand for even higher storage densities has led to the development of optical and magneto-optical digital information storage. Pure optical storage (as in the audio or video compact disk) does not use magnetic materials and is not properly part of this article, but magneto-optical storage is a close relative. In this system, bits of digital information are written onto a magnetic film by pulses of laser light, which locally heat the storage material through its Curie temperature or compensation temperature, after which it cools in a controlled magnetic field.

Reading the stored information is done with a lower-power laser beam: the plane of polarization of the reflected laser light is rotated clockwise or counterclockwise depending in the direction of magnetization of the recorded bit. This optical phenomenon is known as the magnetic Kerr effect. This system has the advantage that only a tiny laser beam affects the magnetic recording material; there is no mechanical contact with a recording head and consequently no friction or wear. The recorded track is also much narrower than in conventional recording with a head, which permits much higher storage densities. The major problems with this system are concerns about the stability of the recording material after many cycles of recording, and the fact that erasing and recording are significantly slower than reading the stored information. A variety of materials have been suggested and tried for magneto-optical recording, and the best material is not yet established. Commercial systems using magneto-optical recording are just becoming available at the time of this writing (1992).

GLOSSARY

Antiferromagnet: Material in which the atomic moments are aligned antiparallel, so that no net magnetization results.

Anisotropy (Magnetic): Directional dependence of magnetic properties, due to sample shape, crystal structure, or stress.

Coercive Field (Coercive Force): Field necessary to reduce the magnetic induction (H_c) or magnetization (H_{ci}) to zero, after applying a saturating field.

Curie Temperature: Temperature at which the saturation magnetization drops to zero.

Diamagnet: Material that has no magnetization in the absence of a field, and develops a weak negative magnetization in an applied field.

Domain (Magnetic): Region in which all the atomic moments are aligned along a single axis.

Domain Wall: Boundary between two domains having different alignment directions.

Energy Product: Quality measure of a permanent magnet material, given by the area of the largest rectangle inscribed under the second quadrant of the hysteresis loop.

Ferrimagnet: Material in which the atomic moments are aligned antiparallel, but do not cancel because the number and/or magnitude of opposing moments is not equal; may show strongly magnetic behavior.

Ferromagnet: Material in which all atomic moments are or can be aligned parallel; may have magnetization in the absence of a field; shows strongly magnetic behavior.

Hysteresis Loop: Plot of magnetic induction or magnetization against field, as the field is cycled from positive to negative values; the area enclosed by the loop is proportional to the energy lost as heat.

Magnetostriction: Change in dimensions of a material when the direction or magnitude of its magnetization is changed.

Néel Temperature: Temperature at which an antiferromagnet loses its magnetic ordering.

Paramagnet: Material that has no magnetization in the absence of a field, and develops a weak positive magnetization in an applied field.

Permeability: Ratio of magnetic induction to field, under some specified condition; if not otherwise specified, usually the maximum value of permeability.

Remanence: Magnetization or induction remaining at zero applied field after applying a saturating field.

Saturation Magnetization: Limiting value of magnetization reached in a strong applied field; value depends on temperature.

INTRODUCTION: ORDERED MAGNETIC STRUCTURES

In no other branch of condensed-matter physics has there been such a proliferation of new ground states as has been observed in studies of magnetic order in recent decades. Until 1932, when Néel postulated the existence of antiferromagnets, ferromagnetism enjoyed its solitary glory, but when neutron scattering made possible the investigation of detailed magnetic moment structures and their excitations, the real proliferation began. In the pure rare-earth metals alone there are helices, fans, cones, and *c*-axis modulated structures; and more structures can be added to the list if one includes the alloys and intermetallic compounds of the rare-earth metal. In all of those the moments that order are associated with electrons in inner shells localized on the atoms, but the itinerant 3*d* electrons of the metals of the first transition group made their own novel contribution when Cr justified Overhauser's prediction that a band of such electrons could prove unstable against the formation of a spin-density wave, with a wave vector incommensurate with the lattice periodicity and dictated by dimensions of the Fermi surface.

The richness of magnetic ordering phenomena, especially when one considers also the nature of the low-lying excitations and the character of the transition from the high-temperature disordered state, makes the field a happy hunting ground for theoretical physicists eager to try out the latest weapons in their conceptual and mathematical armories. In this article, in an encyclopedia of applied physics, however, it seems more appropriate to present mainly the experimental situation and the general concepts that provide some order (in the simplest sense) to what might otherwise seem to be a confusing and arbitrary collection of phenomena.

The principal ground states with which we are concerned are the following:

Ferromagnetism—Spontaneous parallel alignment of atomic moments (normally constrained by magnetocrystalline anisotropy to lie in some specific crystallographic direction). Parameters of interest are the size of the atomic moments, the Curie temperature above which order is destroyed, and the orientation of the moments in the crystal. We deal in a later section with the domain theory required to explain the nature of the room-temperature "demagnetized state" of iron.

Antiferromagnetism—Ordering of magnetic moments on sublattices such that the net magnetization vanishes. The simplest such

digital Encyclopedia of Applied Physics

structures are those where the moments are arranged on crystal lattices like the simple cube or body-centered cube such that all moments that are nearest neighbors of a given up moment have their moments pointing down. However, even within the family of antiferromagnets that can be analyzed in term of sublattices a huge variety of structures is possible, including alternating planes of up and down moments and even a tetrahedral subdivision of the face-centered cubic lattice such that the moments of all four atoms constituting the basis $(0,0,0;\ 0,\frac{1}{2},\frac{1}{2};\ \frac{1}{2},0,\frac{1}{2};\ \frac{1}{2},\frac{1}{2},0)$ point toward the center of the tetrahedron they define. It is clear that the magnetic symmetry will in general differ from the lattice symmetry; the monatomic bcc antiferromagnetic is clearly only simple cubic with a basis, since the atom at $\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$ is no longer the same as that at the origin.

Ferrimagnetism—A structure that is basically antiferromagnetic but where two sublattices carry different numbers of atomic moments, or moments of different sizes, so that in the ordered state a net magnetization remains. The name derives from the family of ferrites $MO \cdot Fe_2O_3$, of which magnetite Fe_3O_4 is the most famous example.

Helimagnetism and related structures—The wide variety of magnetic structures found in the rare-earth metals and their alloys, which was referred to above. Some of the relevant structures are shown in Fig. 1, and full details are given in various chapters in Wohlfarth (1980). These structures arise because the atomic moments are provided by well-localized $4f$ electrons (see Sec. 2), which can only couple via the conduction electrons (see Sec. 5). Their wave-vector–dependent susceptibility, $\chi(q)$, in conjunction with the character of the $4f^x$ state imposed by the crystal fields, dictates the magnetic structure.

Spin-density waves—Just as ferromagnetism can be associated with either localized or itinerant (band) electrons, so can antiferromagnetism. The sublattice approach described above encourages a local-moment viewpoint, but the itinerant $3d$ electrons of chromium sustain spin-density waves such that at any point in the crystal there is a net spin, the difference between spin-up and spin-down local densities. In some dilute alloys of

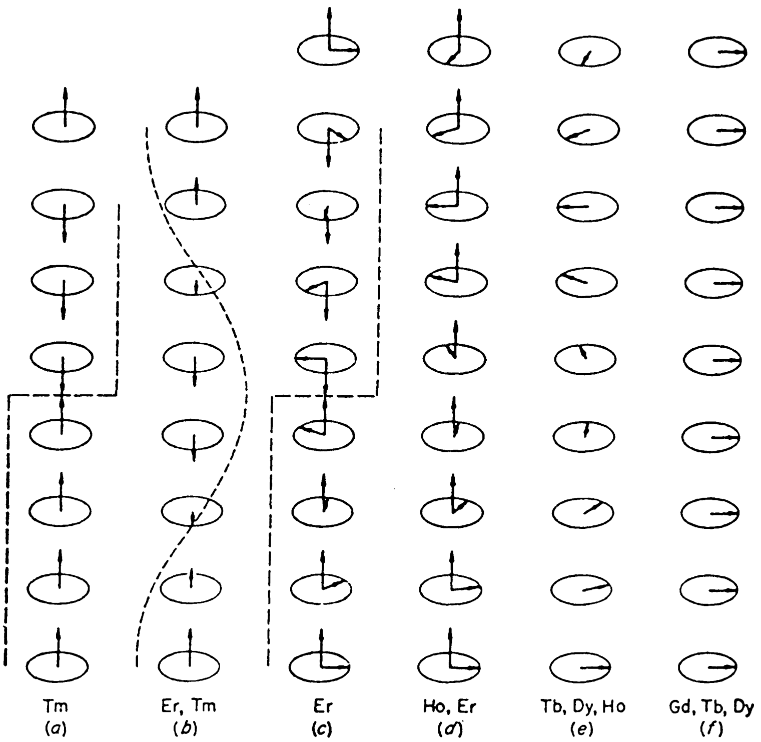

FIG. 1. Magnetic structures of the heavy rare-earth metals (after Koehler, 1972).

other metals in chromium the maximum in spin-up density is at the 0,0,0 position and the maximum in spin-down at $\frac{1}{2},\frac{1}{2},\frac{1}{2}$, and the structure is described as commensurate. Neutron diffraction then shows scattering intensity at the Bragg peaks such as (100), (111), etc., which would not be seen for body-centered cubic symmetry. In pure chromium, however, the wave vector of the magnetic modulation differs slightly from the lattice vector and satellite peaks appear in the neutron diffraction pattern; the structure is then described as incommensurate. (It can be recalled that in many of the helimagnetic rare-earths incommensurate structures are found, although the dominant ordered moments are localized.). Incommensurate structures have also been found in heavy-fermion intermetallic compounds (see HEAVY-FERMION PHENOMENA) with small ordered moments in narrow bands.

Spin glasses—Intensive studies have been made in recent years of the magnetic ground states associated with magnetic moments in amorphous materials or distributed at random over some points of the lattice of a nonmagnetic host. If, as they normally do, the interactions between the moments have both ferromagnetic and antiferromagnetic signs, the ground state, when the material is cooled in zero field below some temperature characteristic of the mean interaction strength, will have no net magnetization, but cannot show the sublattice structure of a conventional antiferromagnet. It is not clear whether this state, in which the moments are frozen, but frozen at random in one of a large number of possible configurations of similar free energy, should be regarded as "ordered"; and arguments continue about the nature of the transition from the paramagnetic state. Recent reviews are given by Binder and Young (1986) and Mydosh (1993). It is clear that if all interactions were ferromagnetic the randomness essential to spin-glass behavior would not prevent ferromagnetism; the other essential ingredient is the competition between ferro- and antiferromagnetic interactions.

1. THE NATURE OF THE ORDERING MOMENTS

In the above discussion of ordered magnetic structures the object becoming aligned was referred to as a magnetic moment, although it became a "spin" in the discussion of itinerant antiferromagnets. The use of "spin" and "moment" as synonyms is common in the magnetic literature, but is not of universal correctness. The origin lies in the evidence that the angular momentum that yields the magnetic moment of iron, like that yielding the moment of a free electron, is the spin angular momentum. More generally the magnetic moment μ of an atom is given by $g_J\sqrt{J(J+1)}\mu_B$, where μ_B is the Bohr magneton, the atomic unit of magnetic moment of size 9.27×10^{-24} J/T, J is the total angular momentum in units of $\hbar$, and g_J is the Landé spectroscopic g factor that takes into account the fact that J can have contributions from both the orbital angular momentum vector (**L**) and the spin angular momentum vector (**S**) and that the latter produces twice as much magnetic moment per unit of angular momentum as the former. Thus

$$g_J = \frac{3}{2} + \frac{S(S+1) - L(L+1)}{2J(J+1)}, \tag{1}$$

which is 1 for $S = 0$ and 2 for $L = 0$.

In materials where atomic or ionic magnetic moments do not interact, the moment given above is the quantity entering the expression for the magnetic susceptibility and is often called the effective moment, μ_{eff}, since the low-field susceptibility, which in the classical Curie-law expression was $N\mu^2/3k_BT$, becomes $N\mu_{\text{eff}}^2/3k_BT$ in a quantum-mechanical treatment. (N is simply the number of magnetic atoms or ions per unit volume.) This topic is discussed in detail in the article PARAMAGNETISM, and here we need only note that in most solid compounds of the $3d$ transition elements, strong crystal fields quench the orbital contribution to μ_{eff}, so that the moments responding to external fields or interacting with one another are "spin-only" moments; while in solids containing $4f$ elements crystal fields are in general smaller than spin-orbit interactions. One can then have situations where, at low temperatures, crystal field splittings, k_BT, and moment-moment interaction energies can be comparable, so that ordered moments have to be considered carefully. Compounds containing actinide ($5f$) elements that order magnetically are still more complicated, for while metals and alloys of the $3d$ elements are generally most appropriately treated with band models, and $4f$ elements with local-moment models, $5f$ electrons may display different characters, depending both on the element concerned and on those with which it is combined.

In transition-metal atoms the electrons in the partly filled shell are d electrons ($l = 2$) so that the effective moments are as shown in Fig. 2 for free atoms or ions, while for the rare-earth elements with $4f$ electrons ($l = 3$) they are as given in Fig. 3.

Even for noninteracting moments two complications to the above picture can arise. One arises from the effects of crystalline electric fields, and is so important in solids containing $3d$ atoms that the orbital moment is normally quenched and the effective moment is given by setting $J=S$ and $g_J = 2$, with the results shown in Fig. 2, since by Hund's rule S always takes its maximum possible value. For the rare-earth elements spin-orbit interactions are normally appreciably larger than either crystal field effects or k_BT, and μ_{eff} has to be calculated (for higher temperatures) by applying all Hund's rules to obtain the values of S, L, and J, but in a few cases the spin-orbit levels are separated by energies comparable with k_BT and J states other than the ground state play a role, which is most apparent when $J = 0$ for the ground state as in Eu^{3+}, since that would yield diamagnetism without the admixture in applied fields of contributions from higher states.

2. INTERACTIONS BETWEEN MOMENTS

The temperatures below which magnetic order is found vary enormously from very low values to temperatures above 10^3 K, but it is immediately clear that very rarely is the responsible interaction a simple magnetic dipole interaction, since the strength of such an interaction between moments at normal in-

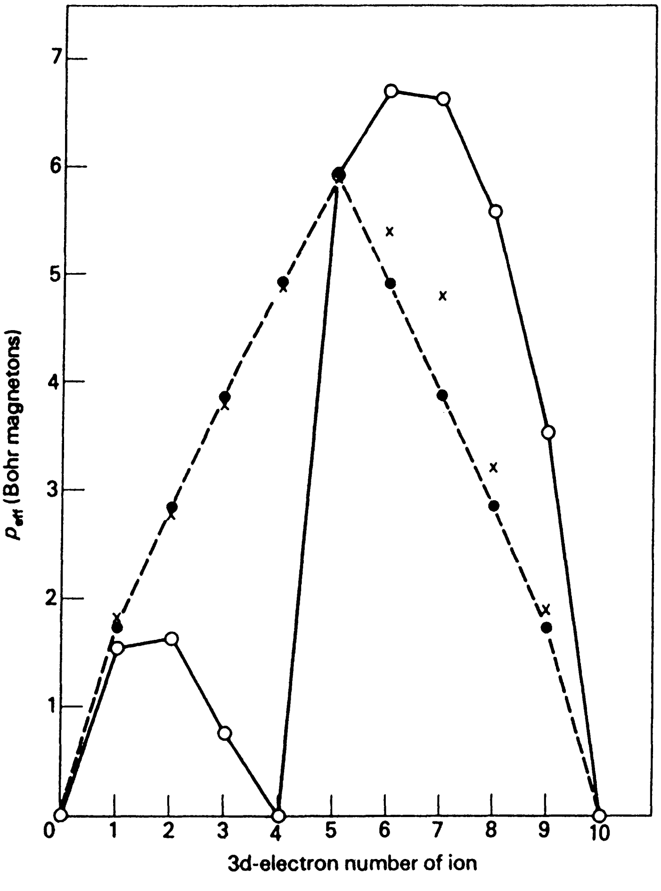

FIG. 2. The effective moments [expressed as $p_{\text{eff}}(= \mu_{\text{eff}}/\mu_B)$] for ions of the $3d$ series. ×, experimental values for salts. ○, theoretical values for full J; ●, theoretical spin only values.

teratomic distances would yield ordering temperatures well below 1 K. The origin of interactions is instead the effect described as *exchange interaction*. This has its origin in Coulomb interactions between electrons, which in combination with the Pauli principle can favor either parallel or antiparallel moment alignment depending on the nature of the electron states. The situation is complicated by the fact that the concept of an exchange integral $\mathcal{J}$ emerged first in the Heitler-London treatment of the hydrogen molecule where $\mathcal{J}$ is negative, favoring antiparallel spins of the two electrons in the lowest energy (bonding) molecular orbital. In the carbon atom, however (with configuration $1s^22s^22p^2$), the Coulomb energy is reduced if the two *p* electrons occupy different atomic orbitals and Hund's rule makes the state of parallel spins lowest in energy. The same holds for two of the *p* electrons of the oxygen atom ($1s^22s^22p^4$).

The simplest object where this effect leads to alignment (positive $\mathcal{J}$) between spins on different atoms is the oxygen molecule O_2. Here bonding *molecular* orbitals are occupied by pairs of electrons with opposite spins, but two electrons remain to be placed in the two antibonding π orbitals and will reduce the Coulomb energy by occupying different orbitals with the parallel spins required by Hund's rule. (A complete treatment of correlation efforts justifies this empirical rule that the triplet state is lower in energy for two electrons in different orbitals.) The resultant magnetic moment makes oxygen gas paramagnetic. (In solid oxygen these moments take up an antiferromagnetic structure through a somewhat more complicated exchange interaction.) It may be noted that the traditional 3*d* ferromagnetic metals, Fe, Co, and Ni, have nearly full 3*d* bands where the highest-energy electrons occupy states of antibonding character. Unlike the O_2 situation, however, these electrons are now in energy bands and ferromagnetism occurs only if the exchange-energy gain is not offset by the need for the electrons yielding the net spin to occupy slightly higher energy states in the band.
]

We have seen how intra-atomic exchange gives a net moment to carbon and oxygen atoms, and the largest spin state is found for the Gd^{3+} ion ($4f^7$) where all seven spins are aligned (and $L = 0$). In gadolinium metal these electrons form part of the ion core (inside the $5s^25p^6$ full subshells) and cannot yield direct interatomic exchange interactions, so that the ferromagnetism of Gd has to be ascribed to *indirect exchange*. Here the polarization of the conduction electrons (in states derived from 6*s* and 5*d* atomic levels) by exchange interaction with a given $4f^7$ moment propagates through the lattice to couple neighboring moments. As with the well-known Friedel *charge*-screening clouds around impurities in metals, this *spin* polarization of the conduction electrons falls off with distance from the local moment and oscillates in sign, so that the effective interaction between two local moments in a bath of conduction electrons can be ferromagnetic or antiferromagnetic.

A final type of exchange of great importance in magnetic oxides is termed *superexchange*. In its simplest form this couples (antiparallel) the spins of two 3*d* ions (e.g., Fe^{2+}) through an intermediate O^{2-} ion. An up-spin 3*d* moment (unshielded by 4*s* electrons) produces an imbalance between the up-spin and down-spin charge clouds of the oxygen 2*p* electrons, the down spins being slightly pushed away toward the other 3*d* ion whose spin they align with their own.

Although it is a topic of rather specialized interest, mention might be made at this point of *nuclear magnetic ordering* where the moments interacting are those given by the spins of nuclei. These moments are smaller by factors of $\sim 2 \times 10^3$ than electronic moments, and no exchangelike mechanism is normally present, so that ordering occurs only at very low temperatures ($\sim 10^{-7}$ K). It has, however, been detected in a number of substances, including metallic copper, where the dipole interaction is assisted by indirect interaction through the conduction electrons. The latter is a Ruderman-Kittel interaction like that which couples the local 4*f* moments in Gd metal, but here the necessary coupling between the nuclear moment and the conduction electrons is the much weaker hyperfine interaction.

3. MOLECULAR FIELD MODELS, MAGNETIZATIONS, AND SUSCEPTIBILITIES ABOVE ORDERING TEMPERATURES

The original Weiss theory of ferromagnetism involved the phenomenological introduction of a molecular field $H_{\text{eff}} = N_W M$ where M is the magnetization and N_W is the molecular field coefficient. If the field acting on the moments is regarded as $\mathbf{H}_{\text{ext}} + \mathbf{H}_{\text{eff}}$ the susceptibility can be calculated by assuming that this is the field to be put into Curie's law $M/H = C/T$. (We have mentioned that C, which was $N\mu^2/3k_B$ in a classical treatment, becomes $N\mu_{\text{eff}}^2/3k_B$ in correct treatments of the low field susceptibility. For a further treatment see PARAMAGNETISM.)

Thus we have

$$M/(H + H_{\text{eff}}) = C/T, \tag{2}$$

so that χ ($= M/H$) is given by

$$\chi = C/(T - N_W C), \tag{3}$$

and the quantity $N_W C$ is normally denoted θ and is called the Curie-Weiss temperature. Thus the susceptibility in this simple approach is expected to diverge as T is lowered to θ.

To examine the behavior at lower temperatures one needs the more complete treatment of paramagnetism that yields the expression

$$M = N g_J J \mu_B B_J(x)$$

where $B_J(x)$ (the Brillouin function) is given by

$$B_J(x) = \frac{2J+1}{2J} \coth\left(\frac{2J+1}{2J} x\right) - \frac{1}{2J} \coth\left(\frac{x}{2J}\right) \tag{4}$$

and $x = g_J J \mu_B H / k_B T$.

From Fig. 4, where we have plotted the spontaneous magnetization M_{sp} (for $H_{\text{ext}} = 0$) versus x with $H = N_W M$, (i.e., $M_{\text{sp}} = x \cdot kT / g_J J \mu_B N_W$), it is clear that below a certain temperature, when the straight line giving M_{sp} falls below the initial slope of the Brillouin-function expression for M, a finite value of

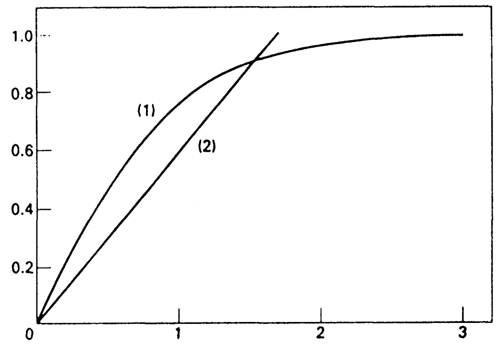

FIG. 4. Graphical solution for the spontaneous magnetization in the molecular-field model. The reduced magnetization M/M_{sat} is plotted as (curve 1) the Brillouin function of x ($= g_J J\mu_B H/kT$), (curve 2) H_{eff}/N_W, which for $H_{\text{ext}} = 0$ is linear in T and x.

M_{sp} is found for $H=0$. This spontaneous magnetization is plotted against T in Fig. 5, and it falls to zero at $T_c = N_W \mu_{\text{eff}}^2/3k_B = \theta$. This identity of T_c (the Curie temperature) and θ is a result of the mean-field treatment, and to explain the normally observed deviations of χ from $C/(T - T_c)$ just above T_c, account has to be taken of correlated fluctuations.

The approach to saturation at low temperatures ($M_s = Ng_J J\mu_B$)* is also not correctly given by the mean-field treatment for the same reason, and a spin-wave approach in that regime yields

$$M = M_0[1 - A(T/T_c)^{3/2}] \tag{5}$$

in good agreement with experiment.

As mentioned above, it was first pointed out by Néel that if a lattice of magnetic moments can be subdivided into two sublattices A and B with antiparallel interactions between them, a similar mean-field treatment, taking $H_{\text{eff A}} = H + N_W M_B$ and a corresponding expression for $H_{\text{eff B}}$, yields

$$TM_A = C'(H - N_W M_B) \quad \text{and}$$
$$TM_B = C'(H - N_W M_A), \tag{6}$$

giving

$$TM = 2C'(H - N_W M) \tag{7}$$

and

$$M(T/2C' + N_W) = H \tag{8}$$

---

[*] Note that this is not $N\mu_{\text{eff}}^2$, since the maximum value of J in the field direction is J, not $\sqrt{J(J+1)}$.

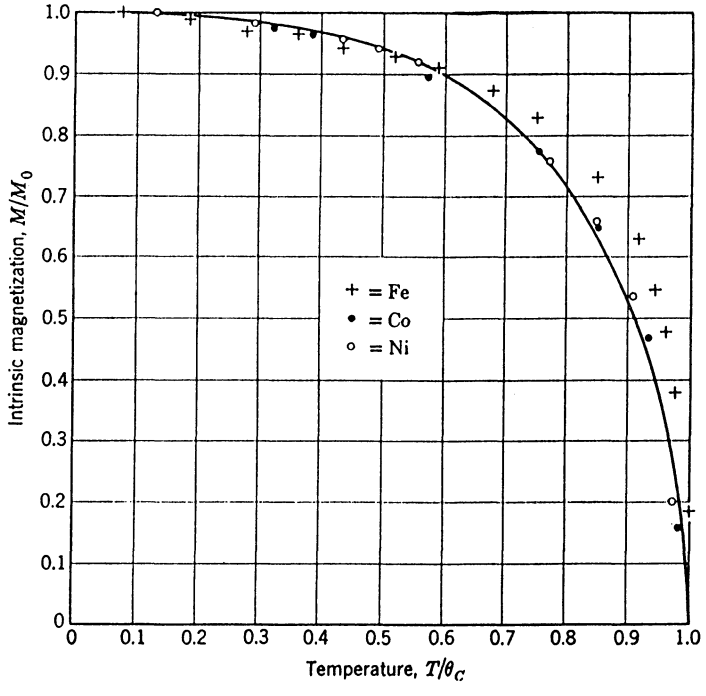

FIG. 5. The spontaneous (or intrinsic) magnetization given by molecular-field theory and the values for Fe, Co, and Ni.

so that, above the temperature of $C'N_W$, $\chi = 2C'/(T + \theta)$ where $\theta = N_W C'$.

Below a temperature T_N ($= C'N_W$) the sublattice magnetization of simple antiferromagnets is found by neutron scattering to follow the type of temperature dependence found for the spontaneous magnetization of simple ferromagnets. Since there is no net magnetization, the susceptibility is linear in field (for low fields), and its magnitude depends on the orientation of the field relative to the direction of the sublattice magnetization; $\chi_\parallel$ tends to zero as T tends to zero, and $\chi_\perp$ is only weakly T-dependent below T_N.

For both the ferromagnetic and antiferromagnetic cases it should be remembered that the linearity of $1/\chi$ with T will not be preserved if crystal-field-split levels have spacings comparable with T, and in some antiferromagnets with this character the ordered moments are given by the appropriate (to the symmetry) combination of M_J values that characterizes the ground state. When crystal fields produce a ground-state singlet i.e., a nonmagnetic atom) a complicated situation will exist with the possibility of magnetic order at low temperatures if the exchange interaction is larger than the excitation energy to higher crystal field levels.

4. MAGNETIC ORDER WITH ITINERANT ELECTRONS: BAND MAGNETISM AND SPIN DENSITY WAVES

Since it is known that the $3d$ electrons of Fe, Co, and Ni occupy bands in the metallic state, it is clear that the above local-moment treatment cannot be appropriate, although it should be remembered that not all the on-site correlations that provide the moments of ions of these elements in paramagnetic salts will be lost in the metallic state. Measurements of g factors show that in these metals the magnetic moments arise almost wholly from electron spin, and the saturation moments, expressed in Bohr magnetons, therefore give the number of unpaired electrons. The basic parameters are shown in the following table:

	Curie temperature (K)	Saturation moment (μ_B)
Fe	1044	2.22
Co	1398	1.72
Ni	627	0.61

In earlier work it was assumed that one-half (spin up) of the $3d$ band was fully occupied at spontaneous saturation at $T = 0$ and that the saturation moment gave the number of empty states in the spin-down band [Fig. 6(a)]. (It should be remembered that even this

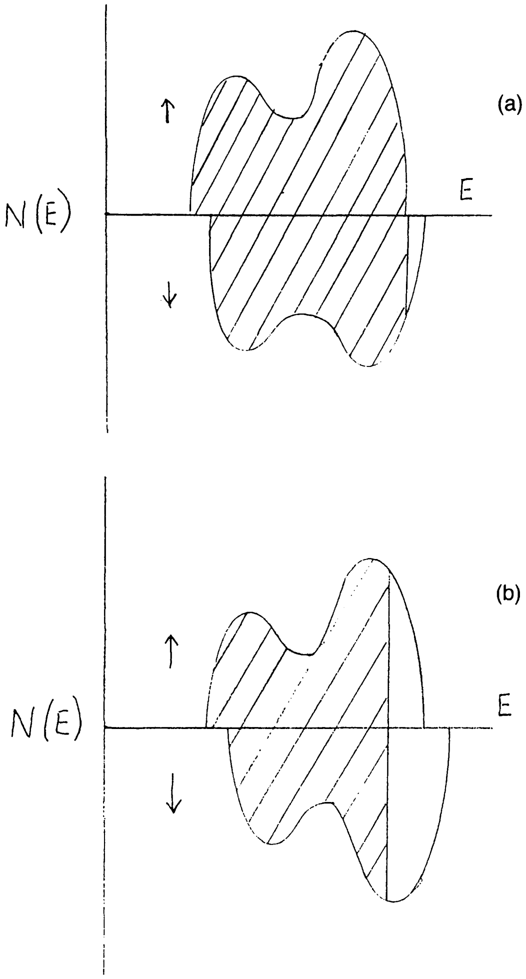

FIG. 6. Occupied and empty d-band states in ferromagnetic transition metals (schematic). (a) A "strong" (fully magnetized) metal, e.g., Ni; (b) a "weak" ferromagnetic, e.g., Fe.

need not be an integer since the 3*d* band overlaps a partly filled 4*s* band). It is now recognized that in Fe the Fermi surface lies in both spin bands, and the saturation moment is $(n_\uparrow - n_\downarrow)\mu_B$ where the *n*'s are the numbers of holes in the two half *d* bands [Fig. 6(b)]. For alloys between the 3*d* metals the maximum saturation moment is found at Fe 30% Co with $2.44\mu_B$. Figure 7 shows the so-called Slater-Pauling curve for binary alloys, and for the sequence Fe → Co → Ni → Cu this supports a collective *d*-band view of the electronic structures, which breaks down for such alloys as Co-Cr and Ni-Cr. It must also fail for Ni-Cu, since the termination of ferromagnetism at 60% Cu does not correspond to the filling of all 3*d* holes, and at higher Cu concentrations they are associated only with Ni atoms, but with $n_\uparrow = n_\downarrow$.

The theory of the $T = 0$ state of the itinerant-electron ferromagnets is now in a fairly satisfactory state (see Mattis, 1988), and the expression for the susceptibility,

$$\chi(0) = \chi_0(0)/[1 - I\chi_0(0)], \tag{9}$$

where $\chi_0(0)$ is the susceptibility at $q = 0$, which is a measure of the density of states that can be calculated from a good band-structure calculation, and I is the exchange energy, formalizes the Stoner criterion for ferromagnetism, $I\rho > 1$, where ρ is the electronic density of states. The situation at finite temperatures is less satisfactory, but the low-lying excitations are discussed in Sec. 5.

Itinerant-electron ferromagnetism is best considered through the wave-vector–dependent susceptibility $\chi(q)$. If the exchange interaction is such that as the temperature is decreased, the susceptibility enhanced by it diverges for the q value corresponding to twice the crystal lattice period (i.e., $q = \pi/a$ for a simple cube), the magnetic ground state will be antiferromagnetic. No pure element satisfies this condition, although a number of fairly dilute alloys of other transition metals in Cr do. Cr itself, as indicated in the Introduction, has an antiferromagnetic ground state ($T_N = 312$ K) characterized by a q value that couples two sheets of the Fermi surface but deviates slightly from the Brillouin-zone vector. (The stabilization energy arising from the introduction of a periodicity that matches the Fermi surface is very similar to that arising in a Peierls distortion of a lattice; with such a match, an energy gap appears that depresses the energy of the occupied states just below the Fermi level while raising that of empty states just above it.)

Even when the dominant contribution to the magnetic moments is made by the 4*f* electrons in the rare-earth metals, the incommensurate periodicities of the exotic structures (Fig. 1) are related to Fermi wave vectors associated with the conduction electrons that mediate the indirect exchange, as described in Sec. 2.

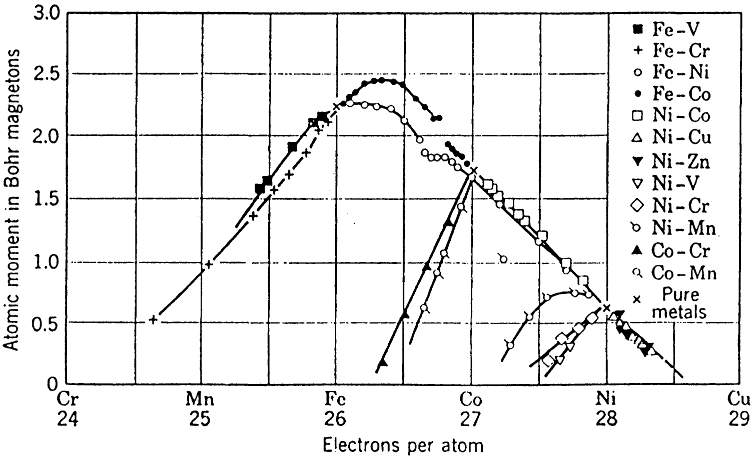

FIG. 7. Average atomic moments for iron-group metals and alloys as a function of electron concentration.

5. EXCITATIONS IN MAGNETICALLY ORDERED SOLIDS

In a simple molecular-field model of a ferromagnet, the natural excitation to consider is that given by turning over a single spin, requiring an energy $E \sim Jz$ where z is the number of nearest neighbors. As in the Einstein model of the specific heat of independently vibrating atoms on a lattice, this gives the (wrong) result of an exponential specific heat. In fact, the excitation is of the whole lattice, and although in the magnetic case this is quantized to give a magnetization less by μ than $N\mu$, the energy is reduced by the fact that the magnetization loss propagates through the lattice, as atomic vibrations do as phonons. The resultant excitation is thus a magnon or spin wave which for low energies can be shown to have an energy $\epsilon(q)$ equal to $\hbar\omega_q$ where $\omega_q = Dq^2$; D is called the spin-wave stiffness and, as with phonons, can be derived from inelastic neutron-scattering measurements. Some branches of ω versus q for ferromagnetic spin waves are shown in Fig. 8(a), and for antiferromagnetic spin waves in Fig. 8(b). It should be noted that in antiferromagnets there is an energy gap in the spin-wave spectrum, related to anisotropy, without which the initial region would be linear in q.

For itinerant-electron magnets, spin-wave-like excitations coexist with excitations from conduction-electron states below the Fermi level to those above, and these now include Stoner excitations, those from one spin half-band to the other. We then have the situations shown in Fig. 9 for the spin nonconserving excitations in (a) a "strong" itinerant-electron ferromagnet (one half-band full) and (b) a "weak" one like Fe where the Fermi level lies in both half-bands. It should be noted that in both cases spin waves above a certain energy will be strongly damped by dissociation into Stoner excitations. (At lower energies magnon-magnon interactions will give some broadening as do anharmonic effects in phonon spectra.)

6. MAGNETIC PHASE TRANSITIONS AND CRITICAL PHENOMENA

Magnetic ordering supplies some illuminating examples of phase transitions that differ from the first-order transitions with latent heats $\Delta L > 0$ such as those between liquid and solid or two crystallographically distinct phases. All such ($\Delta L = 0$) phase transitions can be characterized by an order parameter that goes smoothly to zero as the temperature is raised. The molecular-field model used for the magnetization gives M as a suitable order parameter and predicts a specific heat for a ferromagnet of the form shown in Fig. 10. Close to T_c this fails rather badly, as did the predicted behavior of $1/\chi$, and for the same reason. Correlated fluctuations are at the root of the problem, and a great deal of effort has been expended in attempts to incorporate these within theories of the magnetic and thermodynamic behavior at magnetic ordering temperatures. (For a thorough

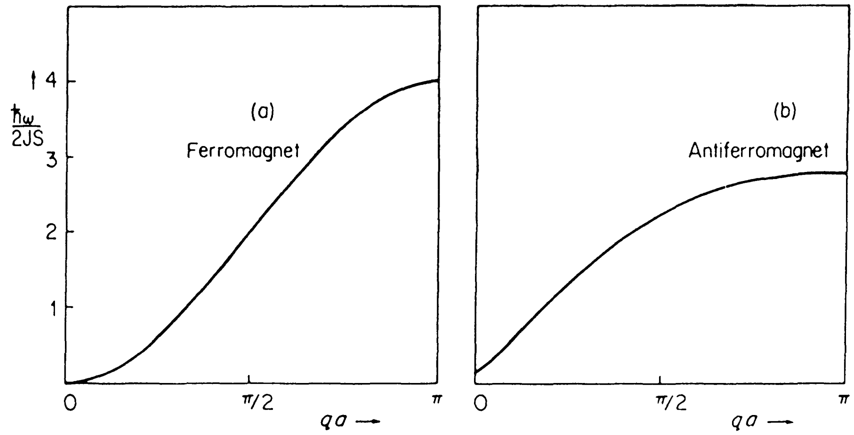

FIG. 8. Spin-wave dispersion curves for (a) a ferromagnetic, (b) an antiferromagnetic.

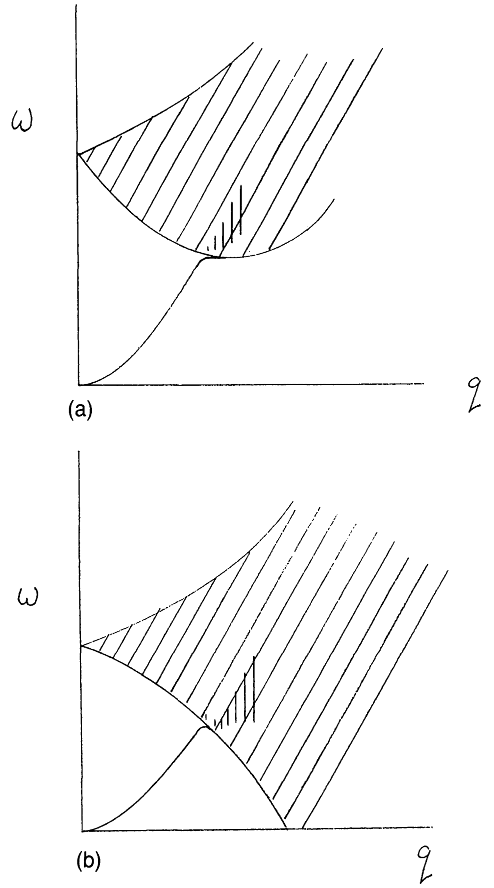

FIG. 9. Excitations in itinerant-electron ferromagnets showing spin-wave modes intersecting Stoner excitations (schematic); vertical hatching corresponds to strongly damped resonances. (a) A "strong" ferromagnet [see Fig. 6(a)]; (b) a "weak" ferromagnet [see Fig. 6(b)].

account see Stanley, 1971, and for an elementary treatment, Goodstein, 1985.)

In all such transitions the theoretical discussions lead to the examination of critical exponents, which express the dependence of some measured property on external variables such as the temperature. An appropriate variable is often $(T - T_c)/T_c = \epsilon$, and critical exponents relate such quantities as the susceptibility, the magnetization (below T_c), and the specific heat to ϵ by expressions such as $\chi \propto \epsilon^{-\gamma}$, where we have seen that $\gamma = 1$ for the simple molecular-field model.

A great deal of effort has been applied to the calculation of critical exponents for models that have specific dimensionalities and types of interaction, but only rarely can measured values of critical exponents provide insights into the fundamental nature of magnetically ordering materials. Comparisons of theory and experiment do exist, however, for a number of model systems (see de Jongh and Miedema, 1974).

7. MAGNETIC ORDER IN INTERMETALLIC COMPOUNDS

Many of the important developments in magnetism in recent years, both in the development of theoretical understanding and in that of new materials of importance in applied magnetism, have been concerned with intermetallic compounds. Such materials make it possible to study in a systematic way the effects of variations in crystal structure and electronic structure on the character and characteristic temperatures of magnetic order, and on the appropriate characteristics (such as remanence and energy product) of materials of potential value as novel permanent-magnet materials.

A particular structure that has been an especially rich source of interesting materials is the cubic Laves-phase structure $MgCu_2$, where the RAl$_2$ alloys in which R is a rare-earth metal have been intensively studied. (Much detailed information on these and other rare-earth compounds is assembled in a valuable review by Buschow, 1980.) In this, as in other series of compounds of the rare-earth metals, the two aspects that play major roles are the crystal-field splitting of the lowest-J multiplet of the R^{3+} ion and the indirect exchange interaction through the conduction electrons, the character of which varies only slightly across the series. A simple analysis of the data is prevented, however, by the fact that in a number of the compounds the crystal-field splittings are of the same order of magnitude as the strength of the indirect exchange.

The same crystal structure is found for a number of RT_2 compounds where T is a transition metal, and while considerations of the sort relevant in the RAl$_2$ compounds are appropriate when T is a 4d or 5d element, a whole new range of considerations enter for those where T is a 3d element. There are then R-R, T-T and R-T interactions to be considered, and many such compounds are ferromagnets with quite high Curie temperatures,

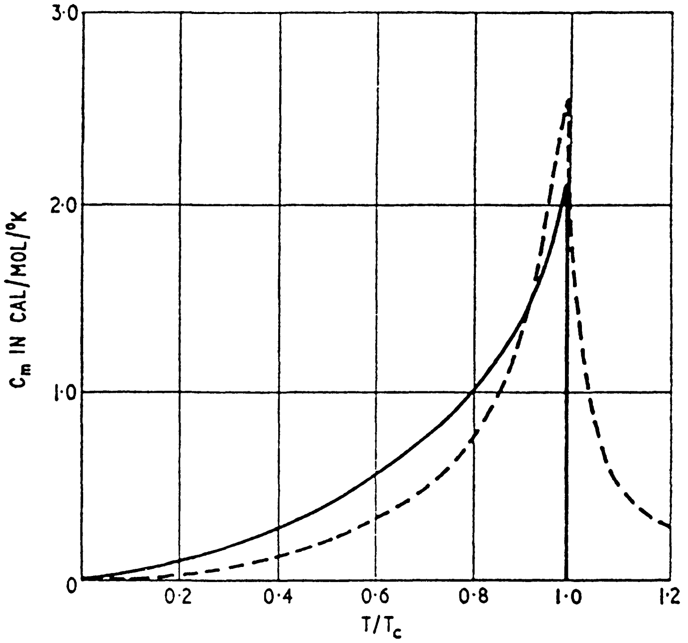

FIG. 10. Magnetic contributions to the specific heat in the molecular-field model (solid line) and in nickel (broken line).

although in the RNi_2 compounds the Ni atoms carry no moment in the presence of the strongly electropositive R atoms.

In the R-3d alloy systems a large number of other intermetallic compounds are also found, ranging from R_3T to R_2T_{17} and RT_{12}, and those with Co have been extensively studied because of the potential as permanent-magnet materials of such compounds as $SmCo_5$, which has a very large coercive force and energy product.

Another group of 4f-3d compounds that has attracted much recent attention because of their even larger coercive forces and energy products is that related to $Nd_2Fe_{14}B$. In some quasi-amorphous or rapidly quenched materials of a range of compositions, coercive fields of around 20 kOe and energy products $(BH)_{\max}$ of more than 10 MG Oe have been reported.

Because of the ability of the 4f configuration of Ce^{3+} to hybridize to a varying extent with conduction electrons, the intermetallic compounds of Ce show a variety of interesting behaviors ranging from superconducting ($CeRu_2$, $CeCo_2$) to antiferromagnetic ($CeAl_2$) and even semiconducting character (CeNiSn). These materials, along with related uranium compounds, have been extensively studied in recent years because of the intense theoretical interest aroused by their very large electronic specific heats which have given them the name "heavy fermions" (see HEAVY-FERMION PHENOMENA). A detailed discussion of these, even of those showing magnetic order, lies outside the scope of this article, and the reader is referred to such review articles as that of Ott (1987). It should be emphasized that such Kondo-effect anomalies arise from the antiparallel effective exchange between the f electrons and the conduction electrons produced by their hybridization, which acts to diminish the local magnetic moments, thereby acting against the onset of magnetic order. However, this moment compensation competes with an indirect interaction favoring magnetic order between f electrons on different sites *through* the conduction electrons, and a delicate balance sometimes exists, which can be pushed one way or the other by "chemical" pressure (i.e., alloying with atoms of different size) or by external pressure.

Alloys of the 3d transition metals with metals other than the rare earths are also a rich source of varying magnetic behavior, much of which was reviewed some years ago by Kouvel (1967). Mention may be made of Ni_3Fe and Ni_3Mn where the effects of the atomic order-disorder transition can be studied, of the equiatomic FeRh alloy, which is ferromagnetic below its Curie temperature of

675 K down to about 350 K where it undergoes a first-order transition to antiferromagnetism, and of the classic Heusler alloy Cu_2MnAl, which was the first example of a ferromagnetic intermetallic compound ($T_c \sim 700$ K, $\mu_{Mn} \sim 4\mu_B$) containing no ferromagnetic element.

8. MAGNETIC ORDER AND SUPERCONDUCTIVITY

Magnetically ordered and superconductive ground states of metals and alloys were long considered to be alternative and mutually incompatible conditions, not surprisingly since for most superconductors applied fields weaker than the molecular fields in ferromagnets will return the material to its normal state. In recent years, however, a number of materials have shown that some types of magnetic order can coexist with superconductivity, and in other materials small changes in composition can replace a magnetic ground state with superconductivity.

Prominent among the latter are the cuprate materials (e.g., La_2CuO_4 and $YBa_2Cu_3O_7$) where changes in the oxygen stoichiometry, in the former by Sr doping, can lead to high superconducting transition temperatures. It has also been known for some time that the temperature of the itinerant-electron antiferromagnet transition of Cr is initially raised to quite high values by alloying with Ru or Re but then collapses at ~20% to be replaced by superconductivity at fairly low temperatures.

Actual coexistence of magnetic order and superconductivity has also been found in two groups of rare-earth compounds, the Chevrel phases (RMo_6S_8 and RMo_6Se_8) and the rare-earth rhodium borides (RRh_4B_4). Some examples of both structures show the coexistence of long-range antiferromagnetic order of $4f$ rare-earth moments and superconductivity associated with the transition-metal clusters. The compound $ErRh_4B_4$ is of particular interest, in that slightly below the range of such coexistence the magnetic order becomes ferromagnetic and the superconductivity is destroyed.

A unique material, Y_9Co_7, shows the presence of bulk superconductivity ($T_c = 2.7$ K) after strong magnetic correlations of ferromagnetic character have shown up at higher temperatures (~5 K), making it the only material where such coexistence involves the magnetism of itinerant $3d$ electrons. It seems likely, however, that the remanence shown by some specimens at ~4.2 K is associated with imperfections in crystallographic order even in samples that are metallurgically single phase.

Recently the heavy-fermion group of Ce and U compounds has yielded examples where neutron scattering shows unambiguously that the small-moment antiferromagnetism setting in on cooling (at 17.5 K for URu_2Si_2) is still present below a much lower superconductive transition (0.9 K for URu_2Si_2). Here both magnetism and superconductivity seem to be associated with the same group of heavy (hybridized f-conduction band) electrons, and this encourages speculation that spin fluctuations rather than phonons may be providing the superconducting coupling mechanism. For a range of Th dopings in the superconducting $U_{1-x}Th_xBe_{13}$ alloys, specific-heat measurements show two transitions, the upper of which seems purely superconductive, but the lower one is found by muon relaxation studies to have some magnetic character.

9. FERROMAGNETIC DOMAINS AND MAGNETIZATION CURVES

In materials that clearly satisfy the conditions for ferromagnetic order, the measured magnetization of a particular sample cannot be explained in terms of the considerations of Sec. 3 and represented by the plot given in Fig. 5. The most striking manifestation of this failure is the possibility of having zero total magnetization associated with a sample of a substance which, by being an ordered ferromagnet well below its Curie temperature, would be expected to have a large spontaneous magnetization.

It has long been recognized that the minimization of the total energy associated with a piece of ferromagnetic material requires the reduction of the energy stored in the magnetic field around the sample, even at the cost of local increases in energy within the sample. This is achieved by the decomposition of the magnetization into domains (Fig. 11) within which the magnetization is given by curves like Fig. 5, but with orientations within

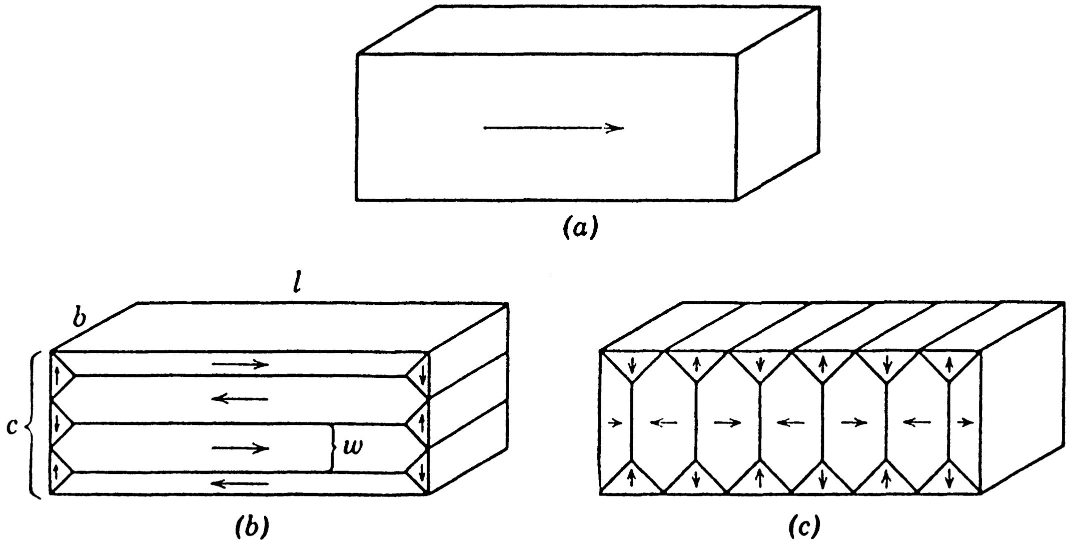

FIG. 11. Possible domain structures that lower the energy from that of the completely magnetized state (a). Configuration (c) has the lower energy.

the domains being such as to reduce the total magnetization to zero. It is clear that a positive contribution to the free energy will be associated with the domain boundaries, where there is a failure to minimize the energy by aligning neighboring atomic moments. This energy increase can be minimized by gradual rotations of atomic moments from one atomic plane to the next (Fig. 12), but the width of the transition region from spin up to spin down will clearly be given by a balance between the saving in exchange energy by broadening this region (the domain wall) and the increase in energy associated with the larger number of moments not lying in the direction favored by magnetocrystalline anisotropy.

The shape and size of the domains that minimize the total energy depend on the crystal structure and the configuration of the specimen, and these can be examined by a number of experimental techniques, such as the Bitter patterns produced by magnetic colloids spread on the surface of the sample or by magneto-optical methods.

The response of a ferromagnetic specimen to applied magnetic fields can be understood in terms of the response of the domain structure to such fields and the possible constraints on boundary movement imposed by imperfections, crystal grain boundaries, etc., within the specimen.

For a small applied field in some arbitrary direction, domains with magnetizations close to the field direction will grow at the expense of other domains (see Fig. 13). For small field increments the boundary movements required will be reversible, but at larger displacements the boundaries are likely to lock at pinning points when the field is reduced. At large fields, where the specimen is effectively one domain, with the magnetization aligned in an easy direction of magnetization, the final approach to saturation consists of the rotation of the magnetization into the direction of the applied field.

When the field is reduced the magnetization will remain finite when the applied field reaches zero at what is called the remanent magnetization, because of the pinning of domain boundaries. A finite field (the coercive force) will be required in the opposite direction to reduce the magnetization to zero. The applications of these principles to the development of materials for specific applications are discussed in MAGNETS AND MAGNETOSTATICS. Traditionally the two classes of magnetic materials of applied significance were "soft" materials, which acquire large magnetizations in small applied fields (i.e., have large permeabilities) and have applications in transformers, generators, and motors, and "hard" magnetic materials, which retain large remanent magnetizations and are suitable for

permanent magnets. Although both types were originally based on metallic alloys, insulating materials such as ferrites and garnets have been extensively applied both for traditional uses and for more recent applications in magnetic recording media.

INTRODUCTION

Nuclear magnetic resonance (NMR) and nuclear quadrupole resonance (NQR) are two valuable techniques for probing structure and dynamics in solids (see Nuclear Magnetic Resonance, Determination of Structures By). Resonance methods, in general, involve inducing transitions between neighboring energy levels available to a system and detecting a signal resulting from the transitions. In NMR and NQR, electromagnetic radiation of the appropriate frequency is used to induce transitions between nuclear energy levels, and the recording of the detected signal versus frequency results in the resonance spectrum.

In NMR, the energy levels available to the nucleus (and thus the shape of the resonance spectrum) depend on the various interactions of a nucleus in an external magnetic field. Because these interactions are dependent on the structural environment of the nucleus, the NMR line shape is a sensitive probe of the nuclear site in a solid. Dynamics (i.e., ionic motion, network vibration, molecular rotation, etc.) can be inferred from the time dependence of these interactions as determined by relaxation-time measurements.

In NQR, no external magnetic field (or a very weak field) is used, and the structural information is gained from the effect on the resonance line shape that results solely from the nuclear quadrupole interaction.

The first part of this article is a general discussion of NMR with emphasis on those aspects that are most important in the study of solids. The basic quantum-mechanical interactions of a nucleus in an external static magnetic field, including the interaction required to produce resonance, along with relaxation mechanisms are discussed in the first two sections; basic detection methods and some applications of NMR to the study of solids are discussed in the last two sections of this part.

The second part of the article deals with the theory, detection methods, and applications of NQR to the study of solids.

1. NMR IN SOLIDS

1.1 Nuclear Interactions

1.1.1 Zeeman Interaction A nucleus with non-zero spin angular momentum, $\hbar\mathbf{I}$, is a magnetic dipole with magnetic moment, $\boldsymbol{\mu} = \gamma\hbar\mathbf{I}$. $\mathbf{I}$ is the nuclear spin vector, whose magnitude is $\sqrt{I(I+1)}$, where the scalar I is an integer or half-integer and is called the spin of the nucleus; γ is the gyromagnetic ratio of the nucleus, and $\hbar$ is Planck's constant h divided by 2π. When the nucleus is in an external static magnetic field of magnitude H, the otherwise degenerate energy levels of the nucleus are split into $2I + 1$ energy levels; the separation between adjacent levels is

$$\Delta E = \gamma\hbar H. \tag{1}$$

Figure 1(a) depicts the Zeeman energy levels for a nucleus of spin $I = \frac{3}{2}$, where m is the magnetic quantum number ($-I \leq m \leq +I$) and increases from $-I$ in integer steps.

In NMR, inducing transitions between energy levels is effected by introducing a time-dependent magnetic field of frequency ν_0, such that $h\nu_0 = \Delta E$. This gives the Bohr resonance condition

$$\nu_0 = \gamma H/2\pi, \tag{2}$$

where ν_0 is typically in the radio-frequency (rf) region. The resulting absorption spectrum is a single sharp peak at ν_0 as seen in Fig. 1(b).

1.1.2 Dipolar Interaction For a system of spins, there is an energy of interaction due to magnetic dipole coupling. Dipole-dipole interactions represent the effect of neighboring nuclear magnetic moments and their associated small magnetic fields on energy levels of the probe nucleus. The effect on the NMR spectrum depends on the magnitudes of the magnetic moments $\boldsymbol{\mu}_i$, their spatial separations $\mathbf{r}_i$, and the orientation of the $\mathbf{r}_i$ with respect to the direction of the external magnetic field, but not on the value of the magnetic field. Because of the random orientation of the dipoles, the effect on the absorption line shape is an overall broadening [Fig. 1(c)]. The dipolar contribution to the full width at half maximum, δ, can be calculated for a Gaussian line shape using Van Vleck's method of moments (Van Vleck, 1948):

$$\delta = 2.36\sqrt{M_2^I}, \tag{3}$$

where M_2^I is the "second moment" for a nuclear spin in the presence of like spins I and unlike spins S. Van Vleck showed that for polycrystalline and glassy samples the second moment can be written

$$M_2^I = \Delta_{II} + \Delta_{IS}, \tag{4}$$

where

$$\Delta_{II} = \tfrac{3}{5}\gamma^4\hbar^2 I(I+1)\sum_i \frac{1}{r_i^6},$$

$$\Delta_{IS} = \tfrac{4}{15}\gamma_I^2\gamma_S^2\hbar^2 S(S+1)\sum_i \frac{1}{r_i^6}. \tag{5}$$

Equations (4) and (5) can be used to determine interatomic separations in solids from the experimental line shape.

1.1.3 Quadrupolar Interaction Nuclei with spin $I = 1$ or greater possess an electric quadrupole moment, denoted eQ, which pro-

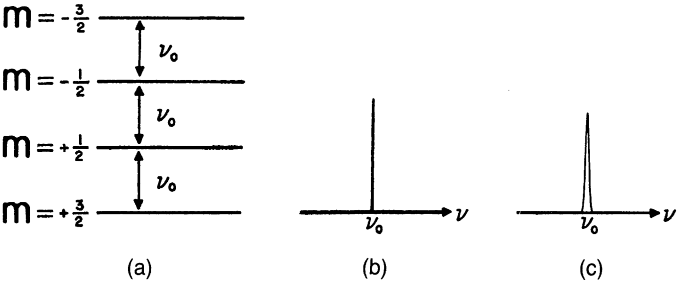

FIG. 1. (a) Energy levels for a spin-$\frac{3}{2}$ nucleus in the presence of a magnetic field. (b) The resultant NMR absorption spectrum is a single peak at the frequency ν_0. (c) Dipolar interactions broaden the resonance symmetrically so that it is not the δ-function response depicted in (b).

vides a measure of the departure from spherical symmetry of the nuclear charge distribution. The quadrupole moment interacts with any electric field gradient (EFG) present at the nuclear site. The energy levels of the nucleus depend on the orientation of the charge distribution with respect to the principal axes of the EFG. Since closed shells of electrons do not generate an EFG, and since the EFG falls off as $1/r^3$, the major contribution arises from bonding electrons. Hence, the quadrupolar interaction is a very sensitive probe of chemical bonding and local atomic arrangements. When the quadrupole interaction is treated as a first-order perturbation to the Zeeman energy levels, the transition frequencies become

$$\nu_{m\to m-1} = \nu_0 - \nu_Q \frac{m - 1/2}{2}(3\cos^2\theta - 1 - \eta \sin^2\theta \cos 2\phi), \qquad (6)$$

where

$$\nu_Q = 3Q_{cc}/2I(2I - 1), \qquad (7)$$

and Q_{cc} is the quadrupole coupling constant:

$$Q_{cc} = eQV_{zz}/h. \qquad (8)$$

The asymmetry parameter η is a measure of the departure of the EFG from cylindrical symmetry and is given by

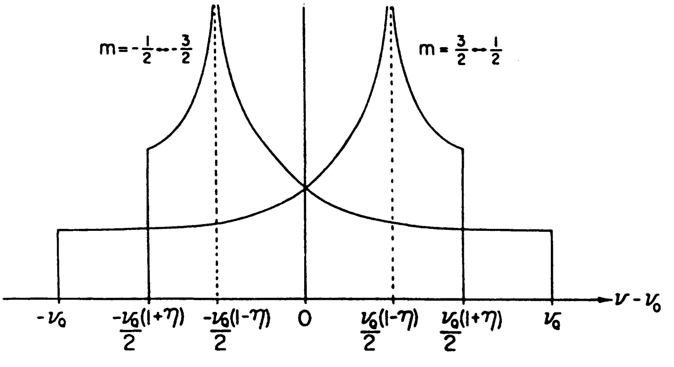
$$\eta = (V_{xx} - V_{yy})/V_{zz} \qquad (9)$$

where V_{xx}, V_{yy}, and V_{zz} are the diagonal components of the EFG tensor expressed in its principal-axis system. With the labeling of the axes chosen such that $|V_{zz}| \geq |V_{yy}| \geq |V_{xx}|$, one finds that $0 \leq \eta \leq 1$. The variables θ and ϕ are the polar angles of the magnetic field as referred to the principal-axis system of the EFG tensor. Note that quadrupole effects on the NMR spectrum, to first order, are independent of the magnitude of the external magnetic field. In a glass or polycrystalline sample, all orientations of the principal-axis system will exist, and the NMR spectrum will be the envelope of the responses for all values of θ and ϕ. The resulting line shape is a powder pattern. Figure 2 is an example of a powder pattern due to a first-order quadrupole interaction for a spin-$\frac{3}{2}$ nucleus from Eq. (6). (Note that the $m = +\frac{1}{2} \leftrightarrow m = -\frac{1}{2}$ transition is not affected in first order by a quadrupolar interaction.) Locating the positions of the shoulders and divergences in an uncomplicated spectrum experimentally determines the values of Q_{cc} and η, the parameters conventionally measured in NMR spectroscopy.

When the strength of the quadrupole interaction is such that second-order effects must be included, the change in the NMR spectrum for a glass or polycrystalline powder is a broadening that varies inversely with the magnitude of the applied field. Most notably, the central transition ($m = \frac{1}{2} \leftrightarrow m = -\frac{1}{2}$) is broadened by an amount that depends on η and Q_{cc} (Fig. 3).

1.1.4 Chemical- and Knight-Shift Interactions

When a magnetic field is applied to a sample, there are induced changes in the electron orbital motion in atoms and, in the case of metals, in the conduction-electron distribution. These effects give rise to chem-



$m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$

ical and Knight shifts in the resonance frequency.

1.1.4.1 Chemical Shifts. The motion of the atomic electrons induced by the applied magnetic field will cause a small shift in the magnetic field experienced by the nucleus. The resulting change in the resonant frequency is termed the chemical shift because it is sensitive to bonding electrons, and is measured in parts per million (ppm). The energy of interaction can be written as the coupling of the spin vector **I** with the magnetic field **H** via the chemical-shift tensor σ:

$$E_{CS} = \gamma\hbar\mathbf{I}\cdot\boldsymbol{\sigma}\cdot\mathbf{H}. \tag{10}$$

Equation (10) is a compact notation wherein the tensor $\boldsymbol{\sigma}$ contains the spatial information derived from the distribution of electronic current densities surrounding the probe nucleus. The components of the chemical-shift tensor, then, are a measure of the symmetry of the nuclear site. The observed spectral frequency is

$$\nu = \nu_0(1 - \sigma_{zz}), \tag{11}$$

where ν_0 is the resonant frequency of the bare nucleus and σ_{zz} is the component of the shift tensor along the direction of the external field. Rewriting this in terms of the diagonal components of the chemical-shift tensor in its principal-axis system, σ_1, σ_2, and σ_3, gives

$$\begin{aligned}\nu = \nu_0[1 &- \sigma_{\text{iso}} - \sigma_{\text{ax}}(3\cos^2\theta - 1)\\ &- \sigma_{\text{aniso}}(\sin^2\theta\cos 2\phi)],\end{aligned} \tag{12}$$

where

$$\begin{aligned}\sigma_{\text{iso}} &= \tfrac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3),\\ \sigma_{\text{ax}} &= \tfrac{1}{6}(2\sigma_3 - \sigma_1 - \sigma_2),\\ \sigma_{\text{aniso}} &= \tfrac{1}{2}(\sigma_2 - \sigma_1).\end{aligned} \tag{13}$$

Because the frequency ν depends on θ and ϕ, the polar angles of the field **H** as referred to the principal axes of the chemical-shift tensor, the spectrum of a powdered crystalline sample or glassy sample will be the envelope of responses for all values θ and ϕ. Representative examples of the resulting powder pattern are shown in Fig. 4.

1.1.4.2 Knight Shift in Metals. The Knight shift (Townes *et al.* 1950; Knight, 1956) in the resonant frequency is also the result of the coupling of electrons with nuclear spins. However, in contrast to the relatively localized bonding electrons in a nonmetal giving rise to the chemical shift in NMR frequency, the conduction electrons in a metal interact collectively with the nuclei, superimposing an internal magnetic field at the nuclear site on the externally applied magnetic field. The magnitude of the Knight shift is typically an order of magnitude larger than chemical shifts, and rather than providing information with regard to the local structure at the nuclear site, it is sensitive to the electronic structure and properties of metals. The components of the Knift-shift tensor $\boldsymbol{\kappa}$ are related to a powder pattern as in the case for chemical shifts described above.

1.2 Effects of the rf Field: Absorption of Energy and Relaxation

In a solid, the collective nuclear spins in their respective sites can be visualized as a spin system coupled to a lattice. (Note that here, use of the term *lattice* is not restricted to the case of regularly arranged atoms as in a crystal, but it also used to denote the more disordered network of atoms in an amorphous solid.) The vector sum of the individual magnetic moments $\boldsymbol{\mu}$ is **M**, the magnetization vector of the spin system. At equilibrium in an external magnetic field, **M**

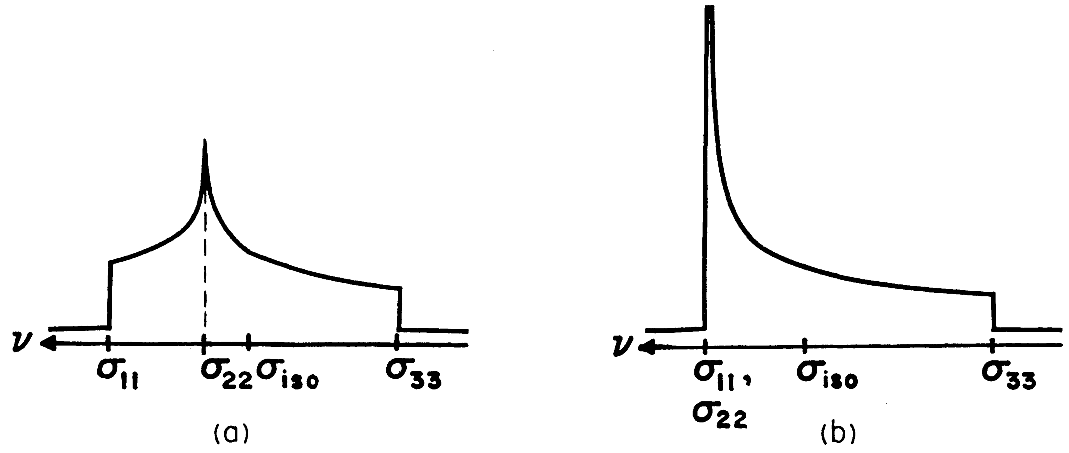

FIG. 4. Chemical-shift powder patterns for (a) a completely anisotropic chemical-shift tensor and (b) an axially symmetric tensor.

is collinear with the axis of the field. Occupation of the Zeeman energy levels (and thus the magnitude of **M**) is determined by the temperature T of the lattice and the strength of the applied field. The various states n with energies E_n will be occupied with the fractional probabilities p_n given by the Boltzmann factor

$$p_n = e^{-E_n/kT}/Z, \tag{14}$$

where Z is the partition function

$$Z = \sum_n e^{-E_n/kT}, \tag{15}$$

and k is Boltzmann's constant.

When rf power is used to excite the spin system, the energy is distributed among the spins via spin–spin interactions characterized by the time constant T_2, the spin–spin (or transverse) relaxation time.

For an external static magnetic field to change the Boltzmann distribution of states, conservation of energy requires that the spin system be coupled to a lattice that can make a transition to an energetically lower state. The mechanisms that couple the spins to the lattice are collectively characterized by T_1, the spin–lattice or longitudinal relaxation time. Thus T_1 determines the time for the magnetization vector to grow in an external field. When rf power is used to excite the spin system, the spin-lattice mechanisms dissipate the energy to the lattice, such that T_1 also characterizes the time for the magnetization vector to return to equilibrium. In solids, T_2 is typically orders of magnitude shorter than T_1; thus for a time on the order of T_2, the spins are in thermal equilibrium with each other and not the lattice. The Boltzmann distribution of states is governed by Eq. (14) provided the temperature T now refers to T_s, the spin temperature (Bloembergen, 1949). As the spin system gives up thermal energy to the lattice, T_s returns towards the lattice temperature T at a rate determined by T_1. For high rf levels and/or long T_1 relaxation times, the spins are unable to transfer energy with sufficient rapidity to the lattice, the occupancies of the energy levels equalize, and the system absorbs no more energy; the system is said to be saturated.

1.3 Detection Methods

The two basic techniques in NMR, continuous-wave (cw) and pulsed spectroscopy, involve exciting the nuclear magnetization with radio-frequency (rf) energy and detecting the subsequent response of the spin system. Each method of excitation has advantages and disadvantages depending on the width of the NMR line and the type of information sought.

1.3.1 Continuous-Wave NMR In cw NMR the nuclear magnetization is irradiated at a constant level, and either the frequency of irradiation or the magnetic field is swept through the region of the resonance condition given in Eq. (2). In the crossed-coil method the transmitting coil, with its axis perpendicular to the external magnetic field, feeds rf into the sample. Recall that a magnetic moment, and hence the magnetization vector for a collection of magnetic moments, will precess about an applied magnetic field with angular frequency $\omega = \gamma H$. When the applied rf is of the same angular velocity as the precessing spins, the angle of inclination is changed, and a small signal will be induced in a receiver coil that is placed such that its axis is perpendicular to both the transmitting coil and the external field. This signal is very small and is usually overwhelmed by random noise. Signal averaging and lock-in detection are the usual means of improving the signal-to-noise (S/N) ratio. One limitation of cw NMR is that the signal is proportional to the rf power used, but rf levels must be low enough to avoid saturating the spin system and thereby distorting the line shape or eliminating the signal. Doping the solid with paramagnetic impurities (which can absorb energy from the spin system through electron interactions) can effectively shorten T_1 and reduce saturation without significantly altering the structure of the sample or the absorption line shape. Signal averaging when used with lock-in detection further increases S/N; however, because of the modulation of the magnetic field there is an upper limit on how fast one can sweep through resonance without distortion. Nonadiabatic superfast passage (NASP) (Segal *et al.*, 1983) has been used to solve this problem. In this method neither lock-in detection nor modulation of the magnetic field is used, so that the external field can be linearly swept through the region of interest in a short time (usually less than 50 ms). The spectrometer output is then fed directly to a signal averager. Higher rf levels can be used than with lock-in detection because the measured line shape is not distorted if the resonance is slightly saturated. This, in combination with the rapid accumulation of signals, allows for better S/N ratios in short time. NASP is limited by the external field sweep range, which is on the order of a few hundred gauss.

Both of these cw techniques are useful for broad lines, which commonly occur in amorphous solids. NASP is preferable unless the line is broader than a few hundred gauss.

1.3.2 Pulsed NMR In pulsed NMR spectroscopy, in contrast to cw NMR in which the frequency or magnetic field is swept through the region of the resonance condition, the entire frequency range of interest is irradiated at once by a short intense rf pulse having a magnetic field magnitude of H_1. For a pulse length of t_p, with angular frequency $\omega = 2\pi\nu = \gamma H_1$ [see Eq. (2)], the sample magnetization will be rotated from its equilibrium position along the z axis by the angle

$$\theta_p = \gamma H_1 t_p, \tag{16}$$

as seen in Fig. 5, and will precess about the z axis with angular frequency $\omega = \gamma H$. The magnetization vector is thus stationary in a frame rotating about the z axis with that frequency. The components of **M** that lie in the xy plane will induce a signal called the free induction in a receiver coil. Immediately following the pulse, the individual spins are aligned, but spin–spin interactions and magnetic field inhomogeneities cause dephasing of the spins with a reduction in the magnitude of **M**. This, along with spin–lattice relaxation mechanisms that return the magnetization vector toward equilibrium, diminishes the free induction. The decaying signal is termed the free-induction decay (FID) and is the one that is accumulated and signal averaged. The Fourier transform (FT) of the real part of the FID gives the NMR absorption spectrum.

The exponential decay of the FID is characterized by a time constant T_2^*, or the apparent T_2. It is inversely related to the line-

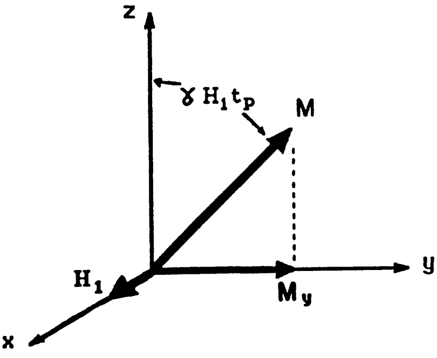

FIG. 5. A pulse of length t_p rotates the magnetization vector from its equilibrium position by an angle $\theta_p = \gamma H_1 t_p$.

width of the absorption spectrum as shown in Fig. 6. In general,

$$\frac{1}{T_2^*} \approx \frac{1}{2T_1} + \frac{1}{T_2} + \gamma\delta H_0. \tag{17}$$

In solids T_1 is usually much longer than T_2; hence, the signal decays before the magnetization has returned to its equilibrium position, and the T_2 term dominates the decay rate. The last term in Eq. (17) represents broadening due to magnetic field inhomogeneities of extent δH_0.

If the magnetization vector has not returned fully to its equilibrium position along the z axis, subsequent pulsing will result in saturation unless the repeated pulse is delayed by a time on the order of several times T_1. In the study of solids, if the structural information obtained from the line shape is the objective, rather than the dynamics inferred from relaxation-time measurements (see Sec. 1.3.2.1 below), the sample is doped with paramagnetic impurities to shorten T_1. Ensuring full relaxation between pulsing is important because nuclei in different structural sites often have different relaxation rates. Even partial saturation will distort the relative spectral intensities due to these sites.

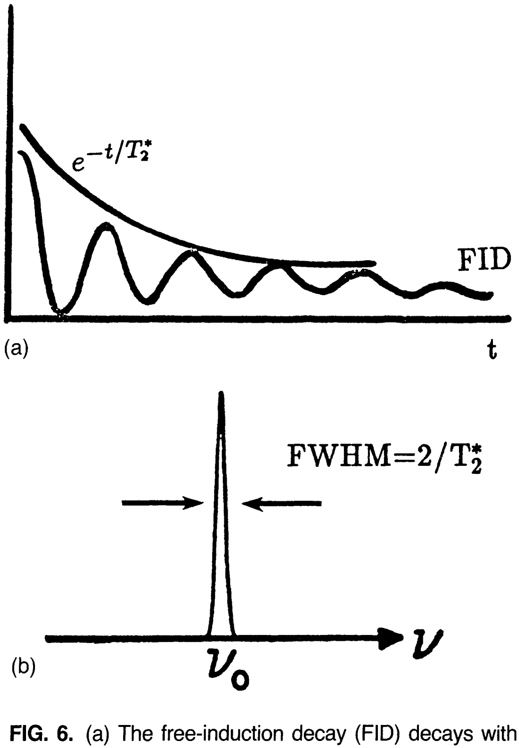

FIG. 6. (a) The free-induction decay (FID) decays with time constant T_2^*. (b) Fourier transform of the FID results in an absorption spectrum with a full width at half maximum (FWHM) inversely proportional to T_2^*. For Lorentzian broadening the FWHM = $2/T_2^*$; for Gaussian broadening the FWHM = $3.34/T_2^*$.

The frequency range of observation is inversely proportional to the pulse length t_p; shorter pulse lengths permit illumination of a broader frequency range. From Eq. (16), a short pulse requires higher rf power to obtain a given tip angle of the magnetization. Pulse lengths are typically on the order of microseconds.

To avoid the rf pulse obscuring part of the FID and to allow for electronic recovery time, data acquisition must be delayed beyond the end of the pulse. For broad lines, when the FID decays rapidly, significant information is lost. Spin-echo techniques can often recreate the early part of the FID, which is obscured by receiver dead-time. In this method (Fig. 7), a 90° pulse is applied at $t = t_0$. [A 90° pulse is defined by Eq. (16) as the pulse length such that $\theta = \pi/2$.] After a certain time interval τ, during which time the spins are dephasing and the FID is decaying, the spin system receives a 180° pulse. This rotates the individual spins 180° around the x axis. The inhomogeneous mechanisms that caused the dephasing of the spins in the xy plane now act to rephase the spins, and at a time 2τ later a spin echo is formed. The echo consists of two FIDs back to back, and the FT of the second half of the echo gives the absorption spectrum. There have been many pulse sequences designed to observe echos in solids, and descriptions can be found in the sources in the Further Reading list.

1.3.2.1 Determination of Relaxation Times. Measuring T_2 is the object of studies in which the aim is to characterize the time dependence of spin–spin interactions in the sample. T_2^* as measured by the FID in a one-pulse NMR experiment differs from the intrinsic spin–spin relaxation time T_2 as seen in Eq. (17). In solids, with $T_1 \gg T_2$, T_2 differs from T_2^* primarily because of inhomogeneities in the applied magnetic field. The Carr–Purcell spin-echo train (Carr and Purcell, 1954) and modifications based on it are designed to eliminate the effects of the magnetic inhomogeneity. In this method, a repeated sequence of 90°–180° pulses as described above results in a train of echos;

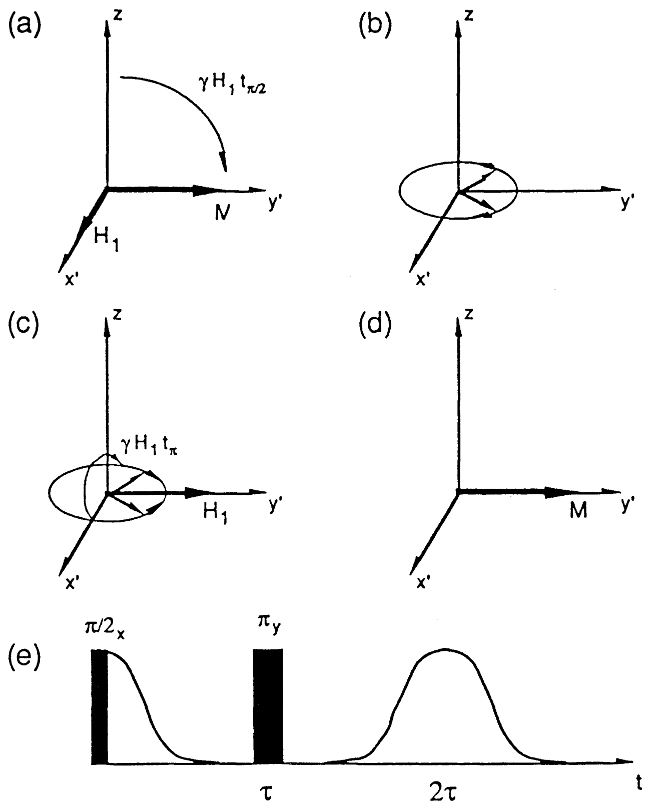

FIG. 7. Formation of the spin echo. (a) At $t = 0$ a 90° pulse is applied, tipping the magnetization vector into the $x'y'$ plane. (b) Because the rate of precession varies for the individual magnetic moments, the spins become dephased and the magnetization decays. (c) At time τ a 180° pulse is applied, thereby flipping all the spins 180° about the y' axis. (d) The individual magnetic moments then become rephased, restoring the magnetization. (e) The spin-echo pulse sequence and the detected signal. The axis along which the magnetic component of the pulse is directed is designated by subscripts; a $\pi/2_x$ pulse indicates that $\mathbf{H}_1$ is directed along the x' axis.

the 180° pulse corrects for dephasing of the spins caused by magnet inhomogeneities, so that the decaying amplitudes of the echo represent dephasing due to intrinsic spin–spin interactions. The decay is characterized by the time constant T_2.

Bloembergen *et al.* (1948) and Torrey (1953) used the temperature dependence of spin–lattice interaction times to determine activation energies and jump times for ionic motion. There are many methods for measuring T_1 values by pulsed NMR; one general category consists of an initial pulse to prepare the spin system followed by a second pulse to monitor the recovery of the spins as a function of waiting time. Two commonly used sequences are known as the saturation-recovery (SR) sequence and the inversion-recovery (IR) sequence. The SR sequences consists of a 90° pulse followed by a second 90° pulse after a time τ. When the interval τ between pulses is greater than T_1, the magnetization vector $\mathbf{M}$ has recovered towards equilibrium such that a second 90° pulse results in a stronger signal. In the IR sequence a 180° pulse is used to prepare (in this case invert) the spins, and a 90° pulse is used to measure signal strength as a function of τ. Another general method of measuring T_1 is to create a "steady state" condition in which the signal achieves a constant amplitude that depends on T_1. One example that is useful for solids is a pulse train of 90° pulses separated by a time τ (Fig. 8).

Slichter and Ailon (1964) and Look and Lowe (1966) showed that slow atomic motions can be studied by experiments analyzed in a reference frame rotating with the Larmor frequency. Measurements of the rotating-frame spin-lattice relations time $T_{1\rho}$, have the advantage that low-frequency motion can be studied while maintaining the higher S/N that goes with stronger externally applied magnetic fields. In these experiments, a 90° pulse is used to tip $\mathbf{M}$ into the xy plane; It is followed by a second rf pulse, now phase shifted such that its magnetic field $\mathbf{H}_1$ lies along $\mathbf{M}$ in the rotating frame. In this frame, the spins experience only the magnetic field of the rf pulse and the

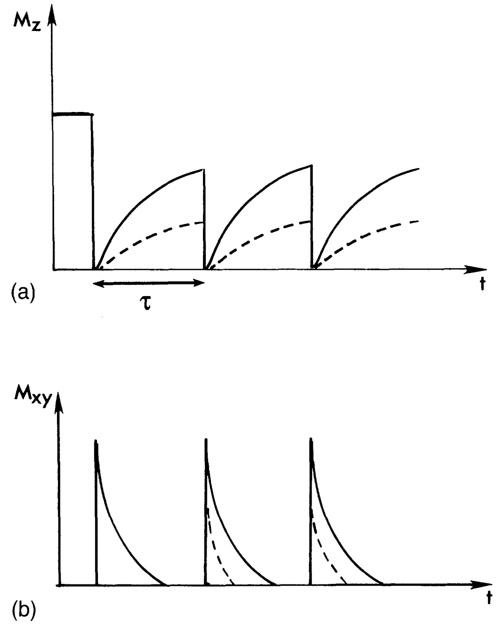

FIG. 8. (a) The z component of the magnetization vector for a sample subjected to 90° pulses separated by an interval τ that is on the order of T_1 (solid line) or shorter than T_1 (dashed line). (b) The xy component of **M** (and the strength of the signal) for the above two cases.

magnetization is said to be spin locked to $\mathbf{H}_1$. Now the spins relax to a smaller equilibrium value of **M** (corresponding to $\mathbf{H}_1$ rather than $\mathbf{H}_0$) with a time constant $T_{1\rho}$. The rf field is turned off after a spin-locking period, and the initial height of the signal as a function of the length of the spin-locking pulse is recorded. $T_{1\rho}$ measurements thus probe motions typified by frequencies on the order of $\nu_1 = \gamma H_1/2\pi$ (usually kHz) rather than $\nu_0 = \gamma H_0 2\pi$ (MHz).

1.3.2.2 Magic-Angle Spinning (MAS). Resolving signals from different nuclear sites requires that the broadening for each line be less than the frequency differences between them. Dipolar, chemical-shift, and first-order quadrupolar interactions that can contribute to the broadening contain terms with an angular dependence of $1 - 3\cos^2\theta$, where θ is the angle between the external field and the internuclear vector (for the dipolar interaction) or is one of the angles characterizing the orientation of the principal axes of the appropriate tensor (chemical shift or EFG) with respect to the field. For $\theta = 54.74°$ these terms are zero, thus narrowing the overall NMR response (Andrew, 1971). In MAS, the sample is placed in a rotor that spins the sample at this angle relative to the static field. Thus any internuclear vector will, on the average, be along the rotation axis and any terms with this angular dependence will average to zero (Fig. 9). To narrow the line effectively, the rate of rotation must exceed the linewidth; otherwise, the transverse magnetization decays faster than the time it takes to complete one revolution.

1.4 Applications of NMR in the Study of Solids

1.4.1 NMR Studies of Nonmetallic Glasses and Polycrystalline Powders Because glasses lack long-range order, only those techniques that probe the short-range atomic and molecular order are useful for determining their structure. NMR has been a valuable technique in the study of both glass structure and dynamics for over 30 years. In glasses (and in polycrystalline powders) the component structural units are randomly oriented with respect to the applied field so that the resonance condition is averaged over all possible orientations. The line shape is then a

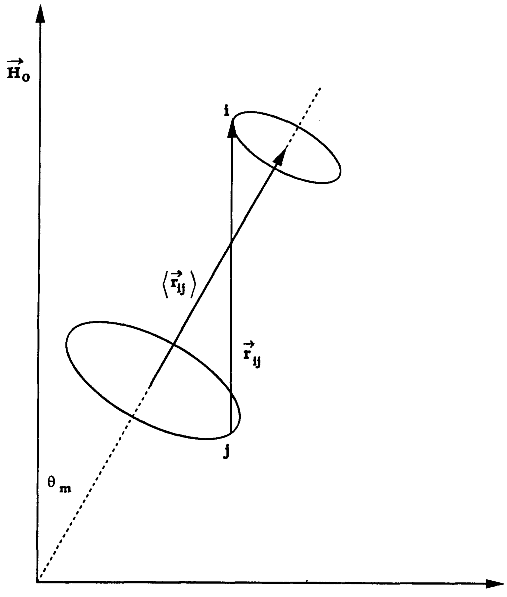

FIG. 9. Sample spinning about an axis at angle θ_m with respect to the external field brings the average positions of the nuclei i and j (and the average internuclear vector, $\langle \mathbf{r}_{ij} \rangle$) to lie along that axis.

composite of the powder patterns due to chemical-shift and quadrupolar interactions. In an uncomplicated spectrum, or one in which the structural sites are well resolved, the positions of the shoulders and divergences in the powder pattern determine chemical-shift tensor values for the different structural units present in the glass and/or the quadrupolar parameters that characterize the nuclear sites. In more complicated cases, structural information can be obtained by computer simulation of the line shape wherein the relative contributions to the spectral intensity of various sites along with their chemical shift or quadrupolar parameters are varied until a best fit to the observed line shape is obtained. Broadening mechanisms are taken into account by convoluting the line shape function with an isotropic broadening function. Most commonly the broadening function is taken to be a Gaussian, which should be exact for the case of dipolar broadening.

Many glass systems have been and are being studied by these methods. An example is the determination of structural sites in silicate glasses. The basic structural unit is a tetrahedron, a silicon atom in fourfold coordination with oxygen, and is denoted Q^n, where n indicates the number of oxygen atoms bridging to other tetrahedral units. The ^{29}Si nucleus is a useful probe for determining structure in these glasses because it is a spin-$\frac{1}{2}$ nucleus and is subject only to chemical-shift and dipolar interactions. Figure 10 schematically displays the various Q^n units along with the ^{29}Si resonance line shape for each. Structural units in multicomponent silicate glasses can often be determined by computer simulation of experimental spectra.

Borate glasses have been extensively studied by NMR. Addition of modifier oxide (e.g.,

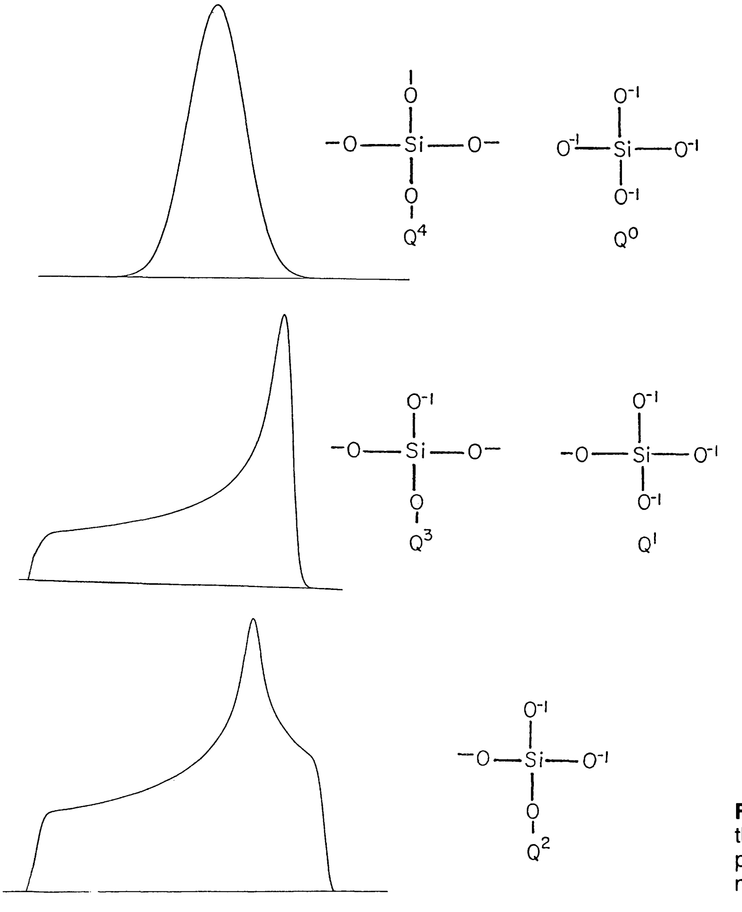

FIG. 10. NMR powder patterns for the Q^n structural units, including dipolar broadening. O^{-1} indicates a non-bridging oxygen (NBO).

alkali or alkaline-earth oxides) to the borate network results in the formation of negatively charged borate units consisting of borons in threefold or fourfold coordination with oxygen. The amounts and types of borate structural units (Fig. 11) vary with the modifier oxide content. Borate glasses are often characterized by the fraction of boron atoms in fourfold-coordination (N_4), the fraction in asymmetric units of threefold-coordination (N_{3A}), and the fraction in symmetric threefold-coordination (N_{3S}). ^{11}B is a spin-$\frac{3}{2}$ nucleus and thus is subject to quadrupolar interactions. The magnitude of the interaction for threefold-coordinated boron atoms is such that it can be treated with second-order perturbation theory at field strengths of 1 T or higher. Figure 12 shows the expected derivative spectrum (i.e., $dP/d\nu$ versus ν where P is the power absorption and ν is the frequency) from a sample containing boron atoms in distinct environments. By matching computer simulations to the observed response, one can extract N_4, N_{3S}, and N_{3A}, along with values of Q_{cc} and η for the latter two cases. The parameters Q_{cc} and η can be obtained for fourfold-coordinated boron atoms in some cases by working at low frequencies, for which second-order effects become apparent, or by observing the satellite transitions (those other than the central transition) arising from the BO_4 units.

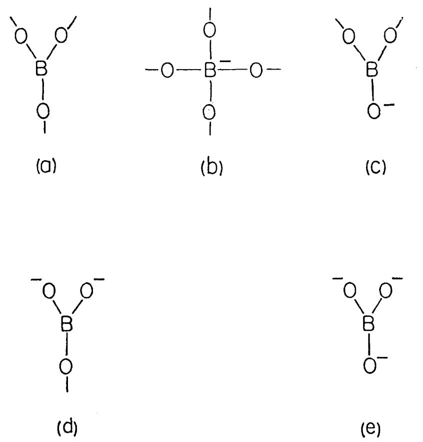

FIG. 11. Structural units found in modified borate glasses. (a) Trigonal $BO_{1.5}$; (b) tetrahedral BO_2^{-1}; (c) asymmetric trigonal BO_2^{-1} with one nonbridging oxygen (NBO); (d) asymmetric trigonal $BO_{2.5}^{-2}$ with two NBOs; (e) symmetric trigonal BO_3^{-3} with three NBOs.

1.4.2 NMR Investigations of Magnetic Materials NMR in magnetic materials was first observed over 30 years ago (Gossard and Portis, 1959) and since then has been used to further the understanding of the correlation between magnetic order and short-range atomic features. Magnetic order of any type in a solid superimposes magnetic fields at the nuclear site. Typically the magnetic hyperfine fields are stronger than the externally applied fields such that resonance for a nucleus with a magnetic moment can be detected even in the absence of the applied field. The shifts of NMR responses by hyperfine interactions are determined by structural symmetries, interatomic distances, type and number of nearest neighbors, magnetocrystalline anisotropy, etc.; thus the shifts provide structural information. Spin-echo techniques are commonly used because the spectra are broad and have very short T_2 relaxation times. Oscillations in the intrinsic magnetic fields of the samples are induced by the rf irradiation, thus increasing the power experienced by the nucleus. The enhancement factor decreases the requirement on the rf power levels compared to NMR of nonmagnetic materials.

2. NQR IN SOLIDS

As in the case of NMR, NQR studies of solids provide both structural and dynamic information. For example, crystallographically nonequivalent nuclear sites can be distinguished by differences in the values of the quadrupole parameters. These parameters are often obtained more readily and accurately using NQR spectroscopy rather than NMR spectroscopy. In pure NQR spectroscopy, the quadrupole interaction does not just give rise to a perturbation of the Zeeman levels; no magnetic field is employed, and so the energy levels are generated entirely by the quadrupole interaction. The NQR resonance is unaffected by chemical-shift anisotropies, and therefore the complicated line shapes found in some cases in NMR are avoided. Because, in NMR, all of the responses from nuclei in sites with different quadrupole interactions cluster around the Larmor frequency

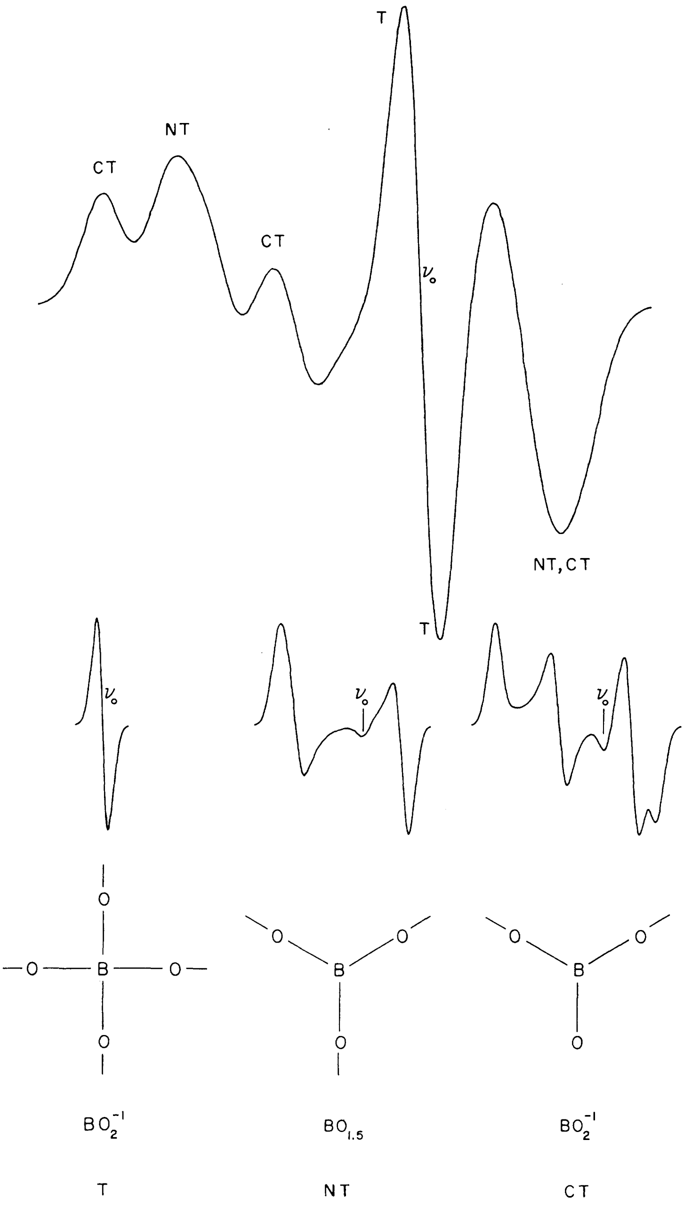

FIG. 12. Derivative spectrum of a dipolar broadened and second-order quadrupolar broadened ^{11}B NMR response. The spectrum is comprised of a weighted sum of spectra due to different sites. The features in the spectrum are labeled T (tetrahedral), NT (neutral trigonal), and CT (charged trigonal), corresponding to the boron units as shown below the spectrum.

ν_0 [see Eq. (2) and Fig. 12], some responses may be unresolved and undetected. This is generally not true in NQR; each site gives rise to one or more resonances at various frequencies determined by Q_{cc} and η. Additionally, for some nuclei such as ^{35}Cl, measurement of the quadrupole parameters by NMR may not be possible because the quadrupole interaction is too large and the resonance is broadened beyond detection.

In addition to measuring Q_{cc} and η, NQR is a valuable technique for obtaining T_1 and T_2. Phase transitions can be detected by their measurement since structural phases are characterized by different relaxation times.

The NQR responses for many nuclei in many solids occur at low frequencies (e.g., less than 5 MHz), a range where resonance methods are relatively insensitive. Since the first successful pure quadrupole resonance experiment was performed (Dehmelt and Krüger, 1950), there have been many variations on the two basic detection methods, cw and pulsed NQR, all aimed at providing a greater sensitivity. These will be summarized after a discussion of the basic theory of pure quadrupole resonance.

2.1 Quadrupole Interaction in Zero Magnetic Field

As noted above, the energy levels are generated entirely by the quadrupole interaction. The magnetic quantum number *m* is used to label the quadrupolar energy levels (although *m* is not strictly a good quantum number unless $\eta = 0$) and allowed transitions are given by $\Delta m = \pm 1$. For spin-1 nuclei the three energy levels are given by

$$E_{\pm} = (hQ_{cc}/4)(1 \pm \eta),$$
$$E_0 = -hQ_{cc}/2, \tag{18}$$

giving rise to three NQR frequencies:

$$\nu_{\pm} = (3Q_{cc}/4)(1 \pm \eta/3),$$
$$\nu_0 = (\eta/2)Q_{cc}. \tag{19}$$

Spin-$\frac{3}{2}$ nuclei have four (two doubly degenerate) available energy levels,

$$E_{\pm 3/2} = (hQ_{cc}/4)\sqrt{1 + \eta^2/3}$$
$$E_{\pm 1/2} = -(hQ_{cc}/4)\sqrt{1 + \eta^2/3}, \tag{20}$$

and only one NQR transition frequency:

$$\nu = (Q_{cc}/2)\sqrt{1 + \eta^2/3}. \tag{21}$$

The transition frequencies for nuclei with other spin values are more complicated and are not reproduced here. In general, for half-integer spins, there are $I + \frac{1}{2}$ energy levels, all doubly degenerate, and there are $I - \frac{1}{2}$ transition frequencies. For a spin-3 nucleus, there are 18 possible transitions. Tabulations of transition frequencies as functions of Q_{cc} and η can be found elsewhere (Butler and Brown, 1981; Creel, 1982).

2.2 Detection Methods

The detection methods that have been developed have various advantages and disadvantages depending on the particular nuclei, the material being studied, and the problem of interest. Historically, pulsed techniques have been widely employed for NQR studies, and are clearly preferable where relaxation times are desired. The quadrupole resonances for some nuclei (^{11}B and ^{27}Al), however, have not been successfully studied by pulsed NQR, and cw methods must be used.

2.2.1 Continuous-Wave NQR There are two categories of cw NQR spectrometers based on the type of generator-detector used. A super-regenerative oscillator was used in the first observation of a pure quadrupole resonance. An oscillator is an *LC* (tank) circuit in which the frequency of oscillation is given by $\omega = 1\ \sqrt{LC}$. A frequency range can be swept with a variable capacitor. A super-regenerative oscillator is one in which the rf amplitude is quenched at a low rate compared to the oscillator frequency by a superimposed wave form. After a quench, while the amplitude of oscillations is building, the oscillator is more sensitive to external signals as its characteristic frequency. In an NQR spectrometer, the super-regenerative oscillator is operated in the coherent mode. That is, the quenching action is incomplete so that the phase of the rf in the coil is maintained. The rf spectrum is then made up of the fundamental frequency plus a number of discrete components that occur at integral multiples of the quenching frequency, all of which can excite nuclear quadrupole transitions. This type of spectrometer is very sensitive but has several disadvantages. The rf output is high, easily saturating many systems. The observed line shape is not predictable, being generally a mixture of absorption and dispersion components, and is complicated by sidebands that result from rf components related to the quenching frequency; thus, the method is not applicable to the detection of closely spaced multiplets or the study of line shapes. To address these problems, a number of modifications to the super-regenerative scheme have been devised, the particular approach depending on the frequency range of interest.

Marginal oscillators were first developed by Pound and Knight (1950) and then by Wang (1955). A significantly improved version was developed by Robinson (1963, 1982), reportedly approaching the theoretical limit in signal-to-noise ratios. In the Robinson spectrometer, the sample is placed in the inductor coil of the *LC* oscillator, and the frequency is swept by tuning the capacitor. When the oscillating frequency is tuned to the NQR frequency, the coupling between the magnetic moments of the nuclei and the rf electromagnetic field induces transitions between the quadrupole energy levels, resulting in the absorption of rf energy by the nuclear spin system. Thus the rf voltage across the coil becomes a function of nuclear absorption. These signals are weak, and lock-in detection is used to improve the S/N. Recent improvements on the Robinson oscillator have resulted in sensitive NQR spectrometers, operable in low-frequency regions, that produce undistorted line shapes. An additional advantage of the marginal oscillator over the super-regenerative oscillator is the low rf output; systems characterized by long relaxation times are not as easily saturated using spectrometers.

2.2.2 Pulsed NQR Pulsed techniques similar to those used in NMR were first developed in 1954 (Bloom *et al.*, 1955) and offer many advantages over cw NQR. There is an overall increase in sensitivity, especially to broad lines, because spin-echo methods can be employed, and the problem of saturation is overcome. Additionally, the line shapes are undistorted and relaxation times can be accurately determined. The chief disadvantage is the unexplained failure of pulsed spectrometers to detect the resonances of certain nuclei such as ^{11}B and ^{27}Al.

2.3 Applications of NQR in the Study of Solids

Because the nuclear quadrupole parameters Q_{cc} and η characterize the nuclear site, experimentally determined NQR transition frequencies provide important information about the local atomic arrangements in a solid. When the probe nucleus is spin-$\frac{3}{2}$ and hence gives rise to only one transition frequency [Eq. (21)] for each site, independent measurement of both Q_{cc} and η is precluded. If however, the nucleus of interest has another isotope of spin 1 or greater than $\frac{3}{2}$, both parameters can be determined precisely. Because the EFG for both isotopes is identical, η has the same value in each case. The ratio of the values for Q_{cc} becomes simply the ratio of the electric quadrupole moments for each nucleus. Therefore, observing the transition frequencies for both isotopes uniquely evaluates Q_{cc} and η. ^{11}B (spin $\frac{3}{2}$) and ^{10}B (spin 3) cw NQR have been used in this manner to study the structure of boron-containing solids.

^{14}N, a spin-1 nucleus, has been used as a probe in pulsed NQR studies of structure and of phase transitions in a large number of nitrogen-containing compounds. The NQR transition frequencies given by Eq. (19) uniquely determine the quadrupole parameters for each crystallographically independent N site. Line shapes, relaxation times, and values of Q_{cc} and η are obtained at different temperatures, thus characterizing structural phases.

GLOSSARY

EFG: Electric field gradient.

FID: Free-induction decay. The net magnetization, precessing freely after an rf pulse, induces a decaying signal in a receiver coil.

Gyromagnetic Ratio (γ): Ratio of the magnetic moment of a particle to its spin moment.

MAS: Magic-angle spinning.

Powder Pattern: The envelope of NMR responses from an averaging of the resonance condition over all possible orientations.

Saturation: Condition in which the spin system is unable to absorb more energy because of insufficient rate of transfer of energy to surroundings. This occurs when the spin system has been irradiated with high rf levels and/or when longitudinal relaxation times are long.

Spin Echo: The reappearance of a NMR signal resulting from rephasing the components of magnetization in the *x,y* plane.

INTRODUCTION

The application of nuclear magnetic resonance (NMR) imaging to medicine has had an enormous impact on diagnostic radiology. High–spatial-resolution, diagnostic quality, medical images can be routinely and noninvasively generated at any angle to, and projection of, the human body. Information can be obtained that depends on the complex interaction of many parameters, allowing, for example, tissue discrimination between normal and diseased states. The NMR signal not only provides morphological data, but also *in vivo* data concerning human biochemistry and pathophysiology based upon the principles and interactions of atomic nuclei, rather than the electrons, as is the case for conventional x-ray radiology.

NMR imaging has become a multibillion dollar industry, with the result that expensive, highly automated imaging systems are rapidly pervading the hospitals of the world. In the interests of public relations, the word "nuclear" was dropped from NMR, and the subject is now commonly known in the medical field by the acronym MRI, or magnetic resonance imaging.

Section 1 gives a brief historical overview of the development of MRI. The rest of the article is devoted to detailing the principles of MRI (Sec. 2) via its analogy to optics, and the equipment needed to perform such experiments (Sec. 3); the latter concentrates on apparatus relevant for imaging, and glosses over general aspects of the spectrometer. Section 4 gives a brief overview of some imaging applications, chosen to show the di-

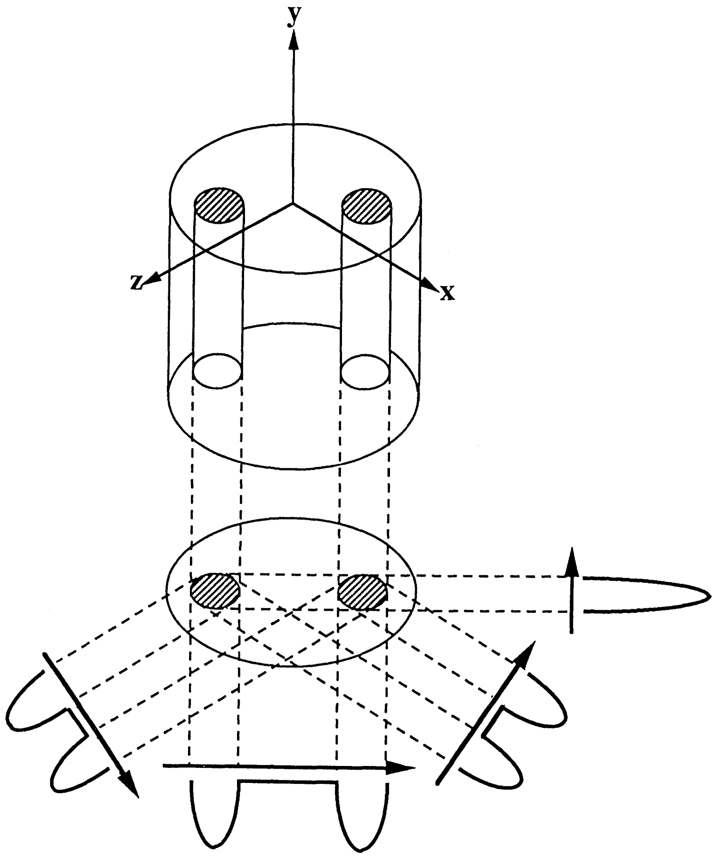

FIG. 1. Schematic of the projection-reconstruction method used by Lauterbur (1973) to create an MR image of two tubes of water. The arrows represent the direction of the magnetic-field gradients used to encode the NMR signal with spatial information, and the various shapes below them represent the one-dimensional projections of the tubes onto the gradients. Projecting the shapes back along the gradients (dotted lines) creates the two-dimensional MR image of the tubes.

component directed along the field, with the direction determined by the allowed quantization levels of the moment. In the presence of a strong magnetic field, a Boltzmann population difference is induced between these levels, with a very small excess of nuclei (about 1 in 10^6–10^9, depending on H_0) aligned parallel to the field. It is this slight excess that is exploited by the magnetic resonance practitioner, making magnetic resonance an intrinsically insensitive technique.

2.1 Influence of Magnetic-Field Gradients

The nuclear environment generates additional magnetic fields that co-add vectorially to $\mathbf{H}_0$ and so influence the precessional frequency of the nuclei, as dictated by Eq. (1). In conventional nuclear magnetic resonance, the spectrum of nuclear precession frequencies produced in this way gives information about the local environment of the spins, and so it is important to ensure that the static field is as homogeneous as possible across the sample. In contrast, imaging is concerned with the application of magnetic-field gradients that are tailored to vary linearly across the sample space, evoking a similar spatial dependence in the Larmor frequency of the spins. The linearly varying magnetic field is applied independently of the static field by means of specially shaped coils. As the magnitude of the field gradient is in practice much less than H_0, ω_0 is only affected by any components parallel to the static field. The local Larmor frequency is then defined as

$$\omega(\mathbf{r}) = \gamma H_0 + \gamma \mathbf{G} \cdot \mathbf{r}, \tag{2}$$

where $\mathbf{G}$ represents the gradient of the applied field component parallel to $\mathbf{H}_0$, and $\mathbf{r}$ is the nuclear spin position vector. In practice, image resolution is not at the nuclear level, and we are dealing with ensembles of spins within finite volume elements centered at positions $\mathbf{r}$.

2.2 k-Space Representation of MRI and its Optical Analogy

In 1973, Mansfield and Grannell applied the concept of a reciprocal-space vector **k** to demonstrate the link between MRI and conventional optics. The **k**-space analysis has since become a way of developing novel imaging schemes by allowing an easier visualization of the scanning modes. A reciprocal vector in **k** space is defined by

$$\mathbf{k} = (2\pi)^{-1}\,\gamma\mathbf{G}t, \tag{3}$$

where t is the duration of the gradient.

As can be seen, both **G** and t are involved in determining **k** space because, unlike x-ray tomography, MR data are acquired in the conjugate (time) domain. The time-domain signal $S(t)$ written in the **k**-space format is given by

$$S(\mathbf{k}) = \int_{-\infty}^{+\infty} d^3r\,\rho(\mathbf{r})\exp(i\gamma H_0 + i\mathbf{k}\cdot\mathbf{r}), \tag{4}$$

where $\rho(\mathbf{r})$ represents the nuclear spin density within the volume element at **r** and i is $\sqrt{-1}$.

Equation (4) is analogous to that of a plane wave scattered from some point P displaced by **r** from the origin O, shown diagrammatically in Fig. 2. The wavy line represents the total accumulated phase γH_0 of the "scattered" wave at the origin. The straight lines represent the additional phase accumulation arising from the "scattering" in the gradient at P. The theoretical wavelength of the fictional MRI wave can be written as $\lambda = 2\pi/k$, and just as in the diffraction limit in optics, it is λ that determines the spatial resolution obtainable in MRI, and not the wavelength of the radio-frequency (rf) radiation at the Larmor frequency. As a result, MRI is able to resolve spatial structures far smaller than would be possible from normal scattering of the radio-frequency electromagnetic wave.

To draw the link between MRI and scattering more clearly (Mansfield and Grannell, 1973), consider a discrete distribution of static spins forming an orthorhombic lattice with unit-cell dimensions a,b,c. The displacement vector $\mathbf{r}_{lmn}(q)$ from the origin to the qth spin site in the (l, m, n)th unit cell is given by

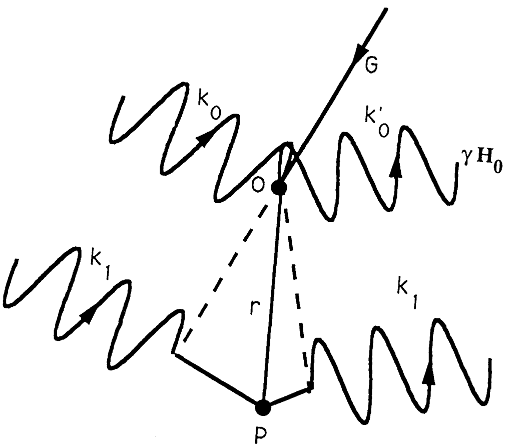

FIG. 2. Schematic of the scattering of the fictitious "NMR wave" from some point P displaced by **r** from the origin O, using an optical analogy to describe the MRI technique. The wavy line represents the total accumulated phase of the scattered wave at the origin ($k'_0\gamma H_0$), while the straight line represents the additional phase accumulation from scattering in the gradient G at P, K'_1.

$$\mathbf{r}_{lmn}(q) = (l + u_q)\mathbf{a} + (m + v_q)\mathbf{b} + (n + w_q)\mathbf{c}, \tag{5}$$

where $\mathbf{a} = a\mathbf{i}$ (**i** is the unit vector), etc. The u_q, etc., are fractions of the primitive-cell dimensions and l,m,n are integers. The NMR signal can now be rewritten as a discrete scattering equation:

$$S = \sum_{l,m,n} a_{lmn}\exp[i2\pi(le + mf + ng)] \times \sum_q f_q \exp[i2\pi(u_qe + v_qf + w_qg)], \tag{6}$$

where $e = ak_x/2\pi$, etc., and $a_{lmn} = 0, 1$. The dimensionless quantities e,f,g are the Miller indices at time t. The term involving the summation over q, which corresponds to signal contributions from within the unit cell, is equivalent to the geometrical structure factor S_k in electron or neutron scattering. The NMR scattering cross section $f_q = 0$ or 1, according to whether resonant spins are absent from, or present within, the cell. This gives plane-wave diffraction from a regular lattice. Hence, the NMR signal $S(\mathbf{k})$ gives rise to a diffraction pattern that, for regular structures, can be used to determine directly the lattice constants, just as in x-ray diffraction studies. More importantly, NMR diffraction measurements carry both phase and amplitude information, which means that the inverse Fourier transformation of the NMR diffraction pattern yields directly the spatial distribution of spins or (more exactly) ensembles of spins.

This conjugacy of signal and spin density is the fundamental relationship of MRI . The NMR signal $S(k_z)$ from a three-dimensional object encoded using a gradient along the z direction can be written in the **k** space formalism as

$$S(k_z) = \int_{-\infty}^{+\infty} \left(\int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \rho(x,y,z) dx\, dy \right) \times \exp(i2\pi k_z z) dz, \tag{7}$$

where the term in large parentheses is called the spectrum of the sample in the presence of the gradient. The spectrum, $P_{xy}(z)$, can be considered as one-dimensional (1D) projection of the three-dimensional (3D) nuclear spin density onto the direction of the field gradient, and for this reason is referred to as the *projection profile*. All nuclei in a plane perpendicular to the field gradient will experience the same field and contribute to the signal amplitude at the same frequency. The projection can then be written as the Fourier transformation of the signal $S(k_z)$:

$$P_{xy}(z) = \int_{-\infty}^{+\infty} S(k_z) \exp(-i2\pi k_z z) dk_z. \tag{8}$$

As can be inferred from Eq. (3), **k** space may be traversed by moving either in time or in gradient magnitude, and the direction of the traverse is always determined by the direction of the gradient G. The way in which the sampled points are distributed in **k** space is known as a raster; two commonly used rasters are those based on Cartesian and polar coordinates.

2.3 Selective Excitation

Efficient and precise excitation of a selected region of the sample is a vital component of most MRI techniques. This is because the imager or radiographer may only be concerned with a particular "dissected" region of the body and may wish to exclude possible conflicting information from other regions. The excitation principle is described below. The bandwidth of frequencies contained in an rf excitation pulse is inversely proportional to pulse duration, i.e., if a pulse has a duration of 1 ms, then only those spins with a resonant frequency within approximately a 1-kHz bandwidth of the Larmor frequency will be stimulated. In pulsed NMR the whole frequency spectrum is normally irradiated using broadband, or "hard," rf pulses, usually intense rectangular (in the time domain) pulses of short duration. The excitation profile of these pulses, a sinc function, is given by the Fourier transform of the pulse envelope; see Fig. 3(a). In MRI what is required is as close to an excitation of a rectangular band of frequencies as is possible. This means that tailored, narrow-band (or "soft") rf pulses have to be employed. Figures 3(b) and 3(c) show the excitation profiles of two widely used soft pulses, a Gaussian pulse and a double-lobed, truncated sinc pulse.

In order to excite a rectangular frequency profile within a required layer, the soft rf pulse has to be applied in the presence of a field gradient. Figure 3(d) shows a homogeneous spin distribution in the form of a cylinder, the axis of which lies along the z axis, with a linear static gradient G_z existing over the sample. Spins that lie in the plane z are at exact resonance and interact strongly with the rf pulse, while those spins on either side of this plane will be progressively less affected the further they lie away from it. In this way, a spatially defined layer of spins has been selected. As can be inferred from the diagram, adjusting the parameters $\Delta\omega$ and G_z changes the width of the selected slice—a thin slice can be obtained using either strong gradients or a narrow-band pulse. By choosing an appropriate direction for the slice gradient, the orientation of the plane can be chosen at will—this is an advantage of MRI over x-ray CT where slices are necessarily normal to the detector-plane axis (the terms *axial, coronal,* and *sagittal* are used to describe the slice orientation). The use of three slice-selective pulses, in quick succession and in conjunction with appropriately oriented gradients, will select a volume of nuclei within the patient.

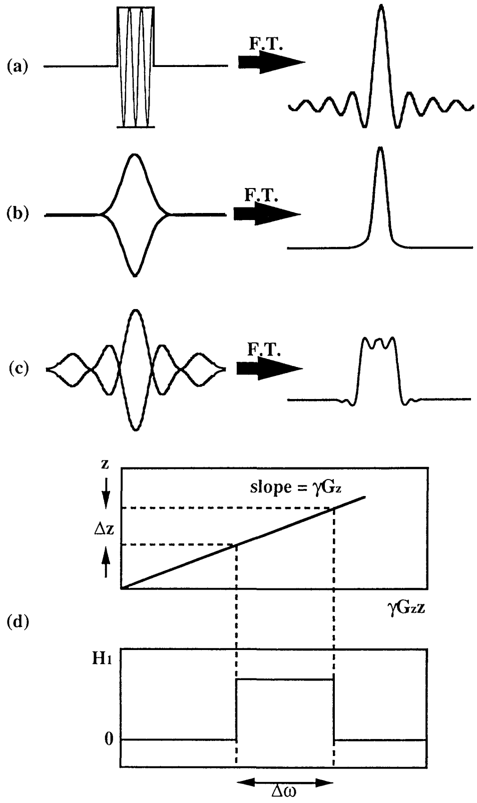

FIG. 3. Schematic of some NMR pulses. (a) A wide-band, "hard," top-hat pulse that excites a profile given by the Fourier transformation (FT) of its envelope, a sinc function. (b), (c) Some commonly used narrow-band, "soft," slice-selective NMR pulses, (b) a Gaussian pulse and (c) a double-lobed, truncated sinc pulse, and their Fourier transformations, a Gaussian and a top-hat excitation profile, respectively. (d) A schematic of the process of slice selection, where the combination of a pulse exciting a range of frequencies $\Delta\omega$ and a magnetic-field gradient of slope γG_z will select a slice, or plane, of thickness Δz in the sample.

2.4 Two-Dimensional Imaging and Reconstruction

If the equilibrium magnetization in a 3D sample is disturbed, for example, by selective excitation, then image reconstruction may be performed in the two dimensions of the slice plane. The resulting image is an average of contributions from across the layer, and the volume element (voxel) will have its depth dimension defined by the slice thickness.

2.4.1 Fourier Imaging Fourier imaging uses the Cartesian raster of Kumar *et al.* (1975), and encodes phase and amplitude information in the NMR signal by means of specifically defined evolution periods. One of the possible timing diagrams and illustration of the method can be seen in Fig. 4. Following slice selection, there is a period of *phase encoding,* so called because the (in this case) G_y gradient imparts a phase modulation to the signal, dependent on the position of the volume elements along the y axis. Phase encoding then corresponds to scanning **k** space along the k_y axis, and since $k_y = (2\pi)^{-1}\gamma G_y t_y$, there exist two extreme cases for accumulating the phase:

1. when G_y is constant and t_y is incremented (Kumar *et al.,* 1975), and
2. when t_y is fixed and G_y is incremented in equal steps (Edelstein *et al.,* 1980).

Following phase encoding, the NMR signal is further spatially encoded in the "read" period, t_x, a process known as *frequency encoding.* As the signal is sampled in the presence of G_x, signal points can be obtained along a single line in **k** space given by $k_x = (2\pi)^{-1}\gamma G_x t_x$.

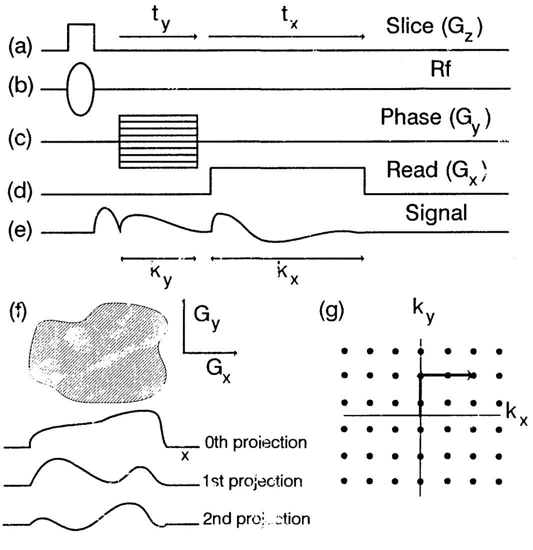

FIG. 4. Timing diagram of one of the possible means of Fourier imaging. After (a)–(b) slice selection, there follows a period of spatial encoding of the NMR signal, using (c) a "phase"-encoding gradient G_y on for a period t_y, and (d) a "frequency"-encoding gradient G_x on for a period t_x. (e) The change in amplitude and phase of the NMR signal due to spatial encoding by the gradients. (f) Projections taken along the x direction for different values of the G_y gradient. (g) An indication of how the **k**-space Cartesian raster is traversed using this technique.

In practice, **k** space is sampled along the x axis under a fixed read gradient, and the process repeated for successively increased values of k_y intercept so that the first quadrant of **k** space is sampled on a raster with the signal sampled along k_x being stored as a row in a matrix. Reversing the y gradient allows the fourth quadrant to be mapped, and since the image density

$$\rho(x,y) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} S(k_x,k_y) \times \exp[-i2\pi(k_x x + k_y y)]dk_x\, dk_y \qquad (9)$$

is (ideally) a real function, the signal $S(k_x,k_y) = S(-k_x,-k_y) = S^*(k_x,k_y)$. A 1D Fourier transformation of the signals obtained in the read period from successive experiments yields a set of profiles partially encoded along k_x; see Fig. 4(f). The set is further transformed along k_y by a second 1D Fourier transform to yield the image of the object.

2.4.2 Projection Reconstruction If the NMR signal is acquired while the imaging gradient **G** is applied in some arbitrary direction, a series of signal points are obtained along a radial direction in **k** space. By varying the direction of the gradient, **k** space may be sampled on a polar raster (see Fig. 5 for a timing diagram and illustration of the method). In practice this is done by applying gradients in the x and y directions simultaneously and adjusting their relative values so that the variable polar angle and constant magnitude are, respectively,

$$\phi = \tan^{-1}G_y/G_x \quad \text{and} \quad |\mathbf{G}| = (G_x^2 + G_y^2)^{1/2}. \qquad (10)$$

Reconstruction can be performed in two ways. The first involves initial interpolation on a Cartesian raster, and subsequent Fourier transformation with respect to k_x and k_y. The second, projection reconstruction, is the same as that performed on x-ray CT data, where the interpolation is performed in real space. The image in polar form is given by

$$\rho(x,y) = \int_0^{\pi}\left(\int_{-\infty}^{+\infty} S(k,\phi) \times \exp(-i2\pi\mathbf{k}\cdot r)|k|dk\right)d\phi, \qquad (11)$$

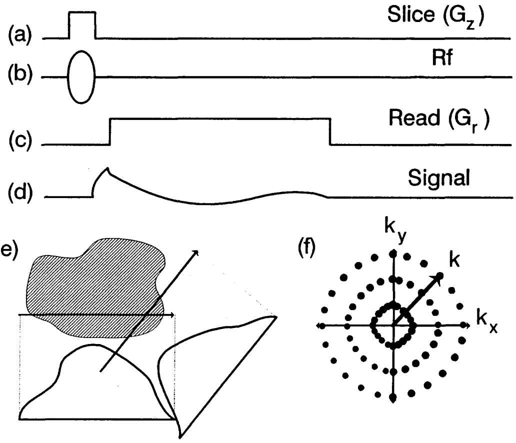

FIG. 5. Timing diagram for the projection-reconstruction technique. After (a)–(b) slice selection there follows (c) a period of spatial encoding of the NMR signal using the gradient G_r, which, in practice, is the vector addition of the gradients G_x and G_y applied simultaneously. (d) The change in amplitude and phase of the NMR signal due to spatial encoding by the gradient, (e) projections taken along different directions in space according to the G_r gradient. (f) An indication of how the **k**-space polar raster is traversed using this technique.

where the inner integral is the filtered profile. In practice, following slice selection, the gradient is swept in angular increments over two quadrants, and at each position the filtered profile is calculated. For each position (x,y) in the image matrix, the projection r along **G** is calculated, and the closest possible value to the filtered profile assigned. This is a process of back-projection and interpolation. The rule for conjugacy of the signal S (Sec. 2.4.1) holds.

In general, Fourier imaging is the preferred technique for two-dimensional MRI. The reasons for this are many and include the following:

1. Fourier imaging samples **k** space more effectively;
2. sampling **k** space in equal steps means that gradient calibration and matching of the driver amplifiers is very important in projection reconstruction (it can be difficult to achieve this in practice);
3. $\mathbf{H}_0$ inhomogeneities manifest themselves as curves in the projected lines making reconstruction difficult (in Fourier imaging they appear as geometric distortion).

2.5 Three-Dimensional Imaging and Reconstruction

The Fourier imaging technique can employ a second phase-encode gradient, with, in this case, magnitude G_z and duration t_z. One method in which it can be employed is to step it in conjunction with the stepped y gradient, i.e., for each step in the z gradient, G_y is allowed to step through its whole range of values, and in this case a full (k_x,k_y) plane is imaged per value of k_z. The image is then reconstructed by a 3D Fourier transformation.

The mathematics of 3D projection reconstruction is essentially the same as for two dimensions except that now a spherical polar, rather than cylindrical polar, coordinate system is used. Three-dimensional projection reconstruction was developed by Lauterbur and his colleagues (Lai and Lauterbur, 1980), and one way of performing this technique is to direct the field gradient $\mathbf{G}_r$ around some path so as to produce a series of 2D projections by reconstruction in the conventional manner. These can be combined using the same algorithm to yield a 3D image.

Both of the above methods employ hard pulses. A third method of generating a three-dimensional image involves sequential imaging of adjacent or interleaved slices. This multislice approach relies on selective excitation ideally disturbing the magnetization in the slice being imaged, so that nuclear spins in other slices remain in thermal equilibrium, available for immediate excitation following the first acquisition. The images can then be separately Fourier transformed and viewed as a series of slices; alternatively, the 2D images may be collated and then interpolated to generate a 3D image. The acquisition of multi(thick)slice 2D images is the preferred method of choice for most clinical imaging; however, it is less appealing (except in the total imaging time sense) as a means of generating 3D images since slice definition is rarely accurate (resulting in out-of-slice excitation and subsequent artifacts when the data are interpolated) and in order to generate slice thicknesses equivalent to 3D pixel resolution, very strong gradients in the slice direction have to be generated [with all the attendant problems (Sec. 3.2)].

2.6 Image Contrast and Resolution

A tissue's "brightness" is directly proportional to the MR signal strength arising from that tissue. In order to distinguish adjacent tissues in an MR image, each must possess different image brightness. This concept is expressed in the term *contrast*, and it is used by the clinician for, for example, differentiating between healthy and diseased tissue. Unlike other imaging modalities, there are a number of parameters that affect image contrast in MRI. These can be divided into two basic groups: parameters intrinsic to the tissue, and extrinsic, operator-dependent factors. In the first category, the principal factors include spin density and characteristic signal-decay time constants T_1 and T_2. The latter category includes the type of imaging sequence, the "repeat" time (T_R), the "echo" time (T_E), and the administration of contrast agents. Manipulation of the extrinsic parameters to maximize the effect of the intrinsic parameters is the great strength of magnetic resonance.

2.6.1 Tissue-Intrinsic Contrast Mechanisms Nuclear spin densities of many tissues in the body only differ by a few percent, and so they do not provide an efficient contrast parameter. More useful is MR relaxation. The nuclei in the body do not exist in isolation, but interact with the fluctuating magnetic fields of neighboring nuclei or the lattice environment. When nuclei in an excited state interact with the fluctuating fields generated by their local molecular environment, they "relax" back to their equilibrium state in a manner determined by the physical and chemical nature of their environments. This is the physical basis of MR, and the strength of these interactions is measured by the "relaxation"-time constants associated with them.

When a sample is placed in a magnet, the population difference is not induced instantaneously. The nuclei nonradiatively transfer some of their magnetic energy to their surroundings, and the population difference rises exponentially and asymptotically towards the Boltzmann equilibrium condition; see Fig. 6(a). The time constant is known as the spin-lattice relaxation time T_1, where the term *lattice* is a general term for the thermal motions of the molecules of which the nuclei are a part. Typical human tissue T_1 values for hydrogen

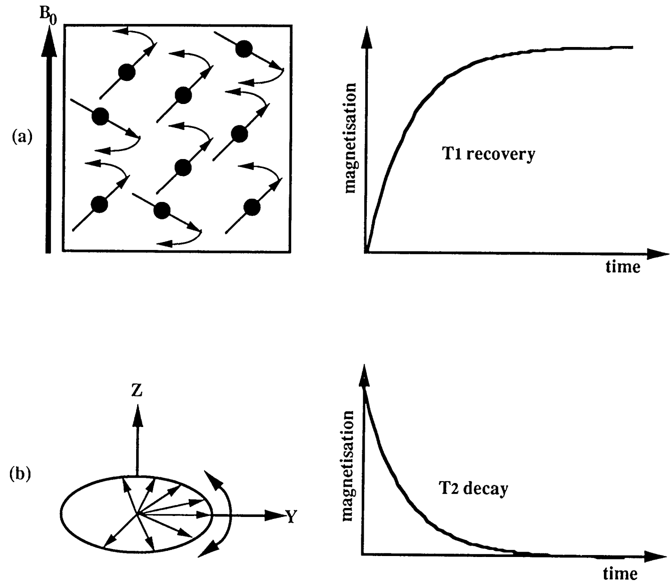

FIG. 6. Schematic of the two most common means of nuclear relaxation. These give rise to contrast changes across MR images. (a) The nuclear spins becoming aligned along the main magnetic field $\mathbf{H}_0$, traditionally taken as the *z* direction. This alignment is not instantaneous, but is exponential and asymptotic with a time constant T_1, the spin–lattice relaxation time. (b) How the nuclear spins, in the transverse *x*-*y* plane, lose phase coherence within a time T_2, the spin–spin relaxation time.

nuclei measured *in vivo* at 0.15 T (they are a function of H_0) are 250 ms for the liver, 600 ms for the spleen, 520 ms for brain grey matter, 380 ms for brain white matter, 700–1200 ms for a brain tumor, and 170 ms for fat.

By applying an rf pulse of the right frequency to the nuclear system, interactions can be induced between the nuclei perturbed to an excited state. At the end of the pulse, the nuclei start precessing in phase; however, they are influenced by the presence of small magnetic interactions that cause the nuclei gradually to lose phase coherence with a time constant known as the spin–spin relaxation time T_2; see Fig. 6(b). In contrast to T_1, T_2 interactions do not involve exchange of energy with the lattice, but between the spins themselves, via flip-flop type interactions. Typical T_2 values for human tissue measured *in vivo* at 0.15 T are 50 ms for the liver, 100 ms for the spleen, 95 ms for brain grey matter, 85 ms for brain white matter, 120–300 ms for a brain tumor, and 80 ms for fat. Note that the slightly higher hydrogen nucleus-density of tumors, and other pathology, tends to oppose contrast due to T_1 weighting and aids contrast due to T_2 weighting.

2.6.2 Tissue-Extrinsic Contrast Mechanisms In order to understand how to manipulate contrast, it is necessary to examine signal strength in a little more detail. Signal strength is proportional to the following:

1. nuclear spin density (ρ);
2. a T_1-weighting term, which is a function of T_1 and T_R;
3. a T_2-weighting term, which is a function of T_2 and T_E; and
4. the usual imaging gradient term.

These all act simultaneously, and the MR signal from within a voxel is more accurately given by

$$\text{Signal} \propto \rho[1 - a\exp(-T_R/T_1)] \times [\exp(-T_E/T_2)]. \tag{12}$$

where a is a pulse-sequence-dependent variable.

The repeat time T_R is concerned with the manipulation of T_1 contrast. After spin excitation using rf pulses, a period of recovery is needed for the spin system to return to equilibrium with its surroundings [$\approx(3\text{–}5)T_1$]. If the next rf pulse (or module of pulses) is applied too soon, the spin system is said to become *saturated* and the numbers of spins aligned parallel and antiparallel to the main field become equal, resulting in no population difference and hence no observable signal. T_1 weighting is increased as T_R is reduced, and in practice this means that certain tissues can have their signals nulled by repeating the experiments so fast that their magnetization has no time to recover and they are excluded from the final image. If T_R is too short there is not enough time for signal recovery in any tissue and, in general, T_R's of 300–800 ms are used.

If magnet inhomogeneities are a dominant source of spin dephasing, the MR signal is said to decay with a time constant T_2^* ($<T_2$). *Shimming* can help reduce the effect, or else a phenomenon known as the *spin echo* may be employed. Spin echoes result from a certain class of experiment that refocuses phase coherence at some time after the initial spin perturbation. One of the simplest experiments is known as the Carr–Purcell (Carr and Purcell, 1954) sequence [Fig. 7(a)]. The first "90°" pulse rotates the magnetization aligned along the z axis (normally taken as the direction of the main field) through 90° about an axis defined by the phase of the rf constituting the pulse, and down on to the x-y plane, where the "transverse" magnetization decays during the period τ because of loss of phase coherence. The second, "180°," pulse flips the relative orientations of the individual spin vectors through 180° [Fig. 7(b)], and the spins rephase during the second τ period, creating a spin echo. Additional rephasings are possible by applying a stream of 180° pulses with intervals 2τ. Note that only loss of phase coherence due to $\mathbf{H}_0$ inhomogeneities can be refocussed in this way. T_E is given by 2τ, and by varying this interval, differential T_2 weighting can be created across an image as a result of the different tissue T_2's. The best T_2 contrast is obtained when T_E is intermediate between the T_2 relaxation times of the tissues, since for very long T_E's, tissue contrast is worsened because all the signals become weak and their differences may be masked by background noise. T_E's vary between 20 and 150 ms in practice, and Fig. 8 shows a simplified representation of image contrast as a function of T_R and T_E.

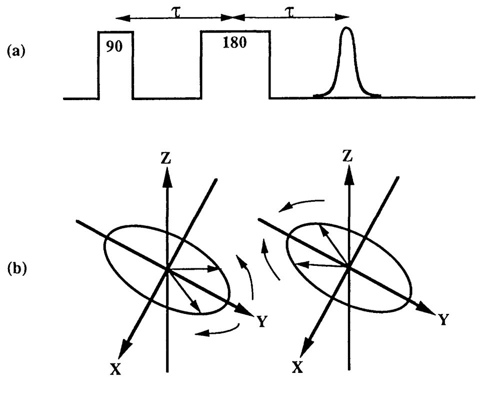

FIG. 7. Schematic of the Carr–Purcell (1954) spin-echo pulse sequence. The 90° rf pulse rotates the nuclei down from the z axis through 90° and onto the x-y plane, about an axis defined by the phase of the rf constituting the pulse. The nuclei are allowed to evolve for a period τ, before the 180° pulse flips the dephasing nuclei through 180°. The nuclei then rephase during the second period τ. Note that only dephasing caused by magnetic field inhomogeneities is rephased in this way.

A common method of enhancing tissue contrast is the use of contrast agents, analogous to the iodine-based ones used in x-ray CT, and most effort has gone into the application of gadolinium diethylene pentaacetic acid (Gd-DPTA), which is still the only one clinically approved. The effect of contrast agents is to reduce the relaxation-time coefficients (more T_1 than T_2), since they are strongly paramagnetic with one or more free electrons, which have a much larger magnetic moment than is associated with such nuclei as hydrogen. The metal atoms of contrast agents are toxic, and they are chelated with very high binding efficiency in order to make them acceptable for human consumption. This means that the number of attractive alternatives for *in vivo* contrast agents (ferromagnetic contrast agents are now being developed) is fairly limited.

2.6.3 Resolution In a conventional imaging system, the resolution is roughly equal to the wavelength of the irradiation used. If this were the case for MRI, then the resolution would be tens or even hundreds of meters. However, as mentioned in Sec. 2.2, MRI resolution is dictated by the strength of the gradient field, and can be written as

$$\Delta x = 2\pi \Delta \nu / \gamma G, \qquad (13)$$

where $\Delta \nu$ is the linewidth associated with the spin interactions taking place within the sample, and is related in some manner to the T_2 (or T_2^*) of the sample. For a typical T_2 of 100 ms and a typical gradient strength of 1 G/cm, the pixel resolution is of order 0.5 mm. In practice, on whole-body systems, in-slice MRI resolutions of 0.25 mm are readily achievable, though with slice thicknesses of 3 mm, a degree of volume averaging within the slice is unavoidable. Equation (13) would seem to indicate that there is no lower limit

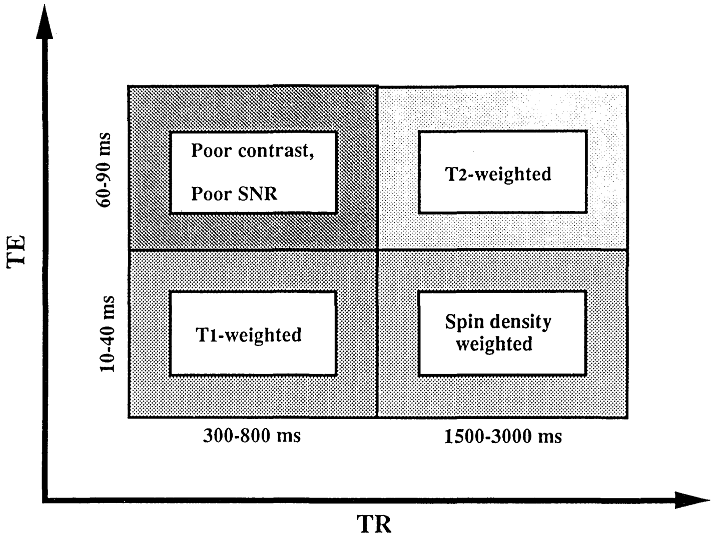

FIG. 8. Representation of how MR image contrast can be manipulated by varying the experimental parameters T_E, the echo time, and T_R, the repeat time. Lengthening T_E increases the T_2 weighting of the images, while shortening T_R increased the T_1 weighting of the images.

to the resolution that can be achieved, provided that enough gradient strength was available. This is, however, not the case. There is a fundamental limit to resolution based on the signal-to-noise ratio (SNR), and the relationship also includes the time taken to acquire the image. The relationship in full is

$$t \approx \left(\frac{S}{N}\right)^2 a^2 \left(\frac{T_1}{T_2}\right) \frac{2.8 \times 10^{-15}}{f^{7/2}} \left(\frac{1}{\Delta x}\right)^6, \qquad (14)$$

where t is the imaging time, a is the rf coil radius, S/N is the desired SNR, and f is the spectrometer frequency (the other terms have their usual meanings). This expression underlines the prime importance of efficient gathering of MR information if imaging times are to be kept as short as possible without sacrifice of SNR or anatomic resolution. The implied dependence of the imaging time on the sixth power of the resolution demonstrates that the sensitivity limit acts as a "brick wall" for the improvement in resolving power by signal averaging (there is a limit to how long a sick patient is able to remain in the magnet!). Even when examining a slice there is a fourth-power dependence, since $(\Delta x)^6$ becomes $(\Delta z)^2(\Delta x)^4$ for a Δz thick slice.

The problem can be alleviated somewhat in terms of the SNR by moving to higher field as $S/N \propto H_0^{3/2}$. However, this is, in turn, offset by the proportionality dependence of T_1 on the applied field, with the result that the recycle delay T_R also increases. Fast imaging techniques are able to produce images (relatively poor resolution) in a few tens or hundreds of milliseconds, but many of them suffer from intrinsically low SNR's. Whichever way the problem is regarded, there is almost always a trade-off involved. Even if clinical MRI resolution were to be brought down to MR microscopy level by some means, other restrictions would come in to play, such as diffusion, which act to decrease the SNR.

3. BASIC EQUIPMENT

In this section we will be concentrating on the apparatus relevant for imaging, and the reader is referred to the encyclopedia entry on MAGNETIC RESONANCE SPECTROMETERS for a more general discussion on NMR spectrometers.

3.1 Magnets

The magnet is the key element in an MRI system. Its role is to provide a high, uniform, and stable polarizing field in which to carry out the scan and a number of approaches to generating these fields have been developed. The advantages of permanent magnets lie in their cheaper cost and much lower stray field. The problems lie in their weight (approaching 100 tonnes, although 5–7-tonne versions are being devised) and poor thermal stability. For these reasons, permanent magnets for

MRI are still relatively uncommon, except in Japan where they have recently taken a significant share of the market. They are built of blocks of magnetic material, e.g., samarium cobalt compounds, ferrites, or more recently, iron–rare-earth–boron materials, and can generate fields of up to about 0.3 T.

By contrast, resistive magnets generate high fringing fields and internal fields up to 0.15 T. These can consume up to 60 kW of electrical power, and that power in the form of heat, has to be dissipated by cooling water. They are usually of the four/six-coil, complex Helmholtz type, consisting of two large central coils of typical size 1.5 m o.d. (outer diameter), and 1 m i.d. (inner diameter). The coils are mounted on a suspension system that allows independent movement of the four coils, thus allowing the magnet to be shimmed (active shims within the magnet may be used). They generate an acceptably homogeneous region over a sufficiently large volume, usually about 1 in 10^5 for 1-m i.d. central coils. The coils are constructed by winding thin bands of aluminum (insulated from one another), of the order of 2 mm thick and 15 cm wide. Aluminum is chosen as a compromise among weight, resistance, and cost, and most designs weigh between 1 and 10 tonnes.

Superconducting magnets represent the majority of magnets deployed in Europe and the United States. Ring magnets, generally made from twisted filaments of niobium-tin alloy in a copper matrix, are enclosed and surrounded by liquid helium to lower the temperature of the windings to 4.2 K. This is then surrounded by a further layer of cooling material, this time liquid nitrogen at 77.4 K, which is used to reduce the boiloff rate of the liquid helium. Superconducting magnets with field strengths of between 0.15 and 4 T have been used for MRI, with room-temperature bores of about 1 m diameter. The magnets are shimmed electrically using an array of shim coils within the magnet, and typical homogeneities are between 10 and 50 ppm (parts per million) over a 45-cm-diam region.

3.2 Gradient System

A gradient system consists essentially of three elements: a control system that defines the required gradient profiles and any compensation that may be required; power supplies to drive sufficient current to achieve the required gradient strength; and the gradients coils that generate the gradient fields.

3.2.1 MRI Gradient Designs There are many varieties of gradient winding designs, the choice being somewhat reduced by the necessity of allowing unrestricted patient access. The geometry of the gradient coils and the direction of the electric current determine the orientation of the gradient, and the design is to produce gradients that vary in a linear fashion, parallel to H_0, i.e., G_z varying as $\partial H_0/\partial z$, etc.

Among the more common designs are those inherited from NMR spectrometers where they were used for magnet shimming. The simplest is the Maxwell pair [Fig. 9(c)], a pair of circular coils, each with the same radius a, but with opposing currents generating a linearly varying field with zero field in the midplane. These are generally used for G_z. The conductor configurations for generating x and y gradients are more complex. The same design can be used for both, one being oriented at 90° to the other. A planar coil configuration was used in early MRI systems, where the linear gradient is generated by four approximately spaced straight wires, all with currents applied in the same direction. The return paths of the coils had to be sufficiently far away so as not to interfere with the main gradient field, and the dimensions of this design were often far too unwieldy for practical whole-body MRI. A third example, Fig. 9(b), is more commonly used in MRI and is known as the saddle configuration. Saddle geometry consists of two saddle coils with four current arcs, two on each end of a cylindrical shaped former, each with associated return paths. It is also possible to modify all three basic coils using a technique known as distributed winding, where the individual wires are distributed over the surface of a cylinder. In this way, field concentrations caused by bunching of the wires, and consequential lowering of the field energy for a given gradient strength, are avoided.

3.2.2 Eddy Currents and Gradient Shielding Two major problems are encountered when gradient fields are rapidly switched on and off. Apart from the large instantaneous voltages present across the coils when the currents through them are quickly altered, there are metal structures in close proximity to the gradient coils. As the gradient field

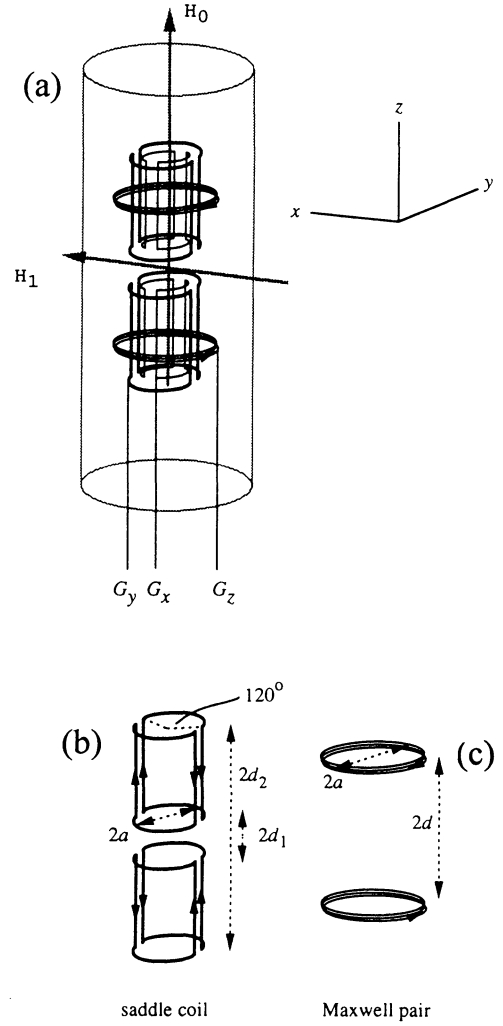

FIG. 9. Schematic of two commonly used magnetic-field gradient coil configurations. (a) The composite gradient set, which breaks down into (b) saddle coil or Golay geometry used for generating both *x* and *y* gradients depending on its orientations within the magnet bore, or the directions of the current flow; (c) Maxwell pair geometry used to generate the *z* gradient. (Reproduced with permission from Callaghan, 1991.)

changes, the changing flux lines passing through the metal surface induce *eddy currents,* which can persist for many milliseconds. Eddy currents cause additional unwanted magnetic fields that cause image artifacts and lengthen the switching time of the gradients. The problem is most severe for superconducting magnets, as a large continuous area of metal in the form of the thermal radiation shield is presented to the gradient fields.

If eddy currents merely changed the value of the gradient following the switch, it would be a simple matter to provide compensation with an appropriate time-dependent cancellation current in the gradient coil. However, many transient harmonics are produced, and each decays with its own decay constant. Several options are available for dealing with this problem. One is deliberately to overide the drive current at the leading and falling edges of the gradient pulse; or the coils themselves may be used to produce fields that compensate for unwanted induced currents. This preemphasis or deemphasis of the coil current relies on Lenz's-law requirement that the sign of the fields associated with eddy currents will be opposed to the change that produces them. The optimization of pre- and deemphasis is a complex process requiring adjustments of a multitude of time constants and amplitudes of exponential currents that are added to the desired wave form, and this compensation can never be perfect. Software correction of images may also be performed but requires exact and detailed knowledge of the eddy-current behavior, which is rarely available. An alternative technique is to employ *reduced-bore* gradients, where the gradients are wound on a former of reduced size as compared to the internal diameter of the magnet, designed to minimize the interaction with the metal surfaces, and hence the amplitude of the transients.

A more effective, and increasingly widely used, method is to ensure eddy-current suppression by using gradient sets whose fields are designed to be zero outside the gradient coil boundaries. *Active shielding* (Mansfield and Chapman, 1987, and references therein) can suppress external fields by up to two orders of magnitude, aided by rapid attenuation of the field with increasing distance from the coil exterior surface. The principle is to add a second layer of current density outside the primary-coil surface, which produces a magnetic field that precisely compensates the primary-coil field at all points in space outside the screen. This involves an entirely new design, as the cancellation currents also produce fields within the sample volume that may act at odds to the field gradients.

3.2.3 Gradient Drivers Whichever gradient coil system is adopted, the design of switched gradient systems is still a difficult problem, involving basic questions of magnet, coil, and power-supply design. The instantaneous power present when a gradient is switched may be many kilowatts, and the energy involved must be dissipated as heat, or stored. Energy-storage techniques involve holding the energy in either a capacitor or an inductor, and such power supplies need sophisticated engineering in order to stabilize the current in the coil once the energy has been transferred with the throw of an electronic switch. The power supplies used to drive each gradient coil can be operated in either constant-voltage or constant-current modes, where the output voltage or current, respectively, follows the drive voltage. Constant-voltage mode is easily implemented, but needs input voltage profiling to overcome coil back emf's. The constant-current mode setup senses the voltage across a resistance in series with the load, and presents this to one input of a difference amplifier that controls the output current. The other input voltage is provided by the voltage from the wave-form generator digital-to-analog converter, so that this voltage wave-form will be faithfully represented as an output current. The maximum current switching speed, di/dt, is limited partly by the power-supply voltage, which must equal $Ri + Ldi/dt$, where L and R are the load inductance and resistance, respectively. The other limitation rate is the bandwidth of the power supply, expressed in the time domain as the *slew rate*, or maximum rate of change of current. In MRI where the large gradient coil sets present a substantial inductive load to the current supplies, the gradient pulses must be turned on slowly using a ramp function. Gradient switching times of 1 ms seem to be standard.

3.3 Radio-Frequency Probes

The rf probe (or antenna) is an essential device, both for transmitting the rf power generated by the transmitter to the sample, and for detecting the nuclear response. Detection of the signal relies on the process of induction, where the precessing nuclei generate a fluctuating magnetic field that induces an emf in a loop of conductor through which the flux passes. The aim is to manufacture a receiving coil in which the maximum emf is generated, and at the same time, when used for transmission, the same coil should generate a homogeneous rf field, $\mathbf{H}_1$.

The most fundamental and important parameters of the rf coil are its quality (Q) factor and its filling factor. The closer the coil is coupled to the patient, the greater is its filling factor (the ratio of the volume occupied by the patient to the total coil volume) and hence the larger the detected emf. Against this must be set the needs of patient access and comfort, and a reasonable homogeneity of $\mathbf{H}_1$ over the region of interest. The Q factor is a measure of how sharply the coil is tuned to the NMR frequency and is the ratio of the reactance (ωL) to the resistance. The higher the Q, the lower the contribution of the coil to the thermal (Johnson) noise on the NMR signal. Unloaded Q factors of several hundred are normal in whole-body imagers. However, the presence of a patient within the coil (human tissue is an ionic conductor at megahertz frequencies) would decrease the Q factor, increasing the coil "resistance" and, hence, the noise. In addition, the rf may not completely penetrate the body, and the so-called *penetration depth* depends on tissue resistivity and the rf frequency. This is not a problem at field strengths of 1.5 T but becomes one at 4 T.

Different coil structures are required for different orientations of the main field. In order to excite the nuclear spins and for efficient flux cutting, the magnetic field lines of the rf coil must be perpendicular to the main field direction. Thus, with a permanent magnet, a solenoidal coil [Fig. 10(a)] gives the best SNR. For the vast majority of superconducting systems no such favorable orientation exists, and other designs are used. The conditions for maximum sensitivity and homogeneous $\mathbf{H}_1$ may be mutually exclusive, and may result in one probe being used for transmission (volume resonators such as slotted-tube, saddle [Fig. 10(b)], and bird cage [Fig. 10(c)] coils) and a second for reception (surface coils [Fig. 10(d)]).

3.4 Transmitter and Receiver

The rf transmitter consists essentially of a frequency source and amplifiers to boost the rf signals to the desired level. RF pulses are formed at low power by gating of a contin-

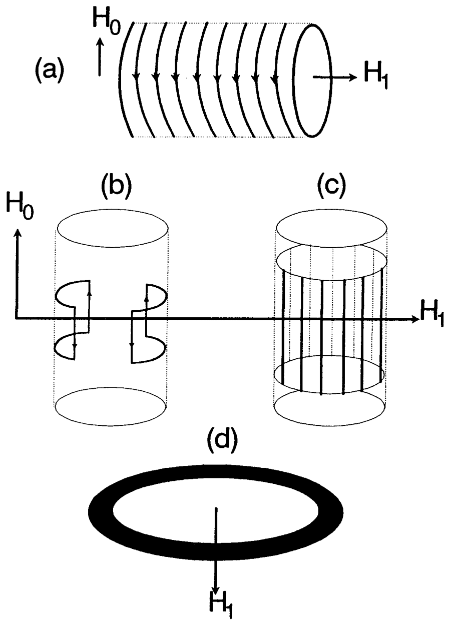

FIG. 10. Schematic of three commonly used radiofrequency coil configurations. (a) A solenoidal coil, which is oriented perpendicular to the main magnetic field, $\mathbf{H}_0$. (b), (c) The "saddle" and "bird-cage" coils, respectively, which are oriented parallel to the main magnetic field. (d) A fourth type of rf coil the surface coil, which, as its name suggests, is placed on the surface of the skin, close to the object which is to be imaged.

uous rf signal on and off with a switch, and are then fed through amplifiers to the sample via the probe. The switch usually has several stages, including sections acting on the amplifier, which then becomes *gated.* This is to ensure that rf does not leak through the switch to the sample between pulses, which would compete with the NMR processes or attenuate the signal by saturating it. Typical on–off ratios are 80–120 dB, equivalent to a voltage attenuation factor of 4 to 6 orders of magnitude.

The receiver consists of amplifier stages to make the MR signals large enough for detection, followed by the detector, which removes the carrier frequency so that only the signal envelope remains. The signal is then further amplified to a size appropriate for digitization. Because NMR is so insensitive, the receiver must amplify and detect the signal without introducing distortion and additional noise. Since the NMR signal in an imaging experiment is spread over a large range of frequencies by the action of the field gradients, a "window" has to be made by using an appropriate filter centered at the carrier frequency, so that only the signal and corresponding part of the noise spectrum will be let through. After amplification, the signal is demodulated into two components in phase quadrature. These are then converted into digital form by analog-to-digital converters (ADC's, normally one for each signal channel), suitable for processing by computer. The sampling rate (typically 10 kHz) is determined by the Nyquist theorem (Black, 1953), to a resolution of between 12 and 14 bits.

The transmitter and receiver are connected to each other, and the rf probe, via a matching network. Because NMR signals are in the microvolt range, whereas the transmitter generates hundreds of volts or more, the receiver has to be decoupled from the network during pulsing, otherwise the receiver electronics become paralyzed for a short time, the "dead time." This can be achieved (as has already been mentioned) by using separate probes for transmission and reception, alternatively using crossed diodes at the receiver input, or using a tuned limiter to the receiver.

3.5 Computer Requirements

The MRI experiment requires a succession of different operations for

1. data acquisition (such as pulse generation, gradient switching, analog-to-digital conversion, etc.), which must be performed according to a strict timing schedule, and
2. data analysis, display, and storage.

All of these require different levels of computer software and hardware, and, in the past, all this was performed by the system's minicomputer. However, it is increasingly the trend nowadays to divide the labor between a dedicated pulse controller for data acquisition and a workstation for data processing, data transfer taking place via some suitable network system. The pulse controller is described in MAGNETIC RESONANCE SPECTROMETERS, and we will confine this discussion to image transfer, display, and storage.

The ability to transfer data quickly and efficiently from the spectrometer is necessary, both for efficient use of the spectrometer and to take advantage of general-purpose computer facilities. The ideal transfer medium in terms of speed and functionality is a network system, and choices include Ethernet, token ring, and fiber-distributed data interface (FDDI) operating at speeds between 4 and 100 Mbps over a variety of cable types. The data then have to be stored, and the demands placed upon archival software and hardware are considerable (for example, image- and time-domain data for a single 256×256×128 3D data set occupies 24 Mwords, or, typically, 96 Mbytes of data). Few standards for archival software as yet exist. The choice for archival hardware is also complicated, consisting of removable magnetic disk, magnetic tape, write once, read many (WORM) optical disks, and rewritable magneto-optical disks. Processing can be divided into five main groups:

1. Reconstruction—creating the image from the time domain data. The major algorithms used are back-projection, and fast Fourier transformation (FFT) and maximum entropy (Press *et al.*, 1988).
2. Processing—including restoration and enhancement. Restoration is used to remove or correct image artifacts; see Sec. 5. Enhancement involves improving the qualitative appearance of the image in order to permit more efficient interpretation by, for example, contrast manipulation, edge enhancement, and voxel interpolation.
3. Analysis—converting image data into quantitative information.
4. Two-dimensional visualization—mapping the pixel's dynamic range (typically 16 bit) to a range of gray levels that can be perceived by an observer (typically 8 bit).
5. Three-dimensional visualization—as above, often with dedicated hardware to achieve interactive speeds. 3D data are often manipulated by interactive selection of a viewing slice extracted from the source data, interpolated, and either displayed separately or "texture mapped" (geometrically distorted) onto the side of a viewing cube or cuboid. The external surface may also be visualized using methods such as surface or volume rendering via ray casting. A "movie" of different viewing directions may be created and replayed to allow the user to construct a 3D impression of the data.

4. IMAGE TECHNIQUES AND APPLICATIONS

The main goal of the radiologist is to seek the best possible image quality in the time available. Ideally, this requires thin, contiguous, nonoverlapping slices with the greatest possible spatial resolution with T_1-weighted, proton-density-weighted, and T_2-weighted images for optimal tissue contrast. At the same time, motion-induced artifacts (see Sec. 5) should be minimized by reducing the imaging time, and patient throughput should be maximized. When specifying a particular MR sequence, the radiologist must decide which "secondary" parameters (contrast, spatial resolution, signal-to-noise ratio, acquisition time, etc.) take precedence for best solving a given clinical question. Determining these specifies the "primary" variables (sequence type, T_R, T_E, slice thickness, number of phase-encode steps, etc.) needed to optimize the secondary parameters. As always, parameter choice requires trade-offs, and consideration must always be taken of the cost involved in changing or selecting a particular parameter.

There is a huge number of possible MR sequences, with the most commonly used sequence on a day-to-day basis being the spin echo. More sophisticated sequences are required for rapid scanning and *in vivo* spectroscopy and spectroscopic imaging, and these are outlined below. Lack of space necessitates leaving out discussions of, for example, flow imaging, which, while not routinely employed, is the subject of much clinical interest. For an in-depth treatise of clinical MRI, the reader is referred to two excellent volumes edited by Stark and Bradley (1992).

4.1 The Spin Echo

The spin-echo phenomenon has already been discussed in Sec. 2.6.2, and reference should also be made to Fig. 8. For spin-echo imaging, tissue contrast is determined by varying T_R and T_E. T_R determines the amount of T_1 or spin-density weighting at short and long values of T_R, respectively. T_1-weighted images (short T_R, short T_E) (see Fig. 11) are best suited for demonstrating anatomic detail, and the shortest possible T_E (usually 10–25 ms) should be used to minimize T_2 effects. In the brain, for instance, spin-density–

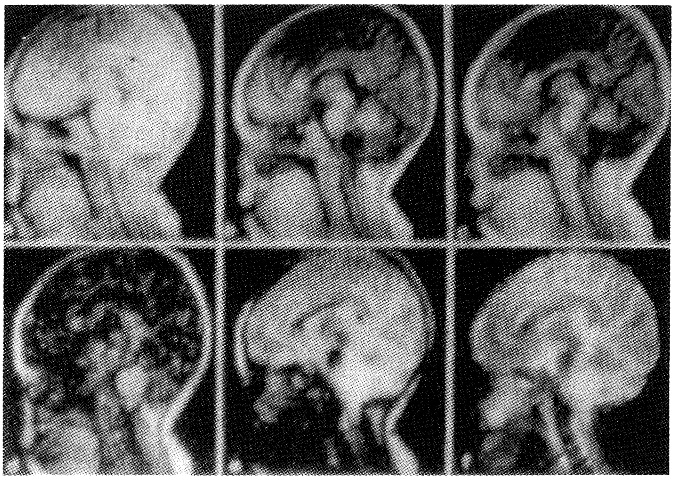

FIG. 11. Proton images of the head and thorax of a 13-year-old boy with a tumor in the medulla (marked by the arrow). (a) A proton density image; (b)–(e) the effect of different T_1 weighting on the image, 500, 300, 200, and 140 ms, respectively [the tumor is most clearly seen in (d)–(e)]. (f) A calculated T_1 image, generated by fitting the T_1-weighted data by a particular function. (Reproduced with permission from Smith, 1987.)

weighted images (long T_R, short T_E) are best suited both to demonstrate lesions and to differentiate between grey and white matter, while T_2-weighted images (long T_R, long T_E) are usually better for demonstrating pathology in the brain or cord. If measuring time were not an issue, the spin-echo Fourier imaging would be the method of choice for most clinical imaging studies. However, spin-echo sequences cannot be accelerated sufficiently, because reducing T_R leads to progressive spin saturation and low SNR, possible significant slice profile deformation ($T_R < T_1$), and considerable rf heating (see Sec. 6) due to fast pulsing of the 180° pulses.

4.2 Rapid Scan Techniques

The original rationale for rapid MRI was for shorter investigational times to improve throughput and patient comfort as well as shorter scan times to reduce motion-related artifacts. With the advent of rapid scanning, however, the possibilities arose for dynamic scanning, cine studies, high-resolution 3D imaging, and flow imaging (angiography). MRI sequences may be classified according to typical measuring times for the acquisition of one cross-sectional image, and are conventional (minutes), fast scan (seconds), and high speed (fractions of seconds).

The bulk of *fast-scan* MRI is based on imaging sequences that combine low flip-angle ($\theta \leq 20°$) rf excitation and gradient-recalled echo (GRE) acquisitions. The low-angle pulse means that only part of the magnetization ($\propto \sin \theta$) is brought down into the x-y plane, leaving an amount ($\propto \cos \theta$) left along the z axis for the next excitation. Consequently, there is no need to wait for full magnetization recovery before the next excitation, and high repetition rates are possible. GRE sequences rely on spin refocussing by a sign change in the frequency-encoding read gradient, eliminating the need for 180° pulses. T_2^*-weighted images generated in this way do not suffer a loss of spatial resolution in comparison to conventional spin-echo images nor suffer from an unacceptable trade-off in SNR. In addition, typical measurement times compare favorably with all time constants of physiologic motions in humans, with the exception of the heart (here data acquisition can be synchronized with the periodicity of the heart motion, a process known as *cardiac gating*). These techniques provide access to functional information on blood flow (angiography) and myocardial movements in cine-MRI movie loops with an apparent temporal resolution of a few milliseconds. An example of a fast-scan imaging sequence is fast low-angle shot (FLASH; Frahm *et al.*, 1986); see Fig. 12.

Scan times of *high-speed* MRI may be as fast as a few milliseconds. In general, such imaging times are achieved not only by technical means but also at the expense of image quality. Spatial resolution may be reduced from the more typical 256 × 256 matrix size to a 64 × 128 matrix size, while SNR penalties are compensated for by significant increases in slice thickness. SNR may be furversity of such applications to which magnetic resonance imaging can be applied and also to give an indication of the multitude of techniques that is available. The last two sections describe common image artifacts (Sec. 5) and the safety aspects of MRI (Sec. 6).

1. HISTORICAL OVERVIEW

The discovery of NMR was made in the United States in 1946, independently by the research groups of Felix Bloch at Stanford (Bloch, 1946) and Edward Purcell at Harvard Universities (Purcell *et al.*, 1946), who were jointly awarded the Nobel prize for physics in 1952 for their discovery. Since then, NMR has had a tremendous impact on chemistry, physics, and other disciplines, and has become an important method for the spectroscopic investigation of matter in many forms. The possibility of applying the newly discovered technique to the study of biological systems was realized early on by Bloch, who obtained a strong proton signal from his finger, but it was only in the early 1970s that the first accounts of the new technique of nuclear MRI were published.

There is still some contention as to who discovered the technique. Gabillard in the early 1950s showed that a magnetic-field gradient can give spatial information about the distribution of an object (Gabillard, 1952), the fundamental principle of nuclear MRI, and in 1959, a Czechoslovakian emigre, Kudravcev, devised a technique for displaying the projection of a quail egg with a surface coil. A patent application submitted by Damadian in 1972 (Damadian, 1974) was the first to show, in principle, the potential scope of MRI, but lacked any implementation. Another patent, submitted in Japan in 1973 by Abe *et al.* (1976), has an implementation similar to that of Kudravcev, and in it they outline many of the techniques used today in MRI.

It was Lauterbur's classic imaging paper of 1973 that established the subject (Lauterbur, 1973). The first practical realization of nuclear MRI using projection–reconstruction [similar to processes used in x-ray computer tomography (CT) scanning] gave an efficient method for generating a two-dimensional representation of proton density and NMR relaxation times; see Fig. 1. In the same year Mansfield and Grannell demonstrated the Fourier relationship between spin density and the NMR signal acquired in the presence of a field gradient (Mansfield and Grannell, 1973).

Industry had, up to that time, played a minimal role in advancing the technique, and it was left to university researchers to develop NMR imaging. This they rapidly proceeded to do, with the concept of slice selection using frequency-selective pulses in conjunction with field gradients coming from Nottingham University, U.K. (Garroway *et al.*, 1974) and the State University of New York, U.S. (Lauterbur *et al.*, 1975), a new efficient method of imaging using two-dimensional Fourier transformation at the Technische Hochschule in Zurich, Switzerland (Kumar *et al.*, 1975), spin-warp imaging by Edelstein *et al.* (1980) at Aberdeen University, U.K.; and fast imaging techniques, such as echo-planar imaging (Mansfield and Pyckett, 1978) at Nottingham University, U.K. Clinical trials of the various techniques began in 1980. More recently, industry (such as Brukermedizintechnik and Siemens of Germany, Philips of Holland, Varian Associates and General Electric of the United States, and Picker International and Oxford Instruments of the United Kingdom) and various universities have collaborated closely on the design and development of MRI hardware and techniques.

2. GENERAL PRINCIPLES

The nuclei of some isotopes contain odd numbers of protons and neutrons and as a result have quantum-mechanical "spin." The combination of positive nuclear charge and spin generates a magnetic dipole moment that interacts with magnetic fields. When a static magnetic field is applied to a nucleus, the nucleus processes about it with a frequency proportional to the magnitude of the applied field, a condition known as Larmor precession and expressed as

$$\omega_0 = \gamma H_0, \tag{1}$$

where ω_0 is the frequency of angular precession, γ is the magnetogyric ratio of the nucleus, and H_0 is the magnitude of the applied field. The precessing magnetic moment has a

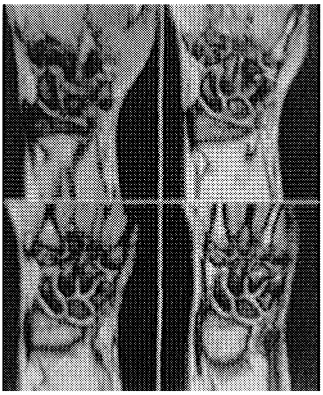

FIG. 12. High-resolution FLASH images of the wrist. These four images (512 × 512) taken at different levels have slice thicknesses of 2 mm, and were obtained with T_R = 150 ms and T_E = 11 ms. (Reproduced with permission from Stark and Bradley, 1992.)

ther compromised by *relaxation convolution*, where successive lines in **k** space may be differently relaxation weighted. T_2-weighted rapid acquisition with relaxation enhancement (RARE; Hennig *et al.*, 1986) and T_1-weighted stimulated echo acquisition mode (STEAM; Frahm *et al.*, 1985) rely on spin rephasing using rf pulses; RARE employs 180° pulses to create multiple spin echoes, with individual echoes phase encoded in a different way by reversing the action of phase encoding in each echo interval [the main application is selective imaging of the cerebrospinal fluid (i.e., myelography) and other body fluids (i.e., urography)]. High-speed STEAM uses two 90° pulses followed by a series of low flip-angle pulses, creating stimulated echoes arising from the action of the low-angle pulses on magnetization stored along the z axis by the action of the second rf pulse. Again, individual echoes are differently phase encoded, and it can be used for cardiac applications and diffusion imaging. T_2^*-weighted echo-planar imaging (EPI; Mansfield, 1977) and high-speed FLASH (saturation weighted) are based on the acquisition of gradient-recalled echoes; EPI employs single rf excitation followed by multiply refocused gradient echoes; high-speed FLASH uses multiple rf excitation and the acquisition of one gradient echo per repetition cycle. Basic EPI employs oscillating gradients along one **k**-space direction in the presence of a static gradient in an orthogonal direction, with the result that **k** space is traversed rapidly in a zigzag fashion. This high-speed imaging technique enables a single cardiac cycle to be imaged at video rates up to approximately 20 frames per second; see Fig. 13. Subsecond FLASH is used for abdominal imaging in which peristaltic motion is effectively frozen. Single cardiac cycle studies of the heart are also possible.

4.3 *In Vivo* Spectroscopy

Magnetic resonance spectroscopy (MRS) is the only noninvasive technique capable of yielding quantitative chemical information from within the body, and the development

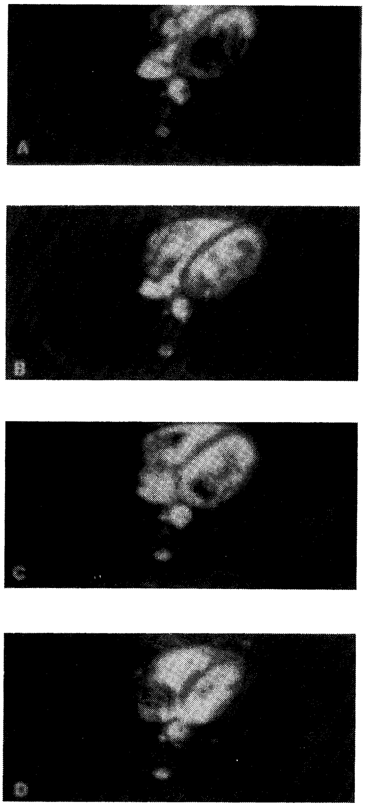

FIG. 13. Four cross-sectional images taken from a 32-frame movie sequence triggered from consecutive heartbeats to span all phases of the cardiac cycle uniformly using MBEST (a variant of EPI). Each image was taken in a single shot lasting 64 ms. The phases of the heart captured are (a) early diastole, (b) mid-diastole, (c) late diastole, and (d) systole. (Reproduced with permission from Ordidge *et al.*, 1989.)

of magnetic resonance spectroscopic imaging (MRSI) provides metabolic information within an imaging format. At a given, highly homogeneous, external field, every chemically distinct nucleus of a given species resonates at a slightly different frequency, resulting in an MR spectrum. This arises from the simultaneous interaction of a nucleus with an electron and of the electron with the static field, such that the electrons effectively shield the nucleus from the static field. Chemical shift allows the spectroscopist to detect a variety of individual protons on a given protein, different phosphorus signals from phosphates on adenosine triphosphate (ATP), or many different carbons of metabolic intermediates: see Fig. 14.

4.3.1 Localization Techniques for Spectroscopy The interpretation of MRS results is greatly facilitated if the volume of tissue giving rise to the signal is controlled so as to correspond to a limited region of interest. For instance, examination of liver is hampered if the spectra also contain signals from overlying muscle. Confining the signal to originate from a desired volume is known as localization, and this requires the use of magnetic-field gradients either in the H_0 field (as in imaging) or in the H_1 field. In the surface-coil, H_1 gradient method, a loop of wire placed close to the region of interest affords rough localization in that metabolites in tissues close to the coil are better detected than metabolites further away, with the degree of localization depending on the size of the coil. This can be improved with the use of *depth pulses*, pioneered by Bendall and Aue (1983), allowing detection of signals from a volume subjected to a particular value of H_1 field strength. Damadian *et al.* (1977) developed FONAR (a static H_0 field gradient method) in which a static magnetic field produces a high-field homogeneity over only a small volume. An analogous approach known as *topical magnetic resonance* (TMR) was developed by Oxford Research Systems (U.K.).

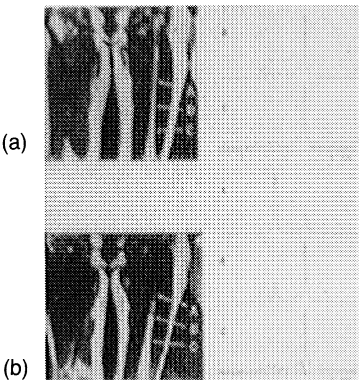

FIG. 14. Proton-stimulated echo images and corresponding spectra from 1-cm^3 voxels in the femoral marrow of (a) a healthy volunteer and (b) a patient with chronic neutropenia, showing differences in cellularity along the length of bone. (Reproduced with permission from Ballon *et al.*, 1991.)

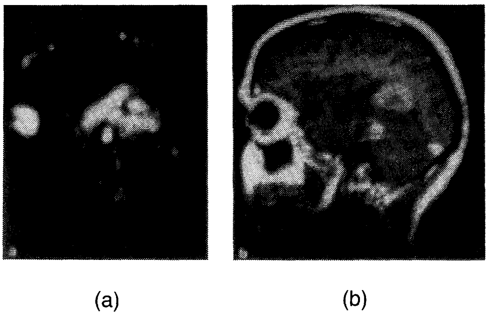
Slice-selective H_0 gradient methods use frequency-selective rf pulses in conjunction with magnetic-field gradients. Depth-resolved surface spectroscopy (DRESS; Bottomley *et al.*, 1984) uses a frequency-selective 90° pulse, with the slice-selective gradient reversed after the pulse to refocus the selected nuclei. Image-selected *in vivo* spectroscopy (ISIS; Ordidge *et al.*, 1986) employs inversion frequency-selective pulses so that a series of acquisitions (adding or subtracting) are needed to achieve localization and remove signal from the surrounding regions. STEAM is the most popular approach to proton spectroscopy, using three 90° selective rf pulses, each applied in succession in the presence of an orthogonal gradient to generate a stimulated echo from the volume defined by the intersection of the three slices.

4.3.2 Spectroscopic Imaging In MRSI, spatial information is obtained by (1, 2, or 3D) phase encoding, and the data are processed to provide a visual image that reflects the distribution of a particular nucleus (such as phosphorus-31) or metabolic species (such as phosphocreatine). To preserve the chemical-shift information, the data are collected in the absence of a frequency-encoding gradient, in contrast to MRI.

Because the concentration of metabolites in tissue is typically more than three orders of magnitude less than that of the protons in the tissue water, high-resolution imaging of metabolite tissues with resolution comparable to MRI is not feasible at the current level of MRS technology. In addition, other nuclei of interest have smaller magnetogyric ratios and hence are less sensitive than protons, an exception being sodium-23, which exists in the body at relatively high concentrations so that low-resolution sodium images have been generated; see Fig. 15. Because of the difficulty, MRS voxel volumes are typically several milliliters or more (MRI may have voxel volumes of 5 μL or less), and the technique is characterized by highest spectral resolution but limited spatial resolution.

4.3.3 Proton Chemical-Shift Imaging Proton chemical-shift imaging (CSI) is primarily used for the separation of fat and water signals and has the high spatial resolution of MRI with good spectral resolution (only two spectral components need to be distinguished). The clinical potential and physical principles of these techniques were demonstrated early in the development of MRI, but sequences that could take advantage of the improvements in magnet, rf coils, and pulse technology have only recently been developed. The frequency (chemical) shift between the water and fat resonances can appear in an image as a spatial mismapping of the two components. If the MR system is tuned to the water frequency, fat will be misplaced in the image relative to its true spatial position in the body (and vice versa). The magnitude of spatial shift depends on H_0 and the strength of the magnetic-field gradients, the bandwidth of the slice-selective pulses, the data-sampling bandwidth, the voxel dimensions, and the chemical shift itself. These chemical-shift misregistration artifacts (CSMA's) are easily visualized in the frequency-encoding direction, but may also occur in the slice-select and phase-encoding directions.



(a) (b)

FIG. 15. Comparison of sodium and proton images of a brain tumor. (a) Sodium image. Note the loss in resolution due to the low concentration of sodium ions and the smaller magnetogyric ratio. There is significant signal intensity in the region of the eye, due to the presence of sodium ions in the humors. (b) A T_1-weighted image enhanced with Gd-DTPA, clearly showing the tumor. (Reproduced with permission from Schuierer *et al.*, 1991.)

Discrimination can be obtained by exploiting the T_1 differences between water and fat by choosing a value of τ that would effectively null the fat signal, short T_1 inversion recovery (STIR; Bydder and Young, 1985), or by using paramagnetic contrast agents to suppress the fat signal, paramagnetic enhancement accentuation by chemical-shift imaging (PEACH, Simon and Szurnowski, 1989); see Fig. 16. Usually, true chemical-shift methods are employed; spectroscopy-based techniques have already been outlined in Secs. 4.3.2 and 4.3.3; phase-contrast techniques, such as the Dixon method (Dixon, 1984), combine "in-phase" (water-fat phase difference = 0°) and "out-of-phase" (water-fat phase difference = 180°) images to generate water-only or fat-only images; frequency-selective pulse techniques, such as CHESS (chemical-shift selective; Haase *et al.*, 1985), are based on narrow-bandwidth, frequency-selective pulses (in the absence of any gradient) to either excite or saturate a specific chemical

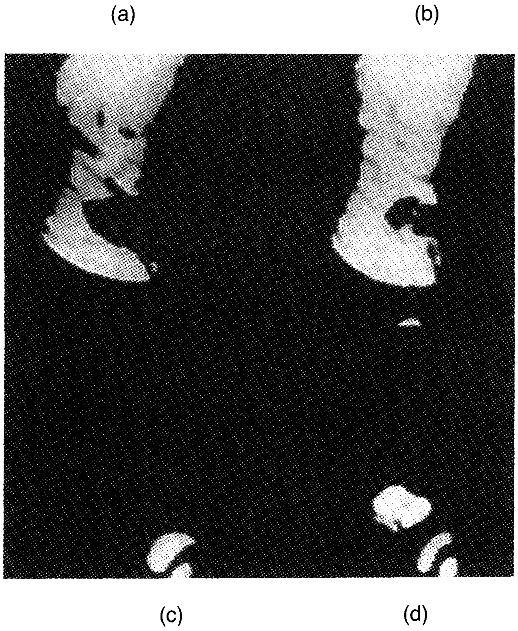


FIG. 16. Conventional spin-echo vs PEACH imaging of the breast. Enhancement is apparent in the breast mass on (b) the post Gd-DTPA image when compared to (a) the precontrast image. There is a much improved enhancing lesion–normal breast contrast using (d) the PEACH technique, particularly when compared to (c) the precontrast fat-suppressed image. (Reproduced with permission from Stark and Bradley, 1992.)

species (these pulses are frequently used as a means of suppressing the dominant water signal in most applications of MRS).

5. IMAGE ARTIFACTS

Artifacts are spurious features appearing on the image, which may arise from the MRI equipment, from some unwanted interaction between the patient and the imaging equipment, or from some external cause. What follows is necessarily a brief introduction, and the reader is recommended to read a comprehensive review by Henkelman and Bronskill (1987).

Anything that distorts or changes the main magnetic field will cause artifacts. Pieces of ferromagnetic material residing in, on, or close to the patient cause local field distortion that can obliterate the image or cause geometrical distortion along with altered brightness, depending on the distance of the object. Temporal variations of the magnetic field also cause artifacts, and random field variation over the time scale of the data collection for the image will give a smearing artifact in the phase-encode direction, the axis in the image defined by the phase-encode gradient.

Any physiological motion in the subject that changes in a regular cyclic manner, particularly if its frequency is harmonically related to the imaging sequence's basic repetition rate, can cause artifacts in the phase-encode direction. Heart motion and relaxed breathing are the main causes. Irregular motion such as fidgeting by the patient or peristalsis of the gut causes featureless smears.

Blood flow in major vessels and the heart can give rise to a number of different artifacts in normal imaging (as outlined in Sec. 4.3, the effects of flow can be put to good use in flow imaging). Constant and pulsatile flow produces changes in intensity due to fresh, unselected spins flowing into the slice between consecutive pulses, and artifacts similar to those due to cyclic motion.

In high-field imagers, the chemical shift between water and fat may cause the "water" and "fat" images to be slightly misplaced from each other in the frequency-encoding direction. At 1.5 T the two Larmor frequencies differ by 200 Hz, equivalent to several pixels of shift. Clinically, this can be confusing and open to misinterpretation. An example is the displacement of an image of the kidney relative to an image of the perinephric fat. Susceptibility effects due to gas pockets within the body can produce nearby field changes of the same order as chemical shift, with consequent distortion of the image.

Machine-generated or machine-specific artifacts cover a very large range. A common source is rf interference, which may arise from external sources or from components of the imaging spectrometer itself. These manifest themselves in the image as single bright dots, lines in the phase-encoding direction, or wide bands, depending on the stability of the source. Transient interference (for example, light switches or thermostats) often result in a characteristic "herringbone" pattern across the image.

Imbalance of the two channels of the quadrature detector (in phase or amplitude) will give rise to ghost-image aliases of the true image, mirrored about the center of the image frame. If the detected signal has been overamplified, the ADC may become overloaded, resulting in truncation of some of the data. This is reflected in nonzero or nonconstant background levels outside the image, edge ringing, and fringing in the outer regions.

6. SAFETY

Potential hazards associated with any medical technique should be considered for the patient, for equipment operators, and for the general public. For all these groups, risks should be kept to a minimum. MRI, by virtue of its nonionizing nature, is considered inherently safe when compared to, e.g., x-ray CT, but possible hazards may arise from several sources:

1. Chemicals—the only chemicals used in clinical studies are contrast agents (and at the moment only Gd-DPTA is in widespread use), and since they are intended for internal use they should be of low toxicity.
2. The biological situation—MRI, being a technique performed upon the intact body, offers no more biological hazard than is generally met in a hospital environment. Special precautions may need to be taken when high-risk patients are to be imaged,

e.g., patients with transmittable infections or with low immunity, such as premature babies or transplant patients undergoing immune suppression.

3. Electrical and electronic equipment—these should always be subject to regular safety checking according to local safety standards.
4. The inherent nature of MR equipment and procedure—this can be further subdivided into two sections:
   - **a.** Effects on nonbiological material—the presence of substantial magnetic fields means that any ferromagnetic object (e.g., steel screwdrivers, scissors, and scalpels) may become projectiles. The torque and attraction of magnetic fields will also affect metal inside the patient, and could have serious repercussions, e.g., twisting magnetically sensitive clips off blood vessels, resulting in hemorrhage. It is widely accepted that patients (or the general public) with cardiac pacemakers should not be exposed to (or allowed close to) MRI equipment.
   - **b.** Biomagnetic interactions—these involve the direct action of one or more of the three types of magnetic field upon the body. Various mechanisms have been put forward for possible effects from *static* field: changes in rate constants of metabolic reactions due to magnetically sensitive free-radical intermediates; alignment of body constituents containing anisotropic magnetic susceptibilities (e.g., DNA molecules, retinal rods, and entire sickled red blood cells); slowing down of ion-diffusion rates in the direction of the field; and induction of flow potentials in arteries. At the field strengths currently in use, the available literature suggests that these are not a source of hazard to patients or volunteers. However, guidelines dictate that the general public is not to be exposed to fields greater than 5 G. Slow, time-varying fields associated with gradient switching could produce eddy currents in conductive loops, possibly leading to "hot spots" where loop boundaries meet, or muscle twitching. These require very strong switching gradient fields (e.g., > 2000 T s^{-1}), not normally experienced in clinical imaging. A lower threshold effect is the generation of visual phosphenes (bright flashes in the eyes), which are not regarded as harmful. Finally, there are the effects of rf fields, whose main effect is generally considered to be local tissue heating. There are guidelines for exposure to rf fields in MRI [the Food and Drug Administration (FDA) in the United States and National Radiological Protective Board (NRPB) in the United Kingdom], based upon the assumption of heating. In both cases, a recommendation is made in terms of a maximum specific absorption rate (SAR) that yields a very small increase in body temperature, stated as about half the basic metabolic rate by the FDA, and as resulting in a body temperature rise of less than 1 °C by the NRPB.

GLOSSARY

Magnet Shimming: The way magnets are constructed and the presence of metallic surfaces close to the magnet mean that the main, static magnetic field is rarely exceptionally homogeneous. In order to compensate for these inhomogeneities, the main field is shimmed. This can be done in two ways: *Passive* shimming involves placing pieces of iron at strategic positions with respect to the main field, while *active* shimming uses magnetic fields generated from coils placed close to, or surrounding, the main magnet.

Magnetogyric Ratio: This is defined as the ratio of the magnetic moment of a nucleus to its angular momentum.

Nuclear Precession: When a nucleus is placed in a magnetic field, the magnetic moment experiences a torque that would tend to align it along the field. However, the angular momentum of the nucleus modifies the situation and causes the nucleus to behave like a gyroscope. In classical terms this means that the magnetic moment precesses about the magnetic field.

Radio-Frequency Pulses: The radio-frequency (rf) pulse is a burst of rf that is applied to the sample by way of an rf probe, and is usually made by gating a continuous source of rf on-and-off for a defined period. Quantum mechanically, the pulse is used to induce transitions between the various energy levels of the nuclear spin system, where the transitions are governed by the Bohr frequency condition. Classically, the action of the pulse manifests itself as a rotation of the nucleus through an angle θ about an axis defined by the phase of the rf. The angle $\theta = 2\pi\gamma H_1 t$, where t is the pulse duration, and the other terms are defined in the text.

Stray Field: This term refers to the magnetic field that is found outside the actual, physical magnet.

27.1
Introduction

The NMR spectrometry is an extraordinarily powerful analytical method, which originally had applications in physics and later to chemistry, biochemistry, biology, pharmacy, geophysics, materials science, and archaeology. Nowadays, this method is widely used in veterinary science and medicine, particularly in clinical research for routine human brain NMR imaging (magnetic resonance imaging (MRI)).

As a method, the NMR spectroscopy is based on resonance phenomenon independently discovered by Bloch *et al.* (1946) and Purcell, Torrey, and Pound (1946), which involves placing nuclear spins in an external magnetic field and their excitation by a radio-frequency irradiation. The energy, thus absorbed by the nuclei, measured in frequency units, is characteristic of the nuclei and their environments and can be used for the structural analysis of the compounds investigated.

Initially, the NMR experiments were performed by physicists to experimentally verify the basic postulates of quantum mechanics that require detailed knowledge and accurate measurements of nuclear magnetic moments. However, the development of the relaxation theory (Bloembergen, Purcell, and Pound, 1948) and also the discovery of chemical shift (Proktor and Yu, 1950) and spin–spin coupling patterns of nuclei have shown the great potential of NMR to describe solids, liquids, and gaseous matter in terms of structural and dynamic properties. Then, fast successes in the radio-frequency technology resulted in the appearance of the first commercial NMR spectrometers (1953), which strongly impacted the research in chemistry and biochemistry. In turn, more complex compounds, such as biochemical molecular systems and aggregates, required more powerful NMR spectrometers, modifications in magnet technology, and developments of new spectroscopic approaches. Therefore, the modern commercial NMR spectrometers represent multiple-pulse devices, capable of experiments in solutions and the solid state, which can operate at very high magnetic fields up to 21.14 T and detect nuclei with a small natural abundance (rare nuclei). In addition, increasing the speed of computers, performing very fast Fourier transformations (FTs), has resulted in routine use of the two- or three-dimensional NMR experiments.

There are numerous techniques and approaches in NMR spectrometry. They are constantly modified and published in original articles, books, and the NMR Encyclopedia. Even a small portion of the NMR methods cannot be covered in this relatively short chapter, the aim of which is to present only the general principles of NMR experiments and their practical applications.

27.2
NMR: General Considerations

After publications of the pioneering works, describing NMR, its practical applications can be grouped under two categories: NMR spectrometry and NMR relaxation. In the first group, an NMR spectrum is studied, which is a frequency-dependent pattern, showing a number of nonequivalent nuclei and their environments. In contrast, the resulting data, collected by the relaxation measurements, are time-dependent and are rather related to dynamics in molecular systems. The first application is more popular among practical chemists or biochemists while the relaxation aspects attract researchers working in molecular physics, physics of solids, and biophysics. However, it should be emphasized that the frequency- and time-dependent data are the essence of the same phenomenon, and knowledge of nuclear relaxation is needed even for recording a simplest NMR spectrum because obtaining a spectrum itself can become difficult or impossible, when relaxation times are extremely long. It is probable that the first attempt to observe NMR for ^{1}H and ^{7}Li nuclei in 1936 was unsuccessful (Gorter *et al.*, 1942) because of long relaxation times. In contrast, short relaxation times broaden NMR lines and often mask their fine structures. Sometimes, the broadenings are very strong and lines become "invisible." This is obviously important even for users applying NMR only for an express structural analysis.

27.2.1
Nuclei in the External Magnetic Field

According to Abragam (1961), a nucleus with nonzero angular momentum, P, possesses a nuclear magnetic moment, $\mu = \gamma P$, capable of interaction with the external magnetic field, where γ is the nuclear magnetogyric ratio, which depends on the nature of nuclei (Table 27.1). The P and the μ are quantized. For example, the projections of the angular nuclear momentum, P_Z, on the OZ axis can be written as

$$P_Z = \hbar \times m_I \tag{27.1}$$

where h ($\hbar = h/2\pi$) is the Planck's constant ($h/2\pi = 1.05457266 \times 10^{-34}$ J s) and m_I is the magnetic quantum number. The latter depends on nuclear spin I and takes values from I to $-I$: I, $I-1$, $I-2$, …, $-I$. In turn, I is a multiple of ½, for example, at $I = ½$, the angular momentum and the magnetic moment are

$$P_Z = \pm\left(\frac{1}{2}\right)\hbar \text{ and } \mu_Z = \pm\left(\frac{1}{2}\right)\gamma\hbar \tag{27.2}$$

Then, the μ_Z (or P_Z) projections, represented as vectors, can be parallel or antiparallel relative to the above Z axis. If the external magnetic field B_0 is applied along this axis, the μ_Z (or P_Z) orientations become energetically nonequivalent. This nonequivalency leads to the, so-called, Zeeman's energy splitting ΔE

^{205}Tl	$^1/_2$	70.5	57.63	15.589	0.140

(Figure 27.1) proportional to the μ_Z magnitude and the strength of the applied magnetic field, B_0:

$$\Delta E = 2\,\mu_Z B_0 \tag{27.3}$$

Then, formulating ΔE, as an energy quantum, $\Delta E = h\nu$, leads to the resonance condition written as

$$h\nu_0 = 2\,\mu_Z B_0 = \gamma \hbar B_0$$

$$\nu_0 = \gamma B_0 \tag{27.4}$$

This condition shows that the nuclear spin, placed into the external magnetic field, B_0, undergoes a single-quantum transition (i.e., the m_I number changes from $-1/2$ to $+1/2$), when an irradiation frequency reaches ν_0 (the Larmor's frequency). The transition results in an energy absorption by lattice, which is registered as an NMR signal. Table 27.1 shows the ν_0 frequencies for different nuclei.

An ensemble of nuclei will populate the Zeeman's energy levels according to factor $\exp(-\Delta E/kT)$, where T is the temperature and k is the Boltzmann's constant (1.380658×10^{-23} J K^{-1}). Thus the low-energy levels are more populated than the high levels, which give raise to macroscopic magnetization, undergoing precession around the B_0 direction

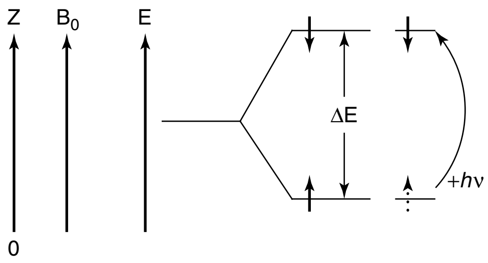

Fig. 27.1 The Zeeman energy levels of nuclear spins $I = {}^1/_2$ in the external magnetic field B_0.

at the ν_0 frequency, responsible for observations of NMR signals. It should be emphasized that the population difference, ΔN, compared with a total number of the nuclei, N, is less: a $\Delta N/N$ ratio is of 8×10^{-6} for ^{1}H nuclei in a field of 2.35 T at 300 K. This condition defines relatively low sensitivity of NMR experiments. As seen in Table 27.1, ^{1}H and ^{19}F nuclei are mostly preferable as target nuclei in this context.

Nuclei with spin > ½ behave similarly in the external magnetic filed. However, a number of the Zeeman's levels increases accordingly. (Such nuclei have nonspherical charge distributions responsible for appearance of nuclear quadrupole moments Q). For example, ^{2}H or ^{14}N nuclei ($I = 1$) give three energetically equidistant levels, corresponding to the μ_Z values of $+\gamma\hbar(1)$, 0 and $-\gamma\hbar(1)$. Because the double quantum transitions (the m_I value changes from +1 to −1) are not observed, the nuclei again produce a single line in an NMR spectrum.

27.2.2
Detection of an NMR Signal – General Principles

Technically, observation of an NMR signal can be realized at the ν_0 irradiation of a sample by the continuous wave (CW) method. The principle schemes of such CW spectrometers can be found in Harris (1986), Sanders and Hunter (1994), or Duel (2002). Here, a spinning sample is situated between the poles of a magnet, radio frequency is applied via an antenna coil, connected to a transmitter, and a receiver coil, surrounding the sample, registers the absorbed energy by electronic devices and a computer. The CW spectrometers imply a sweeping of the magnetic field or the radio frequency when the external magnetic field remains constant.

A simple NMR experiment, where the ν_0 irradiation is performed by a radio-frequency pulse (RFP), is shown in Figure 27.2. The experiment includes three time sections: (i) relaxation delay (RD), (ii) action of RFP, and (iii) recording the NMR data as free induction decays (FID)s, during acquisition time (AT). According to the scheme, the NMR data can be accumulated, when sections from (i) to (iii) are repeated. The resulting FIDs are time-dependent, $f(t)$, and should be converted into the NMR spectra, as the frequency-dependent data, $F(\nu)$, by FT:

$$F(\nu) = \int f(t)\ \exp(-i2\pi\nu t)\ dt$$

$$f(t) = \int F(\nu)\exp(+i2\pi\nu t)\ d\nu \quad (27.5)$$

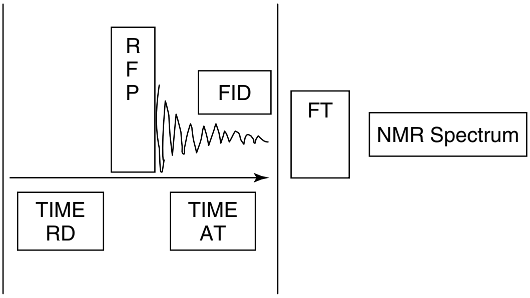

Fig. 27.2 Schematic presentation of the 1D NMR experiment where typical durations of radio-frequency pulse (RFP), relaxation delay (RD), and acquisition time (AT) are of 5–10 microseconds, 1–4 seconds, and 1–3 seconds, respectively.

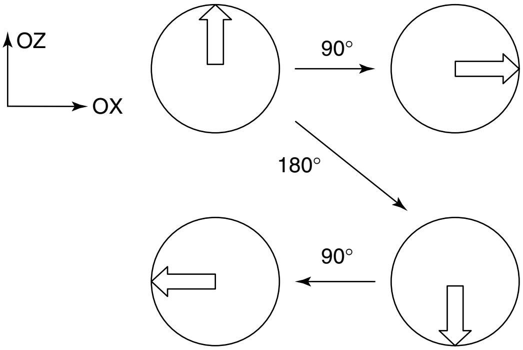

Fig. 27.3 The schematic presentation of the behavior of the macroscopic magnetization vector, **M**, in a rotating coordinate system after action of 90°- and 180°-radio-frequency pulses or two consequent 180°- and 90°-radio-frequency pulses.

Such an experiment is realized on an FT NMR spectrometer equipped with a computer capable of fast FT. It should be emphasized that durations and amplitudes of RFP should be sufficient to rotate the macroscopic magnetization, for example, by an angle α from the magnetic field B_0. According to Ernst *et al.* (1966), the pulse angle, α, is defined as $\alpha = \gamma B_1 t_P$, where B_1 is the power of the pulse and t_p is its duration. Then, the magnetization goes to thermal equilibrium. Figure 27.3 schematically shows the behavior of the macroscopic magnetization vector, **M**, in a rotating coordinate system due to actions of 90°- or 180°-RFPs. Here, the **M** orientation along the positive OX axis corresponds to the maximal intensity of a registered NMR signal. Thus, after a 180° pulse, the signal is not observed or its intensity becomes negative after a combination of 180 and 90° pulses.

27.2.3
NMR Equipment

As shown above, an NMR spectrometer includes the following basic units: a radio-frequency-reference generator, a transmitter, a receiver, a pulse generator, a computer, a magnet, and an NMR probe. All of the units remarkably affect the quality of the NMR spectra and the signal/noise ratio as a measure of sensitivity. However, for experimentalists, a magnet and an NMR probe are most important.

27.2.3.1 Magnets

A magnet is a source of strong, stable, and homogeneous magnetic field to obtain the high-resolution NMR spectra. When characteristics of transmitters, receivers, and other devices of NMR spectrometers do not change, then increasing the magnetic field, B_0, increases the energy, ΔE, population difference $\Delta N/N$ and hence the sensitivity of an NMR spectrometer. Iron magnets (permanent or electromagnets) are relatively unstable, sensitive to the temperature, and create moderate field strengths, corresponding to the working ^{1}H frequency of $\leq$100 MHz. In contrast, modern superconducting electromagnets show excellent stability, good homogeneity and their fields are capable of working at the proton frequency up to 900 MHz. For both types of magnets, stability of the magnetic field needed for the high-resolution NMR experiments can be additionally increased by field-locking. Because deuterium NMR signals coming from deuterated solvents can be well filtered from signals of ^{1}H or other nuclei, they are successfully applied for additional field stabilization.

27.2.3.2 NMR Probes

Generally, an NMR probe represents a single tank circuit needed for irradiation and detection of an NMR signal. According to Kisman and Armstrong (1974), the radio-frequency, coming from the transmitter, must be distinguished from the signal, coming from the probe. In other words, a weak signal has to be measured immediately after the action of a high-power pulse. Such a switching problem gives rise to the, so-called, deed time of the spectrometer. If the deed time is long and the FID is short, the NMR signal loses intensity. Technically, this problem is minimized in modern NMR spectrometers and their standard components reduce the deed times to few microseconds.

The design of NMR probes significantly depends on desired NMR experiments. For example, variable-temperature measurements (usually between −120 and +120 °C) require the corresponding heating/cooling equipments, which provide accurate temperature settings and the absence of significant temperature gradients. Double or triple resonance and gradient-field experiments are also available when NMR probes have a special design. Finally, an NMR probe should be equipped with tools for the mechanical rotation of samples. Low spinning rates (approximately 20 Hz) are generally used for liquids to compensate the nonhomogeneity of the external magnetic field. Very high spinning rates (tens of kilohertz) are needed to suppress strong dipole–dipole interactions in solids. In the latter case, the NMR rotors are oriented at the, so-called, magic angle setting relative to the external magnetic field (see below).

27.3
NMR Spectral Parameters

Nuclear spins in molecules are not isolated and this circumstance gives rise to the phenomena of chemical shift, spin–spin coupling, and relaxation, directly related to chemical structures. In turn, these spectral parameters lead to reliable structural determinations even in the complex cases providing, thus, wide applications of the NMR spectroscopy as an analytical method.

27.3.1
Chemical Shift

Electrons, circulating around nuclei, placed into the external magnetic field, B_0, create a new magnetic field, opposing the initial field. Then, a local magnetic field, B_{loc}, modifies the resonance frequency ν_0, which leads to shielding constant σ, $B_{\text{loc}} = (1 - \sigma)B_0$, or chemical shift $\delta = -\sigma$. Chemical shift δ (Figure 27.4) is measured in parts per million and referred to *internal (or external) standards:* $\delta = \{\nu$ (sample) − ν (reference)$\}$ $10^6/\nu$ (reference) (generally to TMS for ^{1}H and ^{13}C nuclei, H_3PO_4 for ^{31}P nuclei, CF_3COOH for ^{19}F nuclei, and so on).

According to Abragam, three main terms contribute to total constant σ: diamagnetic term σ^{local}(dia), paramagnetic term σ^{local}(para), and magnetic anisotropy term σ^*. The first contribution, caused by the circulation of

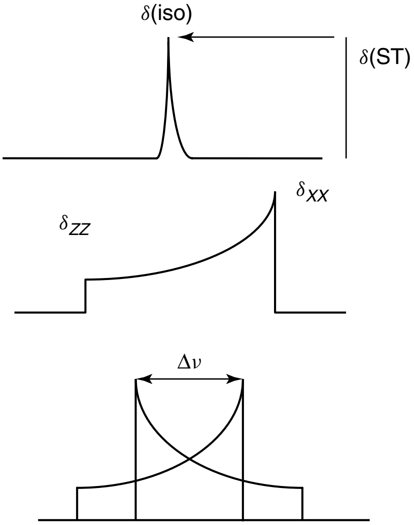

Fig. 27.4 The line shape of an NMR resonance typical of a liquid (a), a static solid with an axially symmetrical screening tensor, $\sigma_{ZZ} \neq \sigma_{XX} = \sigma_{YY}$, (b) and a powder ^{2}H sample with an axially symmetric electric field gradient at deuterium.

unperturbed spherical electrons (s) with mass m_e, is expressed in a simplest form by Lamb's equation:

$$\sigma^{\text{local}}(\text{dia}) = \left(\frac{\mu_0 e^2}{8\pi m_e}\right) \int r\rho_e \, dr \quad (27.6)$$

where μ_0 is the permeability constant, ρ_e is the charge density, and r is the electron-nucleus distance. The second term, formulated by McConnel *et al.* (1958), appears due to perturbed non-spherical electrons (p or d) and it can be described via the average energy of the electron excitation, ΔU, as

$$\sigma^{\text{local}}(\text{para}) = -\left(\frac{\mu_0 e^2 \hbar^2}{6\pi m^2 \Delta U}\right)\langle \text{r}^{-3}\rangle P_U \quad (27.7)$$

Here P_U is named as the p-electron "imbalance" expressed via charge densities and bond orders (Jameson and Gutowsky, 1964). The last (relatively small) term, σ^*, comes from electrons situated at neighboring groups. These groups (for example, bonds C=C or C≡C) create magnetically anisotropic fields and therefore the observed effects depend on orientations of observed nuclei. Combinations of these terms lead to large variations in chemical shifts δ, which depend on the nature of nuclei (Table 27.2). A correct quantum-chemical analysis of chemical shifts is possible, but the calculations are not simple. Therefore, in practice,

Tab. 27.2 Chemical shift ranges, δ (SCS), for different nuclei.

Nucleus	**SCS (parts per million)**[a]
^{1}H	−50 to +20
^{11}B	−130 to +95
^{13}C	−300 to +250
^{19}F	−250 to +400
^{31}P	−125 to +500
^{15}N	−500 to +850
^{195}Pt	−1370 to +12 000

[a] The positive values correspond to low-field displacements.

structural determinations or predictions of the δ values for known structures are based on numerous spectrum/structure relationships or increment equations, which can be found in Harris (1986) or Sanders and Hunter (1994). Finally, the so-called, isotopic chemical shifts (for example, for ^{1}H at ^{12}C and ^{1}H at ^{13}C) are relatively small and their role in the structural analysis is not significant.

27.3.1.1 Anisotropy of Chemical Shift

Screening constants σ are three dimensional and can be characterized by components σ_{XX}, σ_{YY}, and σ_{ZZ} that are also associated with chemical structures (Strub *et al.*, 1983). However, generally, this coordinate system does not correspond completely to a molecular coordinate system, though the Z coordinate is often situated along chemical bonds.

Generally, the σ components differ leading to chemical shift anisotropy, $\Delta\sigma$, defined as $\Delta\sigma = \{2\sigma_{ZZ} - (\sigma_{XX} + \sigma_{YY})\}/3$. The high-amplitude molecular motions in liquids produce the Lorenz-shaped resonances, where the σ_{XX}, σ_{YY}, and σ_{ZZ} components are not observed. Here, the resonances are characterized by isotropic chemical shifts $\delta(ISO)$ (Figure 27.4) or isotropic screening constants $\sigma(ISO)$ determined as $\sigma(ISO) = (1/3)(\sigma_{XX} + \sigma_{YY} + \sigma_{ZZ})$. More complex lines are observed in rigid solids and their shapes directly depend on the σ (or δ) components that are determined from static NMR patterns (Duel, 2002). Figure 27.4 shows a solid-state NMR signal, typical of an axial-symmetrical screening-tensor where $\sigma_{XX} = \sigma_{YY} \neq \sigma_{ZZ}$. A lower symmetry ($\sigma_{XX} \neq \sigma_{YY} \neq \sigma_{ZZ}$) obviously leads to more complicated signals. This is particularly important for heavy nuclei such as ^{19}F, ^{31}P or ^{117,119}Sn.

27.3.1.2 Quadrupolar Splitting

Spins of nuclei, having quadrupole moments Q (for example ^{2}H, ^{14}N, ^{81}Br, ^{127}I, and ^{35}Cl), interact not only with the external and local magnetic fields but also with electric field gradients (EFG) at these nuclei. The energy of interactions is expressed through nuclear quadrupole coupling constant (NQCC), $NQCC = e^2 q_{zz} Q/h$, where eq_{ZZ} is the principal component of the EFG tensor. In rigid solids, the quadrupolar interaction directly affects the shapes of NMR resonances. Figure 27.4 shows a typical ^{2}H NMR spectrum, recorded in a static powder sample, where the signal exhibits the, so-called, quadrupolar splitting, measured in frequency units (kilohertz) and marked as $\Delta\nu$. This shape is observed for systems with the axially symmetric EFG. In the absence of motions, the splitting provides determinations of the NQCC values via $\Delta\nu = 3/4(e^2 q_{ZZ} Q/h)$. In liquids, however, the quadrupolar interaction is not observed because of the fast molecular motions and NMR signals become again Lorenz-shaped.

27.3.2

Influence of an Unpaired Electron on the Chemical Shift

The very high magnetic moment of an unpaired electron affects an NMR frequency via effective magnetic field B_{EF}:

$$\begin{aligned} B_{\mathrm{EF}} &= 2\pi A \mu_B g B_0 S \frac{(S+1)}{3\gamma_N kT} \\ &\quad + \mu_0 {\mu_B}^2 g^2 B_0 S(S+1) \\ &\quad \times \frac{(3\ \cos^2\theta - 1)}{3kTr^3} + B_{\mathrm{BMS}} \quad (27.8) \end{aligned}$$

Here, according to Poople (1983), A is the isotropic electron/nucleus hyperfine coupling constant, μ_B is the Bohr magneton (9.2741×10^{-24} J T^{-1}), r is the electron/nucleus distance, θ is the angle between the electron-nucleus vector and the external magnetic field $B_{0,}$ and g is the electron g factor. The first term produces the, so-called, Fermi-contact (FC) chemical shifts (McConnel *et al.*, 1958). Owing to the direct delocalization of the unpaired electron density on the nuclei, the FC shifts in solids can reach 3000 ppm or higher as a function of the nature of the nuclei and paramagnetic centers. Generally, the chemical shift tensors are axially symmetric at large anisotropies covering ranges up to 3500–4000 ppm (Mali *et al.*, 2005). In a combination with short relaxation times, the nuclei affected by FC interaction are difficult to observe experimentally. In liquids, in spite of the fast molecular motions, the FC shifts can be also significant (up to 100 ppm), mainly due to the very large electron/nucleus coupling.

The second field, causing smaller shifts, corresponds to dipolar electron/nucleus interaction. The interaction strongly depends on distance r and includes an angle-dependent part, $(3\cos^2\theta - 1)$. In liquids, where molecular reorientations with respect to the external magnetic filed are fast, θ is defined as an angle formed by the r vector and an axis of the symmetry of the g factor (Harris, 1986). The corresponding chemical shifts are named as *pseudo-contact*, which are again associated with chemical structure. The last term, B_{BMS}, represents a demagnetization field appearing in a sample due to bulk magnetic susceptibility (BMS). This effect, generally insignificant in diamagnetic samples, plays a very important role in paramagnetic systems (Kubo, Spaniol, and Terao, 1998).

27.3.3
Spin–Spin Coupling

According to the theory, which can be found in Abragam (1961) or Harris (1986), the spin Hamiltonian, describing NMR in isotropic fluids in the limits of the quantum-mechanical formalism, takes the form:

$$h^{-1}\hat{H} = -\sum\nolimits_j (2\pi)^{-1}\gamma_j B_0(1-\sigma_j)\hat{I}_j^z + \sum\nolimits_{\mathrm{j<k}} J_{jk}\ \hat{I}_j\hat{I}_k \qquad (27.9)$$

The first part, modified by screening constant σ, corresponds to isolated nuclear spins in the field, B_0 (see Eq. (27.4)). The second term is spin–spin coupling and J_{jk} is the spin–spin coupling constant. Because the J_{jk} constants are relatively small (typically from 1–2 to 200–300 Hz), spin–spin coupling is considered as perturbation of the first term.

Effects of perturbation on a number of Zeeman's energy levels can be easily shown by attributing the symbols α and β to the parallel and antiparallel mutual orientations for nuclear spins of ½. Then, the spin states for a system, consisting of two nuclei, are $\beta\beta(m_I = -1)$, $\alpha\beta(m_I = 0)$, $\beta\alpha(m_I = 0)$, and $\alpha\alpha(m_I = 1)$. Thus, the first nuclear spin can "see" the second one in two states and its energy levels undergo an additional spitting by energy J measured in hertz. The J constant is a scalar magnitude, has a sign, and is independent of the external magnetic field B_0.

Two magnetically nonequivalent nuclear spins, A and X, form a simple spin system, AX, when the chemical shift difference $\Delta\delta^{AX}$ (measured in hertz) is significantly larger than the spin–spin coupling constant, $J(A-X)$: $\Delta\delta^{AX}(\text{hertz})/J^{AX}(\text{hertz}) > 10$. Generally, line multiplicity N of the A resonance is $N = 2nI + 1$, where n is the number of the X nuclei with spin I. Relative intensities within multiplets are distributed according to the so-called Pascal's triangle. For two protons ($I = ½$), the AX spin system shows two doublets at 1 : 1 intensity ratio for each doublet. In these terms, group $CH_2{-}CH_3$ should exhibit two ^1H resonances as a quartet and triplet, respectively. Decreasing the $\Delta\delta^{AX}(\text{hertz})/J^{AX}(\text{hertz})$ ratio transforms the AX spin system to a strongly coupled system, named as AB, to emphasize the small chemical shift difference. Similarly, simple spin systems AX_2 or AXX' are converted to strongly coupled systems ABX, AMX, AB_2 or ABC, which show complex NMR patterns. Owing to the presence of combinational transitions, their intensities and multiplicities depend on values $\Delta\delta$ and J. Such systems can be analyzed via simulations or fittings to the experimental data by convenient computer programs, using quantum-mechanical formalism. Because the J constant does not depend on B_0, the strongly coupled spin systems are simplified in higher external magnetic fields.

Spin–spin coupling is transmitted via electrons, surrounding the nuclei, and therefore the J constant is a function of chemical structures: electron distributions, atomic hybridizations, and interbond angles. Generally, the total J energy consists of three contributions coming from the spin-orbital (SO), spin-dipolar (SD), and FC interactions (Abragam, 1961) written as

$$H_{\text{SO}} = \left(\frac{\mu_0}{4\pi}\right) g_L \mu_B \gamma_N \hbar \sum 2\, L_e\, I_N\, r_{\text{eN}}^{-3} \tag{27.10}$$

$$H_{\text{SD}} = -\left(\frac{\mu_0}{4\pi}\right) g_S \mu_B \gamma_N \hbar \sum \{ r^{-3}{}_{\text{eN}} I_N S_e - 3\, r^{-5}{}_{\text{eN}} (I_N r_{\text{eN}})(S_e r_{\text{eN}}) \} \tag{27.11}$$

$$H_{\text{FC}} = \left(\frac{2}{3}\right) \mu_0 g_S \mu_B \gamma_N \hbar \sum \delta(r_{\text{eN}}) I_N S_e \tag{27.12}$$

where e and N correspond to electron and nucleus, respectively, L_e is the orbital angular moment operator, r_{eN} is the distance between electron and nucleus, and $\delta(r_{\text{eN}})$ is the Dirac delta function. The function takes a value of 1 at $r_{\text{eN}} = 0$ and 0 otherwise, requiring, thus, the presence of electron density directly on the nuclei. Calculations show that FC contribution usually dominates (Table 27.3) and hence J constants can be interpreted in terms of electron densities.

Spatial proximity of some nuclei, for example, ^{19}F, leads to the, so-called, through-space spin–spin coupling constants (sometimes reaching 100 Hz and more). Here, according to Contreras *et al.* (2000), again FC interaction dominates

Tab. 27.3 Contributions to total spin–spin coupling constants (in hertz).

Coupling constant	Molecule	FC	SO	SD
$^1J(C{-}C)$	C_2H_6	11.99	−0.55	0.3
	C_2H_2	69.43	4.13	2.84
$^1J(F{-}C)$	CH_3F	−126.30	−4.15	6.92
$^2J(F{-}F)$	CF_4	−1.09	6.20	16.73

but the coupling goes via nonbonding electron orbitals.

27.3.4
Nuclear Relaxation

The nuclear spins, excited by a radio-frequency irradiation, are capable of an energy exchange with their environments to reach the initial equilibrium state. There are two principally different relaxation mechanisms. The first mechanism, named as *spin-lattice relaxation,* represents the energetic exchange between nuclear spins and lattice, formulated as a continuum of nuclear and/or electron magnetic moments of any sort. The second mechanism, named as *spin–spin relaxation,* occurs when two (or more) spins undergo "flip–flop motions," which shorten, thus, the spin lifetimes while the total energy of the system does not change (for this reason, such flips are often named as the *energy-conserving spin transitions.* Finally, the relaxation of macroscopic magnetization is given by the Bloch's equations:

$$\frac{dM_Z}{dt} = \frac{-(M_Z - M_Z{}^0)}{T_1} \quad \text{and}$$

$$\frac{dM_{X,Y}}{dt} = \frac{-M_{X,Y}}{T_2} \qquad (27.13)$$

and formulated as recovery of the Z-(longitudinal) component with a time constant T_1 and the Y- and X-(transverse) components with a time constant T_2.

27.3.4.1 Relaxation Mechanisms in Liquids

Nuclear relaxation will be effective if magnetic fields in the spin environments fluctuate at frequencies close to the Larmor's resonance frequency ν_0 (or $\omega_0 = 2\pi\nu_0$). In liquids, such fluctuations are directly associated with thermal molecular motions: rotational reorientations, translational motions, or their combinations. Rapid intramolecular motions also contribute to nuclear relaxation. Molecular motions are characterized by correlation times τ and activation energies ΔE that can be determined from the relaxations data if the mechanism of the process is known.

According to the theory of Bloembergen, Purcell and Pound (1948), nuclei can relax via dipole–dipole, quadrupole, spin-rotation, scalar, and chemical shift anisotropy interactions. Generally, the relaxation rates are written as $1/T_{1,2} = CJ(\omega_0, \tau)$, where C is the coupling strength and $J(\omega_0, \tau)$ is the spectral density function. Relaxation due to dipolar interaction of two identical nuclei can be expressed as

$$\frac{1}{T^{\mathrm{DD}}{}_1} = \left(\frac{2}{5}\right)\gamma^4\hbar^2 r^{-6} I(I+1) \times \left\{\frac{\tau}{(1+\omega_I{}^2\tau^2)} + \frac{4\tau}{(1+4\omega_I{}^2\tau^2)}\right\} \qquad (27.14)$$

$$\frac{1}{T^{\mathrm{DD}}{}_2} = \left(\frac{1}{5}\right)\gamma^4\hbar^2 r^{-6} I(I+1) \times \left\{3\tau + \frac{5\tau}{(1+\omega_I{}^2\tau^2)} + \frac{2\tau}{(1+4\omega_I{}^2\tau^2)}\right\} \qquad (27.15)$$

where ω_I is the resonance frequency. This mechanism is particularly powerful in strong dipolar coupling, $\gamma^4\hbar^2 r^{-6} I(I+1)$, particularly at short internuclear distances r and at molecular motional frequencies close to ω_I. Similarly, relaxation of nucleus A via hetero-nuclear dipolar coupling by nucleus B is described by the following equations:

$$\frac{1}{T_1} = \left(\frac{4}{30}\right)\left(\frac{\mu_0}{4\pi}\right)^2 r(A-B)^{-6}{\gamma_A}^2{\gamma_B}^2 \times \hbar^2 I_B(I_B+1)\left\{\frac{3\tau}{(1+{\omega_A}^2\tau^2)} + \frac{6\tau}{(1+(\omega_A+\omega_B)^2\tau^2)} + \frac{\tau}{(1+(\omega_A-\omega_B)^2\tau^2)}\right\} \quad (27.16)$$

$$\frac{1}{T_2} = \left(\frac{4}{30}\right)\left(\frac{\mu_0}{4\pi}\right)^2 r(A-B)^{-6}{\gamma_A}^2{\gamma_B}^2 \times \hbar^2 I_B(I_B+1)\left\{4\tau + \frac{3\tau}{(1+{\omega_A}^2\tau^2)} + \frac{6\tau}{(1+{\omega_B}^2\tau^2)} + \frac{\tau}{(1+(\omega_A-\omega_B)^2\tau^2)} + \frac{6\tau}{(1+(\omega_A+\omega_B)^2\tau^2)}\right\} \quad (27.17)$$

Because the molecular motion correlation times τ are temperature-dependent, that is, $\tau = \tau_0 \exp(E_a/RT)$, the T_1 plots of Eqs. (27.14) and (27.16) in semilogarithmic coordinates are symmetrical, V-shaped and go through minima. The slops of the curves correspond to the E_a values and the τ-independent minima provide determinations of internuclear distances. Finally, if target nuclei interact with a number of neighboring nuclei, then the corresponding contributions should be summed up.

Nuclei with spins > ½, interacting with the EFG, eq_{ZZ}, relax by the quadrupolar mechanism:

$$\frac{1}{T_1}(Q) = \left(\frac{3}{50}\right)\pi^2(2I+3)(I^2(2I-1))^{-1} \times \left(\frac{e^2 q_{zz} Q}{h}\right)^2\left(1+\frac{\eta^2}{3}\right)\left(\frac{\tau}{(1+{\omega_Q}^2\tau^2)} + \frac{4\tau}{(1+4{\omega_Q}^2\tau^2)}\right) \quad (27.18)$$

where η is the asymmetry parameter (corresponding to 0 at an axial symmetry). The T_1(Q) times can change in large limits ($10^{-4} - 10^4$ ms), strongly depend on the nature of nuclei and particularly on the symmetry of their environments. For example, the ^{14}N T_1 time is as long as 10^4 ms in molecule $Me_4{}^{14}NBr$ due to the completely symmetrical environment of ^{14}N nuclei.

The chemical-shift-anisotropy mechanism (CSA)

$$\frac{1}{T_1}(\text{CSA}) = \left(\frac{1}{15}\right){\gamma_I}^2{B_0}^2(\Delta\sigma)^2 \times \left(\frac{2\tau}{(1+{\omega_I}^2\tau^2)}\right) \quad (27.19)$$

$$\frac{1}{T_2}(\text{CSA}) = \left(\frac{1}{90}\right){\gamma_I}^2{B_0}^2(\Delta\sigma)^2 \times \left(8\tau + \frac{6\tau}{(1+{\omega_I}^2\tau^2)}\right) \quad (27.20)$$

is effective for nuclei with large values $\Delta\sigma$ (^{13}C, ^{15}N, ^{19}F and ^{31}P, for example). As it is seen, at $\omega^2\tau^2 \ll 1$ the relaxation rates become field-dependent and proportional to ${B_0}^2$. This is an experimental test for domination of the CSA mechanism. According to Abragam (1961), the spin-rotation mechanism is remarkable only for small molecules undergoing fast rotation in nonviscous media. This mechanism is valuable when the T_1 times reduce at increasing the temperature.

Generally, different relaxation mechanisms can operate simultaneously. In such cases, contributions that are important for studying the molecular mobility or structural features should be accurately evaluated (Bakhmutov, 2005). It should be emphasized, however, that two “independent” mechanisms can interfere to give cross-relaxation contributions.

27.3.4.2 **Paramagnetic Relaxation**

Fluctuating magnetic fields created by the large magnetic moment of an unpaired electron, $\mu_S = -g_e\beta eS$, can strongly reduce time of nuclear relaxation via dipolar and/or contact interactions. The dipolar mechanism, formulated by Solomon (Solomon, 1955) as controlled by reorientations of electron-nucleus vectors r, is written as (for $S = ½$)

$$\frac{1}{T_1{}^{\mathrm{DD}}} = 0.1\gamma_I{}^2\gamma_S{}^2\hbar^2 r^{-6} \times \left\{ \frac{\tau}{(1+(\omega_I-\omega_S)^2\tau^2)} + \frac{\tau}{(1+\omega_I{}^2\tau^2)} + \frac{\tau}{(1+(\omega_I+\omega_S)^2\tau^2)} \right\} \quad (27.21)$$

$$\frac{1}{T_2{}^{\mathrm{DD}}} = \left(\frac{1}{20}\right)\gamma_I{}^2\gamma_S{}^2\hbar^2\, r^{-6} \times \left\{ 4\tau + \frac{\tau}{(1+(\omega_I-\omega_S)^2\tau^2)} + \frac{3\tau}{(1+\omega_I{}^2\tau^2)} + \frac{6\tau}{(1+\omega_S{}^2\tau^2)} + \frac{6\tau}{(1+(\omega_I+\omega_S)^2\tau^2)} \right\} \quad (27.22)$$

Here, τ is the molecular motion correlation time at rapid molecular motions or the electron relaxation time at slow reorientations. Because the nuclei, situated closer to paramagnetic centers, relax much faster (see the r^{-6} factor), these $T_{1,2}$ times can be rationalized in structural terms.

Bloembergen (1957) has shown that strong FC coupling can lead to this situation when electron-spin flips are directly accompanied by nuclear-spin flips. This mechanism, arising due to delocalization of the unpaired spin density in a nucleus, is given by the following equations:

$$\frac{1}{T_1{}^{\mathrm{CON}}} = \left(\frac{2}{3}\right) S(S+1)\left(\frac{A}{\hbar}\right)^2 \times \frac{(\tau_{E2})}{(1+\omega_I{}^2\tau_{E2}{}^2)} \quad (27.23)$$

$$\frac{1}{T_2{}^{\mathrm{CON}}} = \left(\frac{1}{3}\right) S(S+1)\left(\frac{A}{\hbar}\right)^2 \times \left(\tau_{E1} + \frac{(\tau_{E2})}{(1+\omega_I{}^2\tau_{E2}{}^2)}\right) \quad (27.24)$$

where τ_{E1} and τ_{E2} are the longitudinal and transverse electron-spin relaxation times, respectively. The FC mechanism dominates if under conditions $\omega_S\tau > 1 > \omega_I\tau$ the T_2 time is much shorter than T_1.

27.3.4.3 **Nuclear Relaxation in Solids: Spin Diffusion**

When solids exhibit some kind of molecular motions, then nuclei can relax by all of the above mechanisms. However, the relaxation process is usually nonexponential and described by a stretched exponential, $\exp(-(\tau/T_1)^{\beta})$. Tse and Hartmann (1968) have shown that β of 0.5–0.6 is typical of powder samples. In rigid solids with very restricted motions, nuclear relaxation should be extremely slow. However, even at very small concentrations of paramagnetic impurities, the relaxation rates can increase by the, so-called, spin diffusion, suggested by

Bloembergen (1949). Owing to energy-conserving transitions of spins (mutual spin flips), belonging to dipolar-coupled nuclei, a target spin is "transferred" to a paramagnetic center, where it relaxes effectively by electron-nuclear dipolar interaction. Then, relaxation times are controlled by spin-diffusion coefficients D:

$$\frac{1}{T_1{}^{\mathrm{SD}}} = \left(\frac{1}{3}\right) 8\,\pi NpC^{1/4}D^{3/4} \quad (27.25)$$

$$C = \left(\frac{2}{5}\right) \gamma_I{}^2\gamma_S{}^2\hbar^2\ S(S+1)$$

In turn, D is defined as $D = (\mathbf{M}^{1/2}/30)a^2$, where $C = (2/5)\gamma_I{}^2\gamma_S{}^2\hbar^2\ S(S+1)$, Np is the paramagnetic center density, $\mathbf{M}$ is the second moment of the dipolar internuclear interaction, and a is the internuclear distance. There are two distinguished cases: rapid spin diffusion and diffusion-limited relaxation. $\mathrm{T}_1{}^{\mathrm{SD}}$ relaxation via fast spin-diffusion is always exponential, whereas diffusion-limited relaxation is nonexponential and can be treated by a stretched exponential at $0.5 < \beta < 1$. Kessemeier and Norberg (1967) have shown that the spin-diffusion coefficient D decreases in spinning solids. Thus the $T_{1,2}{}^{\mathrm{SD}}$ times can depend on rates of mechanical rotation. Recently, Grutzer and Dybowski (Grutzer *et al.*, 2001) have found that heavy nuclei, such as ^{207}Pb, can relax via a spin-phonon Raman scattering mechanism.

27.3.4.4 Relaxation Time Measurements

Modern commercial NMR spectrometers provide simple and convenient procedures for measurements of relaxation times. Relaxation times T_1 can be measured by the inversion-recovery (180°-τ-90° *at the varied delay*s τ), saturation-recovery or progressive saturation experiments. To improve the quality of spin inversion, the 180° pulse can be replaced with a composite pulse cluster $90^\circ_\phi\ 240^\circ_\phi\ 90^\circ_\phi$ (see, for example, Harris, 1986). According to Sanders and Hunter (1994), the Hahn-echo (90°-τ-180°-τ-*FID*) or Carr–Purcell pulse sequences (90°x'-τ-180°y'-τ(*first echo*)-τ-180°y'-τ (*second echo*), *and so on*) can be applied to determine the spin–spin relaxation times T_2.

Spin-locking experiments in a rotating coordinate system create conditions providing nuclear magnetization to be aligned along the direction of the applied radio-frequency field. Because this field is smaller by several orders than the external magnetic field B_0, the magnetization decays with a specific time constant, $T_{1\rho}$, determined by significantly slower molecular motions. In solids, where molecular motions are strongly restricted, $T_{1\rho}$ values can differ strongly from T_1 and T_2 times. In contrast, the T_1, T_2, and $T_{1\rho}$ times are practically identical in solutions and nonviscous liquids, where molecular tumbling is fast.

27.4
Spectroscopic NMR Experiments in Liquids

27.4.1
Routine One-Dimensional (1D) NMR spectra

Generally, the routine 1D NMR spectra imply a direct excitation of nuclei with a single-pulse sequence (Figure 27.3). The best sensitivity in such experiments, often requiring a large number of accumulations at long delay times, can be reached when the acting angle of

RF pulses is optimized. In accordance with the Ernst rule (Ernst *et al.*, 1966), at the total RD of 1 s, the angle should be of 8, 25, 33, 68, 86, and 90° if the T_1 time is 100, 10, 4, 1, 0.4, and 0.1 s, respectively.

Rare nuclei, for example, ^{13} C, are often spin–spin coupled by other nuclei, having a high natural abundance, for example, ^{1} H. The ^{13}C lines splitting and their observations are complicated. The NMR spectra of such nuclei are simplified with a broad-band-decoupler technique, which irradiates ^{1}H nuclei during the (RD + AT) time and suppresses, thus, the spin–spin coupling. Besides ^{1}H-decoupling, the signal intensities of carbons attached to protons (for example, groups CH, CH_2 or CH_3) increase due to the nuclear overhauser effect (NOE) (Overhauser, 1953). This effect connects with a perturbation of an equilibrium magnetization of X nuclei at irradiation of A nuclei, when nuclei A and X are coupled by dipole–dipole interaction. Commonly, when signs of γ_A and γ_X are identical, the X intensity increases according to: $I^X\{A\}/I^X{}_0 = 1 + \gamma_A/2\ \gamma_X$. To avoid the NOE, the ^{1}H- decoupler is applied during the AT time only.

Owing to the numerous and well-established relationships "spectrum/ structure," even the routine 1D NMR spectra (multinuclear NMR particularly) are good tools for the determinations of chemical structures. The NOE measurements are also useful in this context. For example, Harris (1986) notes that in a system, consisting of three protons, H(A)···H(B)···H(C), coupled by dipolar interaction, irradiating the H nucleus results in the positive and negative NOE enhancement for H(B) and H(C) nuclei, respectively.

27.4.2
Polarization Transfer in NMR (SPI, INEPT, and DEPT)

When rare nuclei, for example,^{13}C, ^{15}N, ^{29}Si, and so on are coupled by high-γ–nuclei, for example, ^{1}H, their equilibrium population difference can be perturbed by a polarization transfer technique to increase the NMR sensitivity. The physical principles of this technique can be found in the book of Friebolin (1993). Generally, an 180° pulse (selective or nonselective), which inverts the level populations, plays a main role in such experiments, named as signal enhancement by polarization transfer (SPI), insensitive nuclei enhanced by polarization transfer (INEPT) and distortionless enhancement by polarization transfer (DEPT). Among them, the DEPT sequence, shown in Figure 27.5, is most important, particularly for ^{13}C nuclei. Here an evolution time, τ, is calculated as 1/ $2\,^1J$(C−H) and pulse $\theta = 135°$ leads to an ^{1}H-decoupled ^{13}C NMR spectrum with "negative" signals for CH_2 groups and "positive" signals for CH and CH_3 groups.

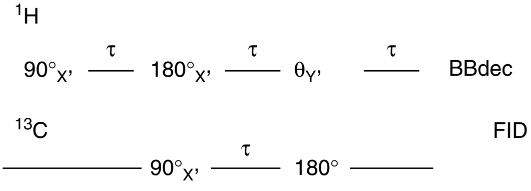

Fig. 27.5 Presentation of the DEPT pulse sequence.

27.4.3
Two-Dimensional (2D) NMR Spectra

The pulse sequences, applied for the 2D NMR experiments, are various and are dependent on target tasks. Many of them, for example, the 2D heteronuclear *J*-resolved ^{13}C NMR spectra, the 2D homonuclear *J*-resolved ^{1}H NMR spectra, the 2D heteronuclear correlated NMR spectra, the 2D relayed NMR spectra, the 2D exchange NMR spectra, and the 2D INADEQUATE NMR spectra can be found in the book of Friebolin (1993). The more complex pulse trains are applied for NMR studies of biomolecules in solutions or the solid state (Duel, 2002). General principles of 2D NMR can be demonstrated by one of the simplest ^{1}H NMR experiments, ^{1}H–^{1}H COSY (correlated spectroscopy), shown in Figure 27.6.

After the first 90° pulse, a nuclear system is developed by proton–proton spin–spin coupling during time t_1. Thus, the first set of time-dependent data, $f(t_2)$, can be recorded after the action of the second RFP during time t_2. The $f(t_1)$ sets are collected at various t_1 values. Then, a double FT, performed for domains t_1 and t_2, leads to two frequency-axes. The resulting spectrum, shown in Figure 27.7, is a square plot, where the diagonal corresponds to the 1D ^{1}H NMR spectrum and cross peaks appear due to scalar spin–spin coupling. Similarly, one can perform a 2D NOE experiment, NOESY, (Figure 27.7) which is a good tool to establish spatial proximity of nuclei or an exchange process between them.

27.4.4
Chemical Exchanges: the NMR Time Scale

Besides nuclear relaxation and spin–spin coupling, reversible exchange processes between distinguishable spin states can also affect line shapes in NMR. These effects are particularly strong when life times (τ) of these states are in a range from 10^{-4} to 10^{1} s, named as the NMR time scale.

Commonly, a chemical exchange between spins *A* and *X* perturbs shapes of their resonances, if the exchange frequency,ν_E, is comparable to chemical shift difference ($\nu_A - \nu_X$), expressed in Hertz. Then, the NMR spectra show a typical temperature evolution (Figure 27.8): the signals broaden and coalesce. A fast exchange, $\nu_E \gg (\nu_A - \nu_X)$, results in a single resonance. If spin states *A* and *X* are equally populated, this resonance appears at frequency $\nu = (\nu^A + \nu^X)/2$.

Generally, spin states can have different populations, they can belong to the same molecule (an intramolecular exchange) or different molecules (an intermolecular exchange) and finally,

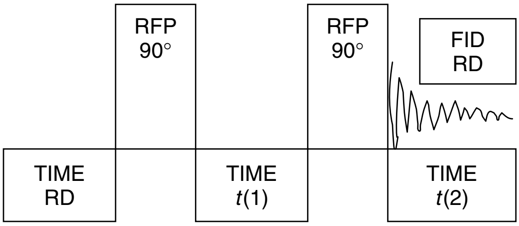

Fig. 27.6 The pulse sequence for a homonuclear proton–proton correlation (COSY) NMR experiment: the second pulse can be 90 or 45°.

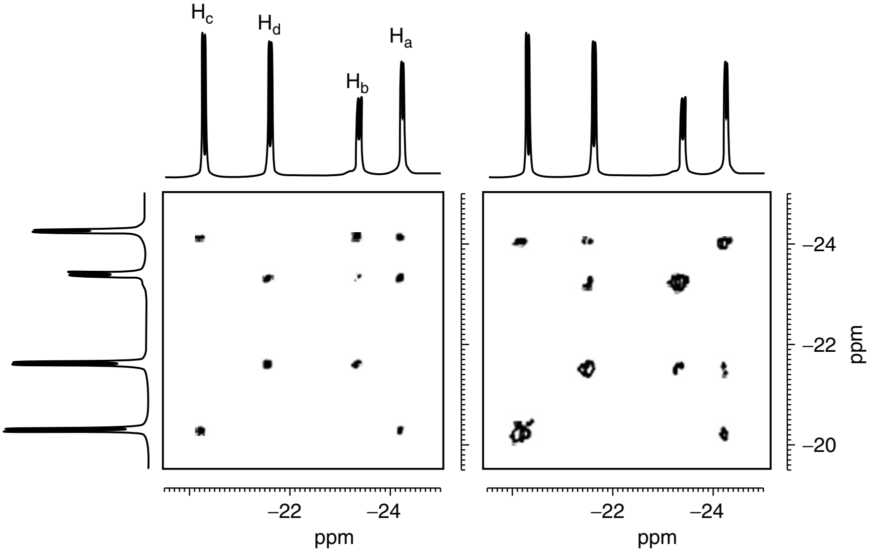

Fig. 27.7 A high-field region of the ^{1}H COSY (left) and NOESY (right) NMR spectrum of the complex $[Ir_2(\mu\text{-}H^a)(\mu\text{-}Pz)_2(H^b)(H^c)(H^d)(NCCH_3)(PPr^i{}_3)_2]$ in C_6D_6: pairs of nuclei H^a/H^c, H^a/H^b and H^b/H^d are spin coupled, while pairs H^a/H^c and H^b/H^d are spatially approximated.

multicenter exchanges are also possible. Because the NMR line shapes in liquids are well established, exchange rates are accurately determined by a full line-shape-computer analysis, which can be found in NMR books cited in this chapter.

At slow exchanges, $\nu_E < \nu_A - \nu_X$, the NMR signals are well separated and remain narrow. However, relaxation times of the exchanging spin states can be averaged partially. Then, the FID's collected by the inversion-recovery experiments will depend on life times of these spin states which, thus, can be determined. Slow exchanges in ^{1}H NMR spectra can be easily established by saturation transfer experiments: irradiation of X nuclei leads to the saturation of the A resonance. For nuclei other than protons, 2D NOESY NMR, known as *two-dimensional exchange spectroscopy* (*EXSY*), is more preferable. Some examples of applications of the above techniques can be found in the books of Friebolin (1993), Harris (1986), and Bakhmutov (2005). It should be emphasized that the effects of chemical exchanges are particularly strong when one of the exchanging states is paramagnetic. In such cases, quantitative characterizations are reached by relaxation time measurements.

27.4.5
Translational Molecular Diffusion via NMR

The influence of magnetic-field inhomogeneity on forming the spin echo has been noted by Hahn (1950). If a static field gradient G is actually present, then a coherent transverse magnetization, created by the first 90° pulse in the Hahn-echo pulse sequence ($90°\text{-}G(\tau)\text{-}180°\text{-}G(2\tau)\text{-}FID$), undergoes an evolution in

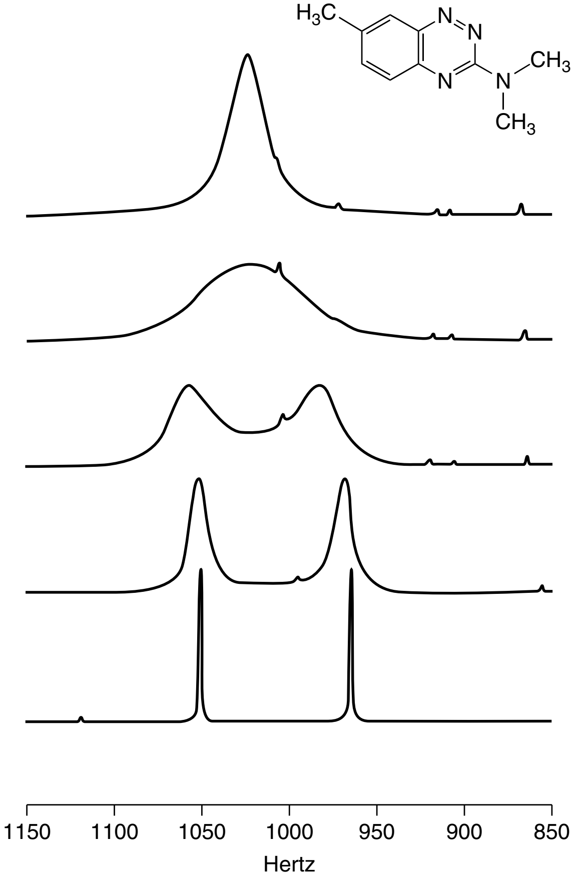

Fig. 27.8 Temperature evolution of the NCH_3 lines in the variable-temperature ^1H NMR spectra typical of a rotation around C—N bond.

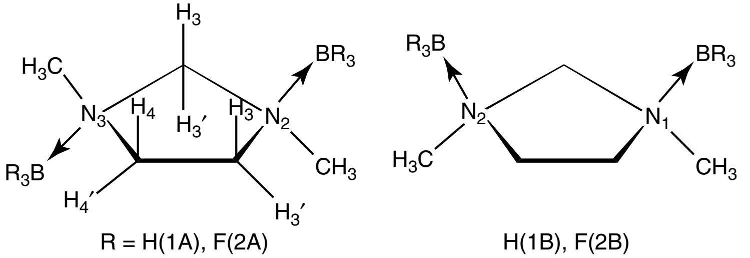
this gradient. After a dephasing time, τ, the second 180° pulse inverts the sign of the net accumulated phase and the spins precess at the Larmor frequencies, reducing their accumulated phases. When the rephasing and dephasing rates are equal, then the magnetization reaches its coherent initial state after time 2τ, forming, thus, a spin echo. Then, the spin echo decays due to T_1/T_2 relaxation and additional factors are directly related to the molecular displacement on the time scale of the spin-echo experiments. At well-defined field gradients, the time correlation functions, describing the spin-echo decays, can be applied for studies of translational molecular diffusion.

Technically, these NMR experiments can be performed with the static-field gradients (SFG) or the pulsed-field gradients (PFG) suggested by McCall *et al.* (1963). As noted by Geil (1998), a combination of large static field gradients with short radio-frequency-pulse-spacings provides measurements of very small diffusion coefficients (10^{-15} m^2 s^{-1}) at a high spatial resolution (10 nm).

27.4.6
Isomeric and Conformational Analysis in Solutions by NMR

One of the key areas of NMR applications in solutions is the molecular conformational/configurational analysis. Because generally the analysis of cyclic molecules involves various NMR methods, such as the variable-temperature NMR spectra, the NOESY or other 2D NMR experiments, T_1 measurements, and determinations of the spin–spin coupling constants and their calculations by a convenient computer program, this aspect of the NMR spectrometry can also be a good illustration of its practical application. A methodology, typical of these studies, is demonstrated here by five-membered cycles 1 and 2, depicted in Scheme 27.1 (Guizado-Rodriguez *et al.*, 2001).

Initial structural formulations of these compounds can be easily carried out on the basis of the ^{1}H, ^{13}C, ^{11}B, ^{19}F, and 2D ^{1}H–^{13}C HETCOR NMR spectra. However, *a priori*, the cycle molecules can exist as trans-(1*A*, 2*A*) and cis-isomers (1*B*, 2*B*) and their cycles can take an envelope (*E*) or twist (*T*) conformations. In addition, usually five-membered cycles undergo fast pseudorotation with insignificant transformation energies and therefore the envelope and twist conformations can be equilibrated leading to observations of the average room-temperature (RT) NMR spectra. According to the RT multinuclear NMR spectra, recorded in C_6D_6, compound 1 gives two isomeric products, 1*A* and 1*B*, in a ratio of 9 : 1. Protons 2 and 2′ in the RT ^{1}H NMR spectrum of the major product are equivalent, whereas protons 5(4′) and 5′(4) are nonequivalent to show a complicated pattern in Figure 27.9. Simulation procedures for the AA′BB′ pattern show that the multiplet can be calculated when the geminal ^{1}H–^{1}H couplings are assumed to be negative and the *J*(5–4′) and *J*(5′–4) constants take positive but different values: 9.5 and 2.5 Hz, respectively. In terms of the modified Karplus equation (Haasnoot *et al.*, 1980), the corresponding dihedral angles should be strongly different. The NOESY ^{1}H NMR spectra of 1*A* in toluene-d_8 recorded at room-temperature and −90°C reveal cross peaks 2(2′)-CH_3, 5′(4)-CH_3 and 5–5′, showing spatial proximity of the above protons. Protons 2 and 2′ remain equivalent even at low temperatures. In addition, calculations of the 5(4′)–5′ (4) patterns, observed in toluene-d_8 at 25 and −90 °C, lead to



Scheme 27.1

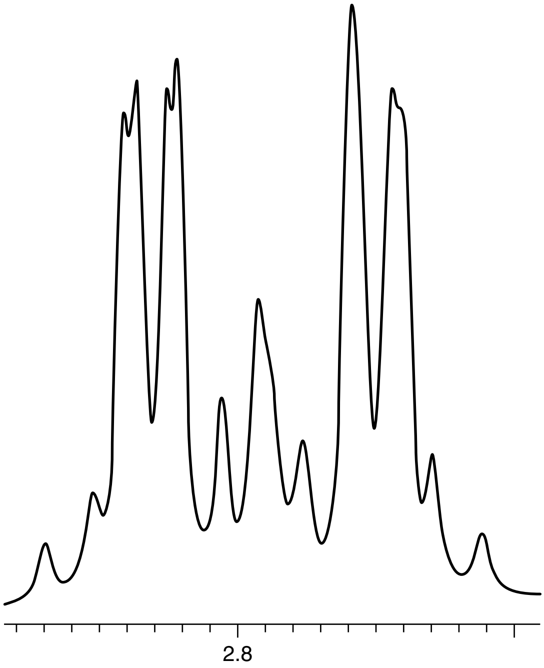


Fig. 27.9 Pattern AA′BB′ observed for protons 5(4′) and 5′(4) in the RT ^{1}H NMR spectrum of 1*A* in C_6D_6.

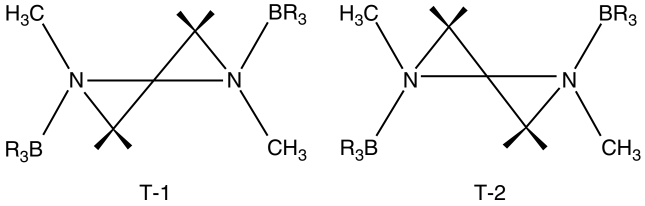
identical results: $^2J(5-5') = -10.5$ Hz, $^3J(5-4') = 9.5-10.0$ Hz, $^3J(5'-4) = 2.0-3.0$ Hz, $^3J(5-4) = 7.0$ Hz, $^3J(5'-4') = 7.0$ Hz, and $^2J(4-4') = -10.5$ Hz. Thus, only a trans BH_3/BH_3 arrangement is possible in 1*A* and its cycle takes twist conformation $T-1$ in Scheme 27.2, which is preferable even at room temperature. Compound 2 shows identical spatial properties. The same (or similar) methodology can be successfully used in the studies of other molecules.

27.5
NMR Spectroscopic Experiments in the Solid State

27.5.1
Wide-Line NMR

Resonance lines in NMR spectra of liquids or solutions are sharp due to the fast high-amplitude molecular motions. For example, line-width of a ^{1}H resonance in liquid water is as small as 0.1 Hz. In contrast, the resonance of ice is dramatically broadened up to $\sim10^5$ Hz. According to



Scheme 27.2

Andrew and Szczesniak, 1995, a primary source of this broadening is magnetic dipolar proton–proton interactions, governed by a factor $(3\ \cos^2\theta - 1)/r^3$, where θ is the angle between the external magnetic field and internuclear vector r. It is obvious that the broadening factor is particularly large for powder samples. A single crystal sample can be oriented in the external magnetic field and its NMR spectrum is analyzed better. For example, a single crystal of $CaSO_4 \cdot 2\ H_2O$ with the relatively isolated protons shows the so-called Pake doublet providing determination of the proton–proton distance (Pake, 1948). Because dipolar interactions depend on the nature of nuclei, line widths of their resonances change drastically. For example, $^{29}Si–^{29}Si$ dipolar coupling produces line widths of 2–3 kHz only. Similarly, hetero-nuclear dipolar and CSA interactions also lead to wide lines in solid NMR. Finally, quadrupolar interactions exceed dipolar interactions by a factor e^2Q/μ^2, where eQ and μ are electric quadrupole moment and nuclear magnetic moment, respectively. All of these effects, particularly important for powder samples, give rise to the solid-state NMR spectra, where directional information "nucleus-nucleus" is lost and line widths mask the presence of chemically different nuclei.

Nevertheless, wide-line NMR can provide structural conclusions based on an approach suggested by Van Vleck (1948). In the limits of the approach, the dipolar second moment (or square width) is calculated in terms of the sum $\Sigma(3\ \cos^2\theta_{jk} - 1)^2/r_{jk}{}^6$ over all nuclei pairs in crystals or the sum $\boldsymbol{\Sigma} r_{jk}{}^6$ in polycrystalline samples. Because of the $r_{jk}{}^6$ factor, nearest dipole–dipole contacts dominate and thus structural information about molecules, groups, or ions can be obtained by comparing the experimental and calculated NMR spectra.

27.5.1.1 Dead Time in Wide-Line NMR

When a magnetization, created by RFP, decays rapidly with respect to the dead time of a spectrometer, FT converts the FID into an NMR spectrum where signal intensities are remarkably reduced and the base line shows strong distortions. This problem, particularly important for solid-state NMR, can be minimized by the applications of pulse sequences Hahn-echo ($90°_X$-τ-$180°_Y$-τ-FID) or solid echo ($90°_X$-τ-$90°_Y$-τ-FID), where τ is echo-delay time. According to Duel (2002), the FIDs can be collected immediately after 180° pulses. For spinning samples, the experiments require echo-delays synchronized with rotor periods.

In paramagnetic samples, resonance lines can be too broad and even unobservable in regular NMR spectra. In such cases, as noted by Mali *et al.* (2005), carrier frequencies in the Hahn-echo experiments can be varied and the resulting Hahn-echo NMR spectra can be summed up to show these wide lines.

27.5.1.2 Relaxation Experiments in Solids

Despite the relatively poor structural information, the wide-line NMR technique is successfully applied for the studies of molecular motions and phase transitions in solids by relaxation time measurements and/or a line-width analysis, briefly reviewed by Andrew and Szczesniak, 1995. The experiments can be performed in a very large temperature range, which is sufficient to characterize the molecular dynamics in materials of all kinds: amino acids, polypeptides, proteins, polymers, rubber, metabolites and steroids, and so on. In solid proteins, for example, it is possible to identify and characterize energetically a number of motions contributing to relaxation rates such as methyl-group reorientations, segmental motions, side-chain motions, and bound-water reorientations. It should be emphasized that solid-state NMR measurements, including T_1 and T_{1D} times and also the rotating-frame relaxation time, $T_{1\rho}$, is sensitive to motions covering the range of frequencies from 10^{-1} to 10^{11} Hz.

27.5.2
High-Resolution Solid-State NMR

At an angle θ of 54.4°, called as *magic angle* by Andrew, factor $(3\ \cos^2\theta - 1)/r^3$, characterizing dipole–dipole interaction, transforms to 0. It has been shown that the broadening effects, observed in static solids, can be reduced by their spinning when the given samples are situated at this angle relative to the external magnetic field. The narrowing effects will be more pronounced at spinning rates close or larger than line widths in static NMR. This principle is basic in the magic-angle-spinning (MAS) NMR spectroscopy leading to high resolution in the solid-state spectra. In practice, the collected spectra show isotropic resonances accompanied by spinning sidebands, which can be quite intense. However, positions of these bands can be changed by rotation at different rates and thus isotropic chemical shifts can be determined. In addition, there are special pulse sequences, which are capable of suppressing the sidebands. According to Duel (2002), one of such scheme is the TOSS pulse sequence consisting of four 180° pulses in a period prior to acquisition.

At intermediate spinning rates ν_R with respect to static line widths $\Delta\nu$ (for example, $\nu_R \sim \Delta\nu/4$) and domination of homonuclear dipolar coupling, the lines observed in MAS NMR spectra are still broadened due to the remaining time-dependent terms. In contrast, the MAS NMR spectra of molecular systems with dominant hetero-dipolar and CSA interactions show sharp lines even at intermediate spinning rates. According to Strub *et al.* (1983), distributions of sidebands in such cases can be used to determine magnetic screening tensors.

Nowadays, the modern commercial NMR spectrometers are equipped with MAS probes, where the spinning rates of 30–50 kHz are routinely achieved. Under these conditions, broadenings caused by the magnetic dipolar interactions, chemical shift anisotropy, Knight-shifts, pseudodipolar interactions, and quadrupolar interactions are canceled and the resulting spectra are determined by the isotropic chemical shifts and spin–spin coupling constants as in liquids and solutions.

27.5.2.1 High-Power Decoupling and Double Resonance

Typically, even in relatively simple molecules, NMR detections of rare nuclei, such as ^{13}C or ^{15}N, and so on, are seriously problematic because of the very strong dipolar interactions at short bond distances $^1H{-}^{13}C$ or $^1H{-}^{15}N$. Generally, these interactions are suppressed by a high-power decoupling technique producing ^1H irradiation when the ^{13}C or ^{15}N NMR FIDs are recorded. The decoupling can be realized by a continuous irradiation at a power of 100–1000 W or by special pulse sequences operating at proton frequency. Among them, sequences Two pulse phase modulation (TPPM), Waugh-Huber-Haeberlen (WAHUHA), and MREV-8 are most applicable (Duel, 2002).

Although, in rigid solids, the homonuclear dipolar interaction $^1H-^1H$ is particularly strong, lines in the ^1H MAS NMR spectra, recorded even at high spinning rates, are still broadened due to remaining dipolar interaction. However, such broadenings can be weakened or completely removed by the application of combined rotation and multiple pulse spectroscopy (CRAMPS), pioneered by Gerstein (1981). The CRAMPS combines sample spinning and multiple-pulse-decoupling sequences (for example, MREV-8).

27.5.3
Cross Polarization Technique

This technique helps strongly to improve a signal/noise ratio in the NMR spectra of ^{13}C, ^{15}N, and other nuclei with long relaxation times, low natural abundance, and low γ values. The task of a pulse sequence

$$^1\text{H } 90^\circ_X \text{ - contact pulse}_{-Y}\ ^1\text{H decoupling}$$

$$^{13}\text{C - contact pulse}_{-Y}\text{ -}^{13}\text{C FID} \qquad (27.26)$$

is a transfer magnetization from the ^1H spins with a high natural abundance to the ^{13}C (or ^{15}N) spins via the dipolar coupling between them. The amplitudes of two contact pulses, operating at proton and carbon frequencies, should be adjusted to achieve the Hartmann–Hahn conditions (Hartmann and Hahn, 1962):

$$\gamma_H B_1(^1\text{H}) = \gamma_C B_1(^{13}\text{C}) \qquad (27.27)$$

Under these conditions, the energy gaps between the ^1H and ^{13}C rotating-frame spin states are equal and the transition requiring energy on ^1H spin can be exactly compensated by the transition releasing energy on ^{13}C spin. This pulse sequence in combination with the MAS technique leads to rapid accumulations of the ^{13}C NMR spectra because the recycling delay is decided by the ^1H (and not ^{13}C) relaxation.

27.5.4
Internuclear Distances from the Solid-State NMR Data

When molecular systems are amorphous or insoluble in common solvents, solid state NMR is the most efficient tool in their structural studies. Traditional NMR applications, based on the solid-state 1D and 2D NMR spectra, can be found in Duel (2002). Technically, collections of the NMR spectra in the solid state and solutions remarkably differ but their interpretations are very similar. It should be noted that most chemists are satisfied with obtaining such data. The other way of structural characterizations by NMR techniques is the high-precision measurement of interatomic distances, illustrated in this section.

Theoretically, information about distances between nuclei can be evaluated from the magnitudes of long-range dipole–dipole interactions. The classical Pake's powder spectrum, (Pake, 1948), expected for two nuclei in a static sample, is shown in Figure 27.10. Here, the shape of the resonance is formed by the superposition of two subspectra (dashed lines) and the distance between the two singularities corresponds to the dipolar coupling constant ω_D. Recalculations of ω_D gives finally a distance between the nuclei. A weak point in this simple approach is obviously connected with a low NMR

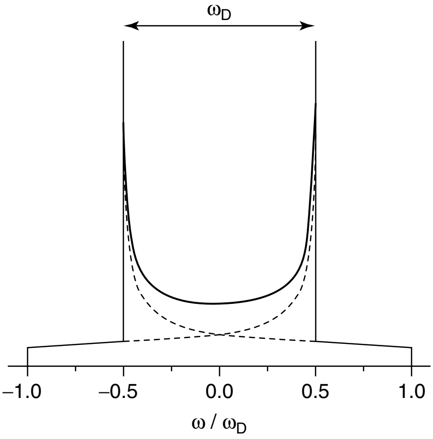


Fig. 27.10 The Pack dipolar powder spectrum. (Reproduced with permission from Lee, J-A and Khitrin, AK (2008) *Concepts Magn. Reson. Part A*, **32A**, 56.)

sensitivity particularly important for rare nuclei. Development of less direct NMR techniques, such as *SLF, PISEMA PITANSEMA, REDOR, TEDOR*, and so on, simplifies the determinations of dipolar couplings and hence internuclear distances. Some methods, their physical basis, and applications can be found, for example, in the book of Duel (2002). Lee and Khitrin (2008) have suggested a technique, specially developed for static samples, which is based on a two-dimensional single-echo pulse sequence, where adiabatic cross-polarization increases sensitivity. This technique, applied for isotopically labeled molecules, for example, glycine, provides the accuracy in measuring internuclear distances C—C and C—N, which is well compared with that in the X-ray and neutron-diffraction methods. For example, distance C_α—N is determined as 1.496 ± 0.002 by NMR and 1.476 ± 0.001 by ND.

27.5.5
Zero-Field Solid-State NMR Experiments

An initial nuclear polarization, needed for detecting NMR signals, is generally created by the strong external magnetic field. On the other hand, nuclei can be polarized by internal magnetic fields, which appear in samples due to their nature. For example, such a zero-field NMR spectrum has been observed by Reif and Purcell (1953) in solid hydrogen due to very strong proton–proton dipolar interactions. Similarly, even in the absence of an external magnetic field, the internal magnetic fields polarize the ^{57}Fe and ^{59}Co nuclei in ferromagnetic iron and cobalt, again resulting in the zero-field NMR spectra.

Other physical principles, considered by Andrew and Szczesniak (1995), are used in the zero-field NMR experiments directed to enhancements of resolution in the NMR spectra of polycrystalline samples. In such experiments, an initial nuclear polarization is created in a sample when it is placed into a strong external magnetic field. This polarized sample is transferred mechanically to an intermediate magnetic field, which, however, is still remarkably larger than local fields existing in the sample due to dipolar interactions. Then, this intermediate field is rapidly switched off and the nuclear spins undergo an evolution, during time τ_1, initiated obviously by the dipolar forces. After this time, the intermediate field is turned on and the sample is again placed into the high magnetic field, where a high-field NMR signal is detected as $I(\tau_1)$. FT of $I(\tau_1)$ gives, thus, a zero-Field NMR spectrum. In other words, this experiment leads to the high-magnetic-field NMR spectrum, recorded, at a high sensitivity, after an evolution of the nuclear spin system in the absence of the magnetic field. Because during the evolution period all directions are equivalent, numerous crystallites in polycrystalline samples will behave identically and the resulting NMR spectra will show sharp lines. Under these conditions even powder samples exhibit dipolar couplings with high resolution, usually reached only in field-oriented single crystals. Andrew and Szczesniak, 1995 note the obvious limitations: the zero-field technique can be successfully used when the spin-lattice relaxation time, T_1, in a low magnetic field is long enough to complete the experimental cycle. Similar zero-Field experiments can be performed for spinning samples. However, acting pulses and rotation rates should be synchronized in such cases.

27.6
Sensitivity Enhancement by Dynamic Nuclear Polarization (DNP)

Applications of the solution and solid-state NMR spectroscopy for many fields of chemistry, biology, and materials science often require a very high sensitivity in NMR spectra. When probing rare nuclei, for example ^{13}C, this is particularly critical when using the techniques considered in the previous sections is not enough. It should be recalled that the sensitivity depends on the natural initial nuclear polarization, which can be enhanced by the specially developed approaches based on optical pumping (Walker and Happer, 1997), parahydrogen-induced-polarization (Bargon and Natterer, 1977), and dynamic nuclear polarization (DNP) (Wind *et al.*, 1985). For example, Bifone *et al.* (1996) have found that optical pumping with laser light can enhance the nuclear polarization of gaseous xenon by 5 orders of magnitude. Among different techniques, the DNP seems to be most important and applicable to solids and solutions containing species with unpaired electrons (paramagnetic metal ions, organic groups, and so on). It is obvious that the systems investigated can be specially doped by such paramagnetic species.

Generally, an electron-nucleus system is described via the Hamiltonian:

$$H = -\omega_e S_Z - \omega_I I_Z + H_{\mathrm{ee}} + H_{\mathrm{en}} + H_{\mathrm{nn}} \qquad (27.28)$$

where the first two terms correspond to the Zeeman's interactions of electron and nuclear spins, respectively, H_{ee} and H_{nn} describe electron–electron and nucleus–nucleus coupling, and H_{en} describes the hyperfine electron-nucleus interaction. In the context of DNP generation, the latter term plays a main role.

Irradiating the samples at (or near) the electron Larmor frequency, ω_e, can lead to simultaneous electron-nucleus spin flips due to electron-nuclear coupling H_{en}. In turn, these flips enhance the absolute value of the nuclear polarization via three mechanisms: an Overhauser effect, a solid effect, and a thermal mixing effect, described in the review of Wind *et al.* (1985). The enhancement factors observed in the nuclear polarization depend on the number of unpaired electrons, the ESR line widths, the nuclear relaxation rates in the absence of electrons, and the amplitude of the microwave field, applied to the sample. Generally, in solids, the enhancement factors can reach 660 and 2600 for ^{1}H and ^{13}C nuclei, respectively.

Technically, the DNP experiments require a special design of an NMR spectrometer and particularly an NMR probe, which should be equipped with a coil that can be double-tuned to ^{13}C and ^{1}H frequencies, for example, and a horn antenna to transmit the microwaves. The simplest enhancement experiments with ^{13}C nuclei imply their direct polarization. A proton polarization via DNP and its transfer to the ^{13}C spins via ^{1}H$-$^{13}C cross-polarization is also possible.

Addenkjaer-Larsen *et al.* (2003) have applied the similar principle for the NMR spectra in liquids to increase the signal/noise ratio by a factor of $>10^3$. This method is based on a low-temperature high-field nuclear polarization performed by a DNP polarizer where a frozen sample is irradiated with microwaves. This instrument is equipped with a superconducting magnet, a liquid-helium cooled sample space, and a special injection tool inside the DNP magnet. This injection tool provides a rapid dissolving of the solid sample in a suitable solvent and thus the resulting solution contains molecules with hyperpolarized nuclear spins. Then the hyperpolarized solution is rapidly transferred into a high-resolution NMR spectrometer where an enhanced NMR signal is registered by a convenient procedure. This powerful method can be successfully applied for different DNP-enhanced NMR experiments *in vitro* and *in vivo*.

27.7
Imaging NMR

High resolution in the NMR spectra, very important for a detailed structural analysis, can be obtained when the strong external magnetic fields are maximally homogenous. Regularly, such fields are created by magnets with bores of a few centimeters, capable of keeping the resonance condition (Eq. (27.4)) in each point through the volume of a sample investigated. In large and heterogeneous samples, requiring obviously wider bore magnets, the resonance condition cannot be satisfied throughout the whole object. Nevertheless, in such cases, the magnetic field can be homogenized only in a small volume of the object and thus a high-resolved NMR signal can be still recorded. Then, this small volume can be "spatially shifted" to collect the next signal. Repeating these experiments finally leads to the distribution of detected nuclei through the volume of the object. This principle is basic in the imaging NMR spectroscopy. The first imaging NMR experiments have been performed more than 30 years ago by the research group of Lauterbur (1973) and resulted in a special design of magnets, NMR probes and also methods for computer treatments of the collected data to construct the image.

Among the various modifications, one of the central places belongs to the variable-field-gradient technique, which focuses the magnetic filed. This technique defines the volume selectivity, important in the practical NMR imaging, and hence the spatial resolution depending on object sizes. At present, the highest spatial resolution, which can be obtained in small objects, corresponds to an element volume of 10^{-5} mm^3.

Because the time needed for the collection of NMR data from such a small element volume significantly increases, the experiments should be highly sensitive. Therefore, ^{1}H NMR plays a main role in the imaging spectroscopy particularly when the objects of studies are living systems. Owing to the discovery that relaxation times ^{1}H T_1 and ^{1}H T_2 in water molecules depend on the characteristics of their bonding, the development of the imaging technique was strongly accelerated to result in magnetic resonance tomography. As it is emphasized by Minati and Weglarz (2007), Echo-imaging, based on the ^{1}H T_2 time measurements by spin-echo sequences, leads to quality of the T_2 images well comparable to that obtained by X-ray tomography.

It is known that at a given gradient strength, a wider NMR spectrum produces a poorer image resolution. Since, for example, ^{1}H NMR spectra in static solids are generally broader than in liquids by a factor of $10^5 - 10^6$, the solid-state imaging experiments require the much stronger gradients focusing the field (Andrew and Szczesniak, 1995). Therefore, solid-state NMR imaging includes the MAS technique and the multipulse coherent averaging technique or their combination reducing the dipolar, CSA, and quadrupolar interactions. However, again, spinning rates and the field-gradient pulses should be synchronized.

INTRODUCTION

Storage has of late been the fastest growing segment of the computer hardware industry. The overwhelming majority of storage products today are based on magnetic recording technology. Floppy disk drives, rigid disk drives, and tape drives all enjoy multibillion dollar markets for computer data storage. Magnetic bubble memories, which attracted much attention in the 1970s, have made it to the marketplace, but only in niche markets where the customer is willing to pay a relatively high cost per bit for a nonvolatile solid-state memory with no moving parts. Magneto-optic recording, after many years of research and development, has also been introduced into the marketplace and is finding significant applications, although its market is still orders of magnitude smaller than that of magnetic recording products. In contrast to some early expectations, the market acceptance of magneto-optic recording is not based primarily on its high areal density, but rather on the fact it offers a removable high-capacity storage medium in a disk format.

Future markets for both magnetic and magneto-optic recording are expected to grow substantially as storage densities increase by orders of magnitude and data rates and access times also improve. In this article the basic principles, state of the art, and future trends for these two recording technologies are described.

1. MAGNETIC RECORDING

Magnetic recording today provides extremely high density and reliable storage of information at a cost that is approaching that of paper. With a storage density of about 20 Mb/cm^2 (1 Mb = 2^{20} bits $\cong 10^6$ bits), magnetic recording media today can store the equivalent of about 1000 pages of text on 1 cm^2. This is more than 50 000 times the storage density on the RAMAC, which was introduced in 1957 by IBM as the first disk drive for storage of digital information. The original 130-mm magnetic disk drive, introduced in 1980, stored just 5 MB [1 B (byte) = 8 bits]. Today, instead of storing megabytes, 130-mm drives store gigabytes, and drives as small as 45 mm store 80 MB.

This astounding rate of progress over a relatively long lifetime of magnetic record-

ing shows no sign of slowing. Fundamental limits to magnetic recording density are still several orders of magnitude away, and recent product announcements and laboratory demonstrations indicate that the industry is increasing the rate of progress rather than approaching practical limits. In the past few years, both IBM (Tsang *et al.*, 1990) and Hitachi (Futamoto *et al.*, 1991) have demonstrated the feasibility of storing information at densities beyond 100 Mb/cm^2 on a disk. Similar advances can also be expected in audio and video recording.

1.1 Fundamentals of Magnetic Recording

Although magnetic recording is practised in a wide variety of formats and serves a wide variety of applications, the fundamental principles by which it operates are similar in all cases. The fundamental magnetic recording configuration is illustrated in Fig. 1. The recording head consists of a toroidally shaped core of soft magnetic material with a few turns of conductor around it. The magnetic medium below the head could be either tape or disk, and the substrate could be either flexible (for tape and floppy disks) or rigid (for rigid disks). To record on the medium, current is applied to the coil around the core of the head, causing the high-permeability magnetic core to magnetize. Because of the gap in the recording head, magnetic flux emanates from the head and penetrates the medium. If the field produced by the head is sufficient to overcome the coercive force of the medium, the medium will be magnetized by the head field. Thus a representation of the current wave form applied to the head is stored in the magnetization pattern in the medium.

Readout of previously recorded information is typically accomplished by using the head to sense the magnetic stray fields produced by the recorded patterns in the medium. The recorded patterns in the medium cause magnetic stray fields to emanate from the medium and to flow through the core of the head. Thus, if the medium is moved with respect to the head, the flux passing through the coil around the head will change in a manner that is representative of the recorded magnetization pattern in the medium. By Faraday's law of induction, a voltage representative of the recorded information is thus induced in the coil.

1.2 The Magnetic Recording Process

During recording the head is used to produce large magnetic fields that magnetize the medium. It was shown by Karlqvist (1954) that, in the case where the track width and length of the poles along the gap are both large compared to the gap length, the fields produced by a recording head could be de-

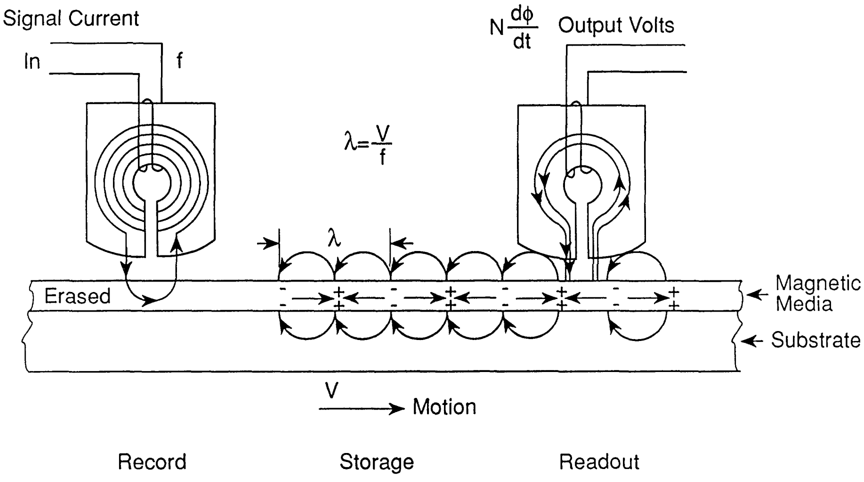

FIG. 1. A diagram illustrating the fundamental magnetic recording configuration.

scribed by

$$H_x = \frac{NI}{\pi g}\left[\tan^{-1}\left(\frac{x + g/2}{y}\right) - \tan^{-1}\left(\frac{x - g/2}{y}\right)\right], \tag{1a}$$

$$H_y = \frac{NI}{\pi g}\ln\left[\frac{(x + g/2)^2 + y^2}{(x - g/2)^2 + y^2}\right], \tag{1b}$$

where H_x and H_y are the longitudinal and perpendicular components of field, as indicated by the coordinates in Fig. 2, N is the the number of turns on the head, I is the current driving the head, and g is the gap width of the head. In this approximation, the contours of equal longitudinal field are described by arcs of circles passing through the gap corners as shown in Fig. 2.

In digital or saturation recording, the recording head is driven with sufficiently large currents that a portion of the recording medium is driven into saturation. However, because of the gradient in the head fields, other portions of the medium see fields less than those required for saturation. This is illustrated in Fig. 2 where the contours for three different longitudinal fields were drawn. In this figure H_{cr} is the remanence coercivity or the field required to produce zero remanent magnetization in the medium after it was saturated, and H_1 and H_2 are fields that would produce negative and positive remanent magnetization, respectively. Note that the head field gradient is the sharpest near the pole tips of the head. This means that smaller head-to-medium spacing and thinner media both lead to narrower transitions being recorded.

Modeling the recording process involves convolving the head field contours with the very nonlinear and hysteretic magnetic properties of the recording medium. A typical *M-H* hysteresis loop for longitudinal magnetic recording media is shown in Fig. 3. Whether the medium has positive or negative magnetization depends upon not only the magnetic field applied, but the past history of the magnetization. If the medium was previously saturated at $-M_s$, then when the magnetic field H is reduced to zero, the remanent magnetization will be $-M_r$; however, if it were previously saturated at $+M_s$, then the remanent magnetization would be $+M_r$. Similarly, if the medium were initially saturated to $-M_s$, then magnetized by a field $+H_1$, and finally allowed to go to a remanent state, the magnetization would go to value M_1. This hysteretic behavior is the basis for the use of the medium for long-term storage of information, but makes the recording process highly nonlinear.

An additional complicating factor in determining the actual recorded pattern is the demagnetizing field of the medium itself. As

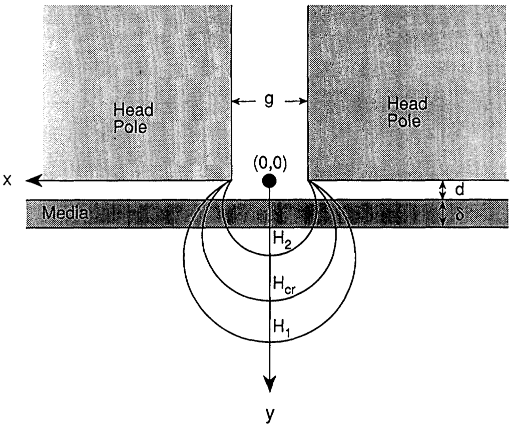

FIG. 2. A diagram illustrating the constant longitudinal field contours in the gap region of a recording head.

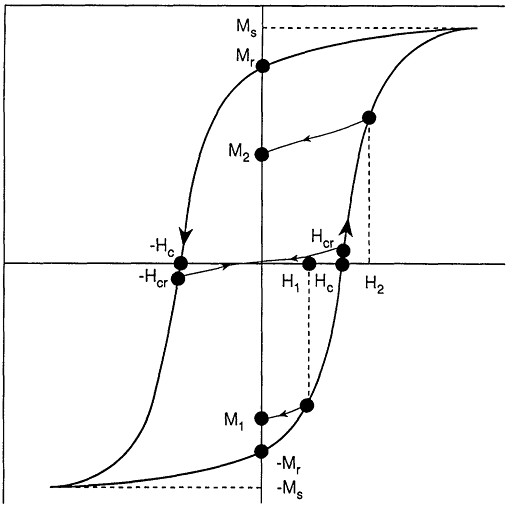

FIG. 3. A remanent *M-H* hysteresis loop for longitudinal recording media.

indicated by the + and − signs in Fig. 1, transitions in the recorded magnetization direction produce effective magnetostatic charge given by

$$\rho_M = -\mu_0 \nabla \cdot \mathbf{M}, \tag{2}$$

which in turn results in demagnetizing fields. The demagnetizing fields outside the medium are what is sensed by the head during readback, but demagnetizing fields also exist inside the medium and act to alter the total field seen by the medium during the record process from that of the head field alone.

Taking into account the head field gradients, the nonlinear *M-H* loop characteristics of the medium, and the demagnetizing fields, Williams and Comstock (1971) developed a model for the recording process. This model predicts the width of a recorded transition, in a material with a square hysteresis loop, to be

$$a = \sqrt{M_r \delta d / \pi H_c}, \tag{3}$$

where δ is the medium thickness, d is the head-to-medium spacing, M_r is the remanent magnetization of the medium, and H_c is the coercivity of the medium. That the transition widens with the product $M_r\delta$ is because the demagnetizing fields increase linearly with this quantity. Similarly, the transition narrows as H_c is increased, because with high coercivity, the medium can resist the transition broadening due to the demagnetizing fields. The increase in transition width with d is because a poorer head-field gradient is obtained with larger head-to-medium spacing.

The nonlinearities of the recording process can be largely removed by a technique referred to as ac bias recording. This is frequently used in analog recording in audio and video recorders. In this technique a high-frequency ac bias is added to the signal to be recorded. This ac bias signal is ramped from a value much larger than the coercivity of the medium to zero. This removes the hysteretic behavior of the medium and causes it to assume a magnetization state that represents the minimum energy state determined by the amount of field produced by the signal to be recorded.

1.3 The Magnetic-Recording Readback Process

As opposed to the recording process, the readback process can usually be modeled as a linear process. This is because the changes in magnetization that occur in either the head or the medium during readback are typically small.

The most common way to model the readback process is to use the principle of reciprocity, which states that the flux produced by the head through a cross section of an element of medium, normalized by the number of ampere turns of current driving the head, is equal to the flux produced in the head by the element of medium, normalized by the equivalent current required to produce the magnetization of that element. For a magnetic recording head, which produces the longitudinal field $H_x(x,y)$ when driven by NI ampere turns of current, this principle leads to the following expression for the voltage induced in the head by a recording medium with magnetization $M(x,y)$ and moving with velocity v relative to the head:

$$e = \frac{\mu_0 W v}{I} \int_d^{d+\delta} \int_{-\infty}^{\infty} \frac{\partial M_x(x-\bar{x},y)}{\partial \bar{x}} \times H_x(x,y)\,dx\,dy, \tag{4}$$

where W is the track width of the head.

This expression shows that the readback voltage induced in the recording head is linearly dependent upon the magnitude of the magnetization in the recording medium being sensed and the relative head-to-medium velocity. The linearity of the readback process ensures that analog recordings such as those recorded on audio or video tapes are faithfully reproduced.

1.4 Magnetic Recording Media

There are a wide variety of magnetic recording media available today. Different applications require different media; however, in many cases the same application will be able to utilize a variety of different competitive media.

Just a decade ago, essentially all recording media consisted of fine acicular magnetic particles embedded in a polymer and coated either onto flexible substrates such as Mylar for floppy disks and tapes or onto rigid Al-

alloy substrates for rigid disks. Today, although such particulate media are still widely used for tape and floppy disks, thin-film media have almost entirely taken over the rigid disk business and metal evaporated thin-film media have been introduced into the tape marketplace. Furthermore, many new particle types have been introduced.

1.4.1 Particulate Recording Media The most common particulate recording media today are γ-Fe_2O_3, Co surface-modified γ-Fe_2O_3 (γ-Fe_2O_3 that has a surface coating of Co), CrO_2, and metal particle media. All of these particles are acicular in shape with aspect ratios of the order of 5 or 10 to 1. The particles are sufficiently small that it is energetically most favorable for them to remain in a single-domain saturated state. Because of demagnetizing effects caused by the acicular shape, the magnetization prefers to align along the long axis of the particle.

As was noted in the discussion of Eq. (3), to achieve higher recording densities requires media with higher coercivity. The coercivity of a particle is determined by the field required to cause the magnetization to switch by 180°. If the magnetization remained in a single-domain state during the switching process, then the coercivity should be given by

$$H_c = (N_a - N_b)M_s, \tag{5}$$

where N_a and N_b are the demagnetizing factors in the directions transverse and parallel to the particle axis, respectively. In practice the coercivity is measured to be less than this. This has been explained as being due to the fact that the magnetization does not remain uniform during the switching process, but switches inhomogeneously (White, 1984). In addition to the effects that the shape anisotropy of the particles have on the coercivity, crystalline anisotropy can also be used to control coercivity.

The coercivity of a medium that is made from particles is determined by the distribution of coercivities of the particles, their orientation in the medium relative to the fields from the head, and their interactions among each other. The coercivities of a variety of particulate recording media are summarized in Table 1.

Although coercivity is indeed an important parameter for magnetic-recording media, it is by no means the only one. Particle size affects medium noise because, at any time, the head is sensing a fixed volume of the medium. Since the particles are quantized and there are statistical variations in their switching behavior, the power signal-to-noise ratio of the medium varies linearly with the number of particles contained in that volume. To reduce particulate-medium noise, it is therefore generally desirable to use small particles.

There is a limit, however, to how small particles may be made and still remain stable. When the thermal energy kT is comparable in magnitude to the energy required to switch a particle, $\mu_0 M H_c$, the particle becomes unstable and may switch as a result of thermal excitation. This phenomenon is known as superparamagnetism and can lead to decay of recorded magnetization patterns over time.

The remanent magnetization of the medium is important because it directly affects the signal level during readback, as shown by Eq. (4). The remanent magnetizations of several particulate media are listed in Table 1. Obtaining high remanent magnetization in a particulate medium requires the use of particles with high saturation magnetization and a high volume packing fraction of particles in the polymer binder. Obtaining a high volume packing fraction of particles in the binder, however, can lead to nonuniform distributions of particles and agglomerates of many particles, which switch together, also causing noise during readback.

Generally, then, to obtain a good high-density particulate recording medium it is desired to have adequate coercivity (to achieve the required recording density), to have small particles (for low noise) with a very narrow switching field distribution (to obtain a narrow transition), to have them oriented along the direction of recording (to obtain a large remanence), and to have them uniformly dispersed (to obtain low modulation noise) with high packing density (to obtain large signals).

1.4.2 Thin-Film Recording Media Thin-film recording media generally have excellent magnetic properties for high-density recording. Since they are nearly 100% dense (voids at the grain boundaries reduce the

density somewhat), they can be made to have the highest possible magnetization. Because of their high magnetization they can be made extremely thin and still provide adequate signal during readback. This helps narrow the recorded transition since the head-field gradient is sharper for thinner media, as was discussed in reference to Fig. 2.

Thin-film media can also be made extremely smooth. To achieve the smallest possible head-to-medium spacing and therefore the sharpest head-field gradient and the least spacing loss, smooth media are required.

Thin-film media were first made by plating, but today sputtering is generally preferred. Sputtering enables one to incorporate more elements into the films and to achieve higher coercivity. The coercivity of sputtered thin-film media can be made very high. In volume production today are media with coercivities of 100 kA/m; however, media with coercivities up to 250 kA/m have been made and appear promising (Velu and Lambeth, 1992). Such high coercivities are adequate to achieve more than an order-of-magnitude higher recording density than today.

Numerical models indicate that noise in thin-film media increases when the grains in polycrystalline films are strongly coupled by exchange effects (Zhu and Bertram, 1988). Exchange-coupled films tend to exhibit zigzag transitions, such as the ones indicated in Fig. 4. With exchange coupling the zigzags are much larger and produce more jitter in the transition position relative to the location where the record current in the head goes through zero. Experimental studies have indicated that the introduction of nonmagnetic elements that segregate to the grain boundaries and careful control of the sputtering conditions to achieve a porous microstructure at the grain boundaries, to reduce the exchange coupling, reduce such transition jitter (Chen and Yamashita, 1988).

1.5 Magnetic Recording Heads

1.5.1 Ferrite Heads Early recording heads consisted of toroids of magnetically soft ferrites, such as NiZn-ferrite and MnZn-ferrite, with a few turns of wire around them. For high-density recording applications, however, ferrite can no longer be used, because the saturation magnetization of ferrite is limited to about 400 kA/m. Saturation of the pole tips of a ferrite head begins to occur when the deep gap field in the head approaches one-half the saturation magnetization of the ferrite. Since the fields seen by the medium are one-half to one-quarter of the deep gap field, media with coercivities above

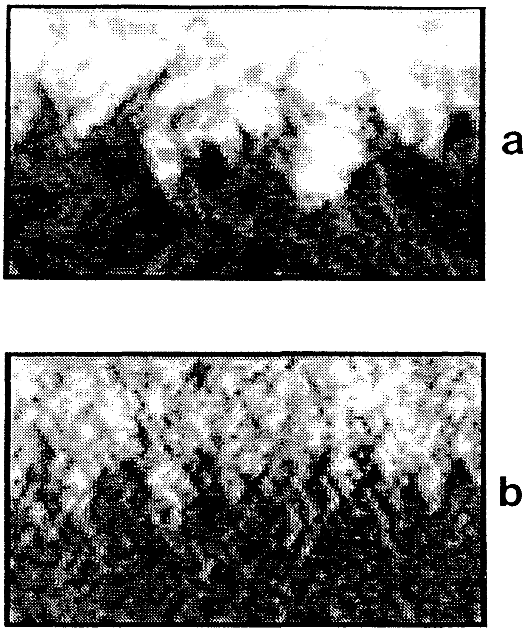

FIG. 4. Magnetization patterns of simulated recorded transitions (a) in a film having exchange coupling between grains, and (b) in a film having no exchange coupling between grains (Zhu, 1992).

about 80 kA/m cannot be reliably written with a ferrite head. High-density thin-film disk media, metal particle media, and metal evaporated media therefore cannot be written with a ferrite head.

1.5.2 Metal-in-Gap Heads Magnetically soft alloys of metals such as Permalloy (NiFe) and Sendust (FeAlSi) have saturation magnetizations of the order of 800 kA/m, about twice that of ferrites, but, because they are metallic, may suffer from eddy-current losses when operated at high frequencies. To overcome the limitations imposed by eddy currents, they are used in layers thinner than a skin depth at their operating frequency. To prevent saturation of the ferrite heads, the high-magnetization metals are applied to the pole faces of the ferrite, making a so-called metal-in-gap (MiG) recording head, as shown in Fig. 5. Since the corners of the pole faces are the first parts of a ferrite head to saturate, the high-magnetization metals enable these MiG heads to be operated to nearly twice the field to which a ferrite head can be operated. Because the layer of metal is thin, it can furthermore be less than a skin depth, and eddy-current losses do not limit performance at high frequencies.

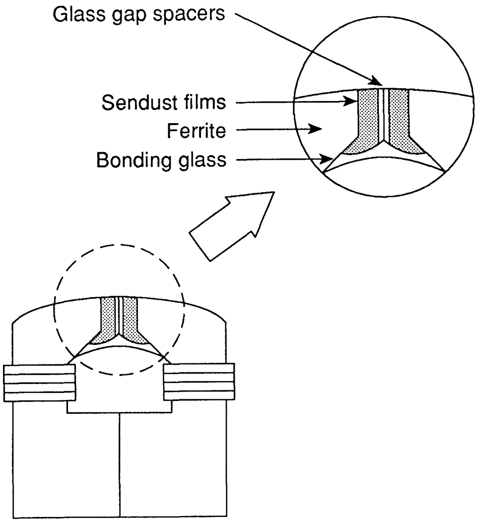

FIG. 5. A diagram of a metal-in-gap (MiG) recording head (Hoagland and Monson, 1991).

1.5.3 Thin-Film Heads Yet another solution to the saturation problem of ferrite heads is to use thin-film heads. Thin-film heads are made of Permalloy and are therefore metallic, but the films are made thinner than the skin depth, and, consequently, the heads operate well at high frequencies. A diagram of a thin-film head is shown in Fig. 6. It consists of a bottom yoke of Permalloy, some insulating layers, a spiral conductor, and a top of Permalloy that is joined to the bottom yoke at the back gap, but separated from it by a thin insulator at the recording gap. These thin-film heads are made using photolithography and microfabrication techniques similar to those used in the manufacture of semiconductor devices. The thin pole tips of these heads actually sharpen the headfield function and, consequently, the pulse shape produced by an isolated transition, although at the expense of some undershoot, as illustrated in Fig. 7. Because thin-film heads are made by photolithographic techniques, they can be made extremely small and with low inductance. This, too, helps extend the frequency of operation.

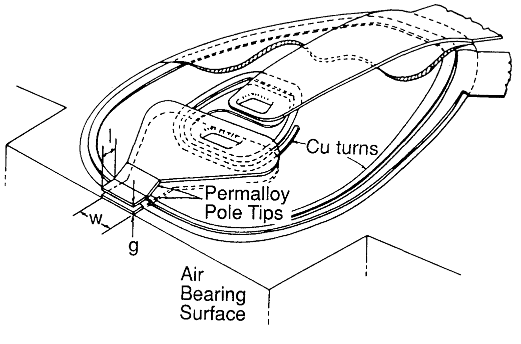

FIG. 6. A diagram of a thin-film head (White, 1984).

1.5.4 Magnetoresistive Heads A relatively new head that is now being used for readback of information in high-density recording is the magnetoresistive head. Magnetoresistive (MR) heads are based on the phenomenon of magnetoresistance in which the electrical resistance of a magnetic material is dependent upon the direction of magnetization in the material relative to the direction of current flow. An unshielded magnetoresistive head is depicted in Fig. 8. Current flows in one end of the head and out the other. The resistivity of Permalloy, from which the head is made, varies as

$$\rho = \rho_0 + \Delta\rho \cos^2\theta, \qquad (6)$$

where θ is the angle that the magnetization in the Permalloy makes relative to the direction of current flow, ρ_0 is the isotropic resistivity, and $\Delta\rho$ is the magnetoresistivity. When the recording medium with a changing magnetization pattern moves under the MR head, the stray fields from the medium cause a change in the direction of magnetization and, consequently, a change in resistance in the head. With a constant-current source driving the head, the head will therefore exhibit a change in voltage across its terminals.

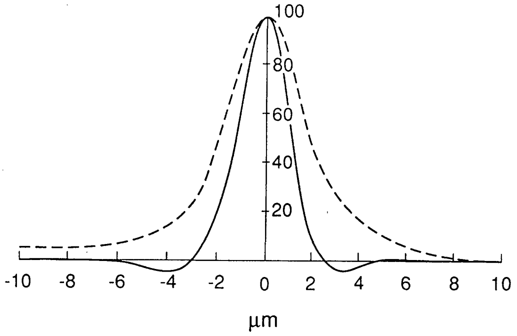

FIG. 7. Pulse shapes for (dashed curve) long- and (solid curve) short-pole heads normalized for equal amplitude (Valstyn and Shew, 1973).

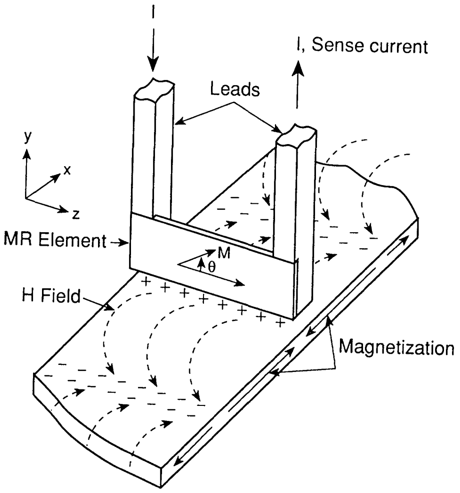

FIG. 8. An unshielded magnetoresistive element (Hoagland and Monson, 1991).

Magnetoresistive heads are typically more sensitive than inductive heads and therefore produce larger signal amplitudes during readback. The increased sensitivity and the fact that the read head is independent of the write head can be used to make a write/read head combination in which the write head writes a wider track than the read head senses. Thus adjacent track interference is reduced during the readback process.

Another advantage of the MR head is that it senses magnetic flux ϕ, not the time rate of change of flux $d\phi/dt$ as an inductive head does. Consequently, whereas the inductive head output voltage is dependent upon the head-to-medium velocity as was shown by Eq. (4), the output voltage of a MR head is independent of velocity.

2. MAGNETO-OPTIC RECORDING

The initial magneto-optic recording products introduced in late 1989 to the market place stored about 600 MB of information on a double-sided 130-mm removable disk. Typically these drives are too large to fit in the standard drive bays on a personal computer and therefore are stand-alone units. Data rates obtainable from these devices are about 1 MB/s, and access times range from about 50 to 100 ms. Both of these performance factors are slow compared to rigid magnetic disk drives, where data rates of 2–3 MB/s and access times of 10–15 ms are commonly obtained.

More recently a second generation of magneto-optic drives has been introduced. These drives use single-sided 90-mm removable disks to store 127 MB of data. Data rates and access times are still about 1 MB/s and 50–100 ms, respectively, but the drives have been made small enough to fit into a standard 90-mm drive bay on a personal computer.

Neither the 130-mm nor the 90-mm magneto-optic drive products enjoy a market that is significant compared to that of magnetic hard drives, but the markets for these products are growing rapidly. Sales were estimated at US$261 million in 1991 and are projected to grow at a 26% rate in the next six years (Abraham and Freeman, 1992).

In the future it can be expected that magneto-optic recording will advance significantly. Standards for the next generation of magneto-optic drives call for doubling the disk rotation speed from 1800 to 3600 rpm. This will double the data rate and shorten latency times, even without increasing the linear bit density. Density increases will be achieved through the use of higher numerical aperture objectives to produce a smaller spot size, run-length limited codes, and more advanced signal processing. Seek times will likely also be reduced, leading to access times in the 20- to 30-ms range. Direct overwrite, which will shorten the time to update a record, will also likely be introduced. For the more distant future, researchers are working on laser diode sources and media that will operate with blue (400-nm wavelength) rather than infrared (800-nm) light, thus permitting a quadrupling of areal density. Thus it appears that substantial advances in magneto-optic recording technology can be expected.

2.1 Fundamentals of Magneto-optic Recording

In magneto-optic recording technology, a focused laser beam is used to write and read reverse magnetic domains in a magnetic thin film having a strongly temperature-dependent coercivity and magnetization perpendicular to the film plane. The writing and reading processes are schematically illustrated in Figs. 9(a) and 9(b), respectively. To write a reverse domain into a magnetic film with all its magnetization pointing in the upward direction, a magnetic field **H** is applied antiparallel to the magnetization. This field is significantly less in magnitude than the room-temperature coercive force of the thin film, however, and so it alone has no effect on the magnetization. If the beam of a diode laser is then focused to a micrometer-sized spot and pulsed onto the film surface, the film temperature in the illuminated region will increase, typically by amounts of the order of 300 °C. Since the coercivity decreases as the Curie temperature (which is typically selected to be about 200 °C) is approached, the magnetization reverses within the heated area. When the thin film cools after the laser pulse,

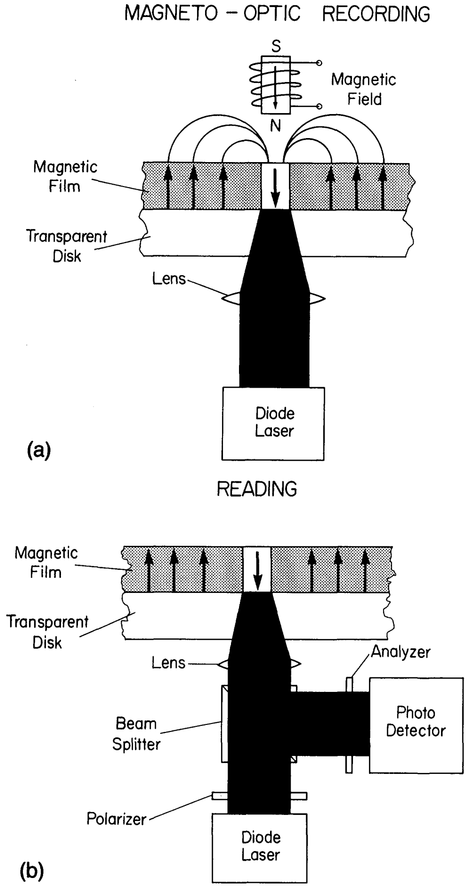

FIG. 9. (a) Magneto-optic recording process. (b) Magneto-optic reading process.

the reverse domain of magnetization is frozen in. Such a reverse domain at a particular location on a circumferential track on a disk could represent a 1 in a binary memory, while the absence of a reverse domain could represent a 0.

To read the stored information the polar Kerr magneto-optic effect is used, as illustrated in Fig. 9(b). A reduced light level from the diode laser is used so that the laser beam does not disturb the recorded information during readout. The diode laser light is plane polarized and focused onto the magneto-optic disk. Upon reflection from the magnetic layer, the plane of polarization of the light is rotated through a small angle θ_K by the polar Kerr magneto-optic effect. The direction of rotation depends upon whether the magnetization is directed upward or downward. The reflected light is analyzed with a second plane polarizer (the analyzer), and the changes in reflected polarization are converted into changes in light intensity that are then detected with the photodetector. Thus the recorded binary pattern of magnetic domains may be read out using the polar Kerr magneto-optic effect.

To overwrite information in the magneto-optical drives available today it is first necessary to erase the old information. This is done by reversing the magnetic field used to write the domains in Fig. 9(a) and turning on the focused laser beam continuously as the sector to be erased passes by. Then, on the second rotation of the disk, the field is again reversed so that it is once again in the direction shown in Fig. 9(a), and the diode laser is pulsed to write the new information. This double-pass overwrite procedure increases the time required to update a record and is a significant disadvantage for magneto-optic recording as compared to magnetic recording where the new data are written directly over the old. The reason this double-pass overwrite is necessary is that to overwrite random data directly, it would be necessary to modulate the magnetic field used to determine the direction of magnetization during the writing process at the full data rate. This requires a small recording head close to the magnetic thin film and eliminates a key advantage of magneto-optic recording—having a large head-to-medium spacing. Methods to achieve direct overwrite, which are being aggressively pursued in research laboratories throughout the world, will be discussed later.

2.2 Magneto-optic Recording Media

The manufactured magneto-optic media today consist of sputtered amorphous alloys of rare earths and transition metals. These materials exhibit a uniaxial anisotropy such that the magnetization prefers to lie perpendicular to the film plane. In these alloys the rare-earth and transition-metal subnetwork magnetizations are antiferromagnetically coupled. Thus rare-earth-transition-metal (RE-TM) films are ferrimagnetic. The temperature dependences of the rare-earth and transition-metal magnetizations are schematically illustrated in Fig. 10. At low temperatures the magnetization of the rare earths dominates and the net magnetization points in the same direction as the rare-earth magnetization. However, at high temperature the transition-metal magnetization dominates and the net magnetization points in the direction of the transition-metal magnetization. At an intermediate temperature, called the compensation temperature T_{comp}, the two subnetwork magnetizations are equal and opposite in direction, causing the net magnetization to go to zero. At sufficiently high temperatures, thermal energy over-

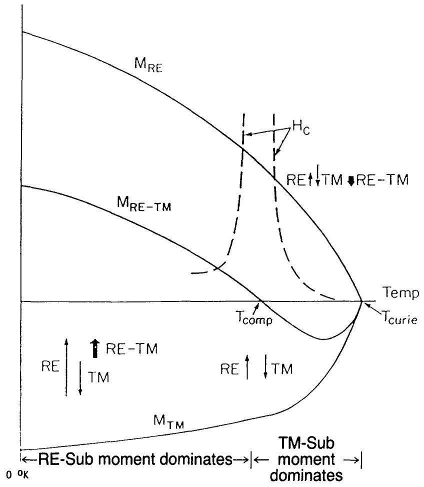

FIG. 10. The temperature dependences of the rare-earth magnetization (M_{RE}), transition-metal magnetization (M_{TM}), net magnetization ($M_{RE\text{-}TM}$), and coercivity (H_c), of an amorphous rare-earth-transition-metal alloy.

comes the exchange coupling and the ferrimagnetic behavior vanishes at the Curie temperature.

The compensation behavior of these materials gives rise to the strong temperature dependence of coercivity H_c that is required for magneto-optic recording. As the compensation temperature is approached, the net magnetization **M** tends toward zero. Since the energy coupled into the magnetization by an externally applied field **H** is $-\mu_0\mathbf{M}\cdot\mathbf{H}$, as the compensation temperature is approached, increasingly large amounts of field must be applied to overcome energy barriers to reversal of the magnetization such as anisotropy. Hence as the compensation temperature is approached the coercive force tends toward infinity. Conversely, as the Curie temperature is approached, thermal energy tends to help in destabilizing the magnetization and only a small field is required to cause switching. Hence the coercive force H_c tends toward infinity at the compensation temperature and toward zero at the Curie temperature, as suggested in Fig. 10.

The most widely used RE-TM materials are alloys of Gd, Tb, Fe, and Co. As explained in detail elsewhere (Kryder, 1989), these alloy systems allow one to adjust independently the compensation temperature, the Curie temperature, the magnetization-coercive force product MH_c, and the uniaxial anisotropy perpendicular to the film plane.

For future high-density recording it is anticipated that 400-nm-wavelength laser light sources will be used. By shortening the wavelength of the light by a factor of 2, both the linear bit density and the track density may be improved by a factor of 2, leading to an increase in areal density by a factor of 4. However, the Kerr magneto-optic rotation θ_K produced by RE-TM films typically decreases as the wavelength of the light is shortened. This, combined with the fact that the read laser intensity must be reduced when a smaller spot is read and that there are fewer photons and therefore higher shot noise when shorter-wavelength light is used, means that the signal-to-noise ratio degrades in RE-TM films when shorter-wavelength light is used.

To overcome the problems with RE-TM films when 400-nm light is used, other materials are being investigated. Garnets (Gomi and Abe, 1989; Shono *et al.*, 1989) and transition-metal multilayers such as Pt/Co and Pd/Co (Zeper *et al.*, 1989; Lin and Do, 1990) appear promising. Both provide enhanced magneto-optic effects at short wavelengths of light.

2.3 Magneto-optic Recording Heads

A magneto-optic recording head today contains a large number of discrete optical components. A schematic diagram of a typical head is shown in Fig. 11. A laser diode, typically with a wavelength of about 800 nm, is used as the light source. Since a laser diode emits an elliptically shaped beam, some means are typically used to circularize the beam after collimation by a collector lens. In Fig. 11 this is illustrated as being done by an anamorphic prism. After passing through the anamorphic prism and a beam splitter, the laser beam is focused by an objective lens through the transparent substrate of the magneto-optic disk onto the magnetic thin film, in which the information is stored in the form of reverse domains. After reflecting off the disk, the light returns to the beam splitter and is deflected toward a polarizing beam splitter. This polarizing beam splitter is set at 45° to the incident plane of polarization of the light from the laser. Thus, if there were no rotation of the plane of polarization of the light by the disk, 50% of the light would go to each quadrant photodiode assembly. On summing the signals to the four photodiodes from each quadrant photodiode and differentially detecting the sums from each quadrant photodiode assembly, the output would then be zero. With a magneto-optic signal, however, the signal at one quadrant photodiode would go up by a certain amount Δ, while the signal at the other goes down by the same amount; thus the differential signal would be 2Δ. This differential detection system also cancels out, to first order, all intensity variations that arise from the laser or changes in reflectivity of the disk. This common-mode noise rejection is very important to obtaining a good signal-to-noise ratio from the very small magneto-optic effect.

For focus control, the objective lens is mounted in a voice-coil assembly that moves it vertically relative to the disk (not shown in Fig. 11). The system is designed so that when the laser beam is properly focused on the disk, the laser beam also comes to a focus on the aperture plane of the cylindrical len-

ses before the quadrant photodiode detectors. In that case the cylindrical lenses have no effect on the beam and the quadrant photodiode detectors are illuminated with a circular beam. The focus error signal is derived by summing the signals from photodiodes A_1 and A_3 and subtracting that sum from the sum of the signals from photodiodes A_2 and A_4. With a circular beam, as is the case when the disk is properly focused, $A_1 + A_3 = A_2 + A_4$ and there is no focus error signal. However, when the disk is too close to or too far from the objective lens, the light will no longer focus on the aperture of the cylindrical lens, and the quadrant photodiode detector will be illuminated with an elliptical beam with its major axis along $A_1 + A_3$ or $A_2 + A_4$, depending upon whether the objective is too close to or too far from the disk, as indicated in the diagram of quadrant photodiode A in Fig. 11. Thus the difference signal $(A_1 + A_3) - (A_2 + A_4)$ will provide a focus error signal, which can be used for feedback to the voice-coil assembly that moves the objective lens back into focus.

For track following the so-called push-pull tracking sensor is frequently used. With this sensor the zero-order and first-order diffracted beams from a grooved disk return through the objective lens and interfere with one another, causing illumination on the quadrant photodiodes as illustrated in the diagram of quadrant photodiode B in Fig. 11. When the beam is centered directly on a groove or midway between two grooves, the two first-order beams are identical, and they interfere equally with the zero-order beam; however, when the beam is off center, they interfere differently. By aligning the quadrant photodiode detector so that one first-order beam falls on the left half of the detector $(B_1 + B_4)$ and the other falls on the right half of the detector $(B_2 + B_3)$, one can then derive a tracking error signal from the difference $(B_1 + B_4) - (B_2 + B_3)$. This tracking error signal can then be used to control a voice-coil assembly to translate the objective in the radial direction on the disk, thus providing a servo system for track following.

The use of discrete optical components makes a magneto-optical recording head massive and bulky in comparison to a magnetic-recording head. This has two very significant drawbacks:

1. the large mass limits the acceleration that the head can undergo and thus slows the seek time,
2. the size of the head makes it impossible to place several disks closely together on

a spindle, as is commonly done in magnetic hard drives.

Thus the large size of magneto-optic heads are a major reason why magneto-optic drives have longer seek times and have lower capacity than magnetic hard drives.

Recently manufacturers have been introducing magneto-optic drives with split heads to reduce the seek time. In these heads the laser and detector optics are in a stationary location beside the disk, and a collimated beam is sent to and from a much smaller moving module containing a 90° mirror, focusing lens, and voice-coil fine servo. By minimizing the mass of the moving element in this way, seek times can be significantly reduced.

To reduce the size and mass of optical heads, a number of alternative technologies are under consideration. These include the use of optical fibers (Opsasnick *et al.*, 1991), thin-film holographic optical elements (Sincerbox, 1989; Ono *et al.*, 1989), nonmechanical scanners (Arimoto *et al.*, 1990), and integrated head structures (Ura *et al.*, 1986; Valetta, 1989; Ura *et al.*, 1988; Arimoto *et al.*, 1990).

2.4 Direct Overwrite

As noted above, present magneto-optic recording drives require two passes of the disk to overwrite old information. This places them at a significant disadvantage compared to rigid disk drives that can simply write the new record over the old. There are currently at least three approaches to solving this problem and providing direct overwrite in a magneto-optical drive. The most straightforward approach is to use a magnetic recording head flying close to the disk to provide the rapidly modulated magnetic field required to overwrite data at the full data rate (Nakao *et al.*, 1987).

This technique reportedly works well at the data rates of present drives. Reportedly, the jitter in the position of the domain walls is actually smaller with this technique than when the laser is pulsed. This has led to the suggestion that such field-modulation overwrite could utilize run-length limited codes that pack more than 1 bit per transition.

The disadvantages of this technique include the fact that only single-sided disks may be used, since the magnetic head must be close to the magnetic layer. In addition, the double-sided head is more complex and adds to the cost of the drive, and the inductance of the head may place limitations on the frequency at which this technique may be applied.

The first direct overwrite scheme to be proposed (Shieh and Kryder, 1986) uses a laser beam modulated between two different energy levels to record or erase domains selectively in a single magnetic layer. This technique utilizes specially designed materials in which a high-energy laser pulse writes a domain, whereas a low-energy pulse destabilizes the domain and causes it to collapse. Critical to the operation of this technique is a high domain-wall mobility and a significant difference in the thermal gradients achieved during writing and erasing.

This single-layer laser modulation technique is the most attractive to implement from a systems point of view, because it utilizes a single magnetic layer, not substantially more difficult to manufacture than present media, and because it also could use present magneto-optic heads (Kryder and Schultz, 1989). Double-sided media would be allowed, and data collected thus far indicate that the technique does not restrict the data rate. In fact, the technique presently works better at higher data rates than at low data rates.

The problem with this technique is that an adequate signal-to-noise ratio has not yet been achieved. The accepted standard calls for a 45-dB carrier-to-noise ratio (CNR) in a 30-kHz slot bandwidth. Recently this standard has been met, but only barely (Schultz *et al.*, 1993). Further improvements are expected.

The third overwrite technique also uses laser modulation, but it utilizes multilayer exchange-coupled media (Saito *et al.*, 1987; Kaneko *et al.*, 1989; Fukami *et al.*, 1990). With three- and four-layer media, CNR in excess of 50 dB has been achieved. Because of the multiple layers and the criticality of their parameters, this technique is expected to add significantly to the cost and to degrade from the yield of manufactured media. On the other hand, if adequate yield can be achieved, the technique does not require any other changes to the drive.

In summary, at least three direct overwrite schemes are being actively pursued. Each of them has its own advantages and shortcomings. It is too early to select a definite winner, but it appears likely that magneto-optic drives will offer direct overwrite in the near future.

3. CONCLUSIONS

Magnetic recording today finds a wide spectrum of applications and formats ranging from relatively low-density, low-cost floppy-disk drives and audio recorders to high-density video cassette recorders, digital audio tape recorders, computer tape drives, rigid disk drives, and instrumentation recorders. Magnetic recording media are used for storing audio, video, and computer data and a wide variety of data from instrumentation. They are used for both temporary and long-term archival storage. Formats range from tape, which has the highest volumetric packing density and lowest cost per bit stored, to rigid disks, which provide fast access to a large volume of data. The performance of this technology and the applications for it are expected to expand even more rapidly well into the next century.

Magnetic recording technology has increased storage density by more than a factor of 50 000 over the past 35 years since it was first used in a disk format for computer data storage; however, there is no sign that this rapid pace is slowing. Indeed, fundamental limits, set by superparamagnetism, are estimated to be yet several orders of magnitude from where we are today. Furthermore, recent product announcements and developments in research laboratories suggest that the rate of progress is likely to increase. Storage densities of over 100 $\mathrm{Mb/cm^2}$ are likely by the end of this decade, and densities of 1 $\mathrm{Gb/cm^2}$ appear likely in the early twenty-first century. Multilayer thin-film media, thin-film write heads utilizing high-magnetization thin-film multilayer materials, and magnetoresistive write heads are expected to be among the new technologies which make this occur.

Magneto-optic recording has only recently been introduced to the marketplace. Areal storage densities are high, but the volumetric storage densities are no higher than in rigid magnetic disk drives containing multiple disks. Data rates and access times are currently about a factor of 2 or 3 times slower than on rigid disk drives, and costs at the drive level are higher than for rigid disks. This leaves the removability of the magneto-optic medium as its main advantage. Presently the medium costs about \$0.50/MB. The technology, however, is young, and both cost reductions and improvements in storage density and performance are expected. Higher numerical aperture objectives, improved signal processing, improved track-following servos, and shorter-wavelength laser sources combined with improved media for short wavelength recording are expected to increase the storage density. Over an order of magnitude improvement is likely. Lighter and smaller heads will lead to improved seek times. Direct overwrite will reduce the time to update records, and both higher bit density and higher spindle rotation rates will lead to higher data rates. The higher spindle rotation speed will also shorten the latency time. A removable 50-mm magneto-optic disk that will store a few GB of data with data rates and access times only slightly poorer than those of rigid magnetic drives appears likely by the year 2000.

This material is based in part upon work supported by the National Science Foundation under Grant No. ECD-8907068. Portions of this article have been previously published in an article entitled "Magnetic Recording" in the *Electrical Engineering Handbook*, published by CRC Press, Boca Raton, FL, in 1993, and in *Annu. Rev. Mater. Sci.* (1993), **23**, 411–436.

GLOSSARY

Coercive Force or Coercivity: The magnetic field required to reduce the mean magnetization of a sample to zero after it was saturated.

Compensation Temperature: The temperature at which the subnetwork magnetizations of a ferrimagnetic material cancel each other, producing zero net magnetization.

Curie Temperature: The temperature at which thermal excitation becomes sufficiently large that a magnetic material has no spontaneous magnetization in zero applied field.

Demagnetizing Field: The magnetic field produced by divergences in the magnetization of a magnetic sample.

Direct Overwrite: The process of writing new information over old with no intervening erasure process.

Longitudinal Recording: Magnetic recording in which the magnetization lies in the plane of the medium and parallel to the track.

Magnetoresistance: The resistance change produced in a magnetic sample when its magnetization is changed.

Perpendicular Recording: Magnetic recording in which the magnetization lies perpendicular to the plane of the medium.

Remanent Coercivity: The magnetic field required to produce zero remanent magnetization in a material after the material was saturated.

Remanent Magnetization: The magnetic moment per unit value of a material in zero field.

Saturation Magnetization: The magnetic moment per unit volume of a material when the magnetization in the sample is aligned (saturated) by a large magnetic field.

Superparamagnetism: A form of magnetism in which the spins in small particles are exchange coupled, but may be collectively switched by thermal energy.

Uniaxial Anisotropy: An energetic preference for the magnetization to lie parallel (or at right angles to) a single axis in a magnetic material.

INTRODUCTION

Magnetohydrodynamics (MHD) is the study of the motion of electrically conducting fluid in the presence of a magnetic field. It is woven from two threads. The first is electrodynamic: the motion of the fluid creates, from the prevailing magnetic field $\mathbf{B}$, an electromotive force (emf) $\mathbf{V} \times \mathbf{B}$, where $\mathbf{V}$ is the fluid velocity. This emf sets up an electric field $\mathbf{E}$ and drives electric currents of density $\mathbf{J}$ which (by Ampère's law) modify the magnetic field. The second thread is fluid dynamical: the field and current create a Lorentz force $\mathbf{J} \times \mathbf{B}$, which modifies the fluid flow.

The two threads together constitute more than the mere sum of the two. New time scales and new phenomena, particularly the Alfvén wave, arise in MHD that are completely absent in electrodynamics and fluid dynamics

separately. MHD differs essentially from electrohydrodynamics (EHD) in the nature and magnitude of **E**. In EHD, large electric fields are externally applied; in MHD, the electric field is produced by the system itself from the emf created by the motion and is therefore of order $\mathcal{V}\mathcal{B}$, where $\mathcal{V}$ and $\mathcal{B}$ are typical magnitudes of **V** and **B**.

MHD phenomena arise in two main contexts: through *controlled*, man-made engineering applications and through the *uncontrollable* evolution of naturally occurring objects, such as planets, stars, and galaxies. Clearly, the latter should not occupy a large place in an encyclopedia devoted to applied physics, and only one section of this review (Sec. 10) is devoted to it. Controlled MHD may itself be divided into two main parts: the MHD of liquid metals and the MHD of ionized plasmas. Both these areas have important technological applications.

Liquid metals cool the cores of fast fission reactors; their use in the blankets of fusion reactors is also envisaged, both to remove heat and to breed tritium. The possibility of generating electricity in conventional, fossil-fuel power stations by direct MHD conversion (i.e., without the use of turbines) has also been extensively investigated. Metallurgical processing provides interesting applications of MHD, including the levitation, heating, and stirring of casts by high-frequency magnetic fields.

Fusion reactors confine the reacting plasmas by strong magnetic fields. Such "magnetic bottles" are prone to instabilities that shorten the confinement time of the plasmas so drastically that thermonuclear fusions in the reactor are too few for its commercial viability. The understanding and removal of such instabilities has for many years been a central target of MHD research. And today plans are afoot for the construction of large reactors in which the energy released by thermonuclear reactions exceeds that expended in their operation.

MHD is a comparatively young subject, a landmark paper by Alfvén in 1942 often being considered to mark its birth. Today it is such a vast and rich field that the choice of topics here has had to be constrained. The lack of a full discussion of MHD turbulence is particularly regretted. Sources that deal with this topic are cited at the end of the article. It was also impractical to reference even all the most significant papers, and the literature cited below consists principally of books and reviews.

The first two sections of this article summarize the underlying theory it uses; they may be of little interest to readers familiar with electromagnetism and fluid mechanics, who may wish to skip to Secs. 3–5 in which the MHD of liquid metals is studied. Experiments on MHD are notoriously difficult to perform, and the emphasis is therefore on theory and its interpretation. Readers anxious to know more about the current experimental situation might profit by studying a recent book by Moreau (1990). Theory relevant to magnetically confined plasmas is expounded in Secs. 6–9. Readers wishing to study this field in greater depth should benefit by reading a book by Freidberg (1987). Topics of astrophysical MHD are adumbrated in Sec. 10.

One aim of this article is to describe MHD phenomena in as simple terms as possible. For example, although an MHD theory has been developed that is relativistically covariant, we shall be concerned here with conducting fluids moving with velocities $\mathcal{V}$ much less than the speed (c_0) of light. Since it would be inconsistent to supplement nonrelativistic equations of fluid motion with relativistic equations of electromagnetism, we shall use only the reduced "pre-Maxwell equations," in which the displacement current is absent (see Sec. 1). This action requires little defense, since most (though not all) MHD research assumes that relativistic effects are negligible.

Somewhat more questionable was the decision to limit the discussion here to the MHD of dense conductors that are well described by Ohm's law and move according to the laws governing a Newtonian fluid. In defense of this simplification, one may argue that, even though to obtain a quantitatively good description it may be necessary, especially in the case of rarefied plasmas, to replace our dense fluid by a more realistic though a necessarily more complicated model, the dense fluid is sufficient to demonstrate many of the interesting phenomena of MHD in a qualitatively accurate way. Even the full theory of a Newtonian fluid is unnecessarily intricate for our purposes, and we therefore concentrate on two special cases that suffice for almost all our needs: the *incompressible* viscous fluid and the *inviscid* compressible fluid (see Sec. 2). Deviations from these models are described in qualitative terms only.

Table 1 lists some of the MHD parameters, together with their values in different MHD situations. A table of notation appears at the end of the article. SI units are used throughout the article, and (as above) typical sizes of physical variables are denoted by calligraphic letters; e.g., a length characteristic of a body is written as $\mathcal{L}$; a typical flow speed is, as above, $\mathcal{V}$. A familiarity with vector calculus is assumed, including use of the summation convention for repeated suffices.

1. ELECTRODYNAMICS

This section summarizes the electromagnetic ("em") basis of MHD in SI units. Readers for whom this summary is unnecessary may wish to refer to the table of notation at the end of this article and then skip forward to Sec. 2.

1.1 Basic Equations

MHD is principally concerned with fluids moving with speeds $\mathcal{V}$ small compared with c_0, the velocity of light in vacuo. Naturally, the basic dynamics is then Newtonian, and the basic electrodynamics is also nonrelativistic; i.e., it is pre-Maxwellian, so that

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \mathbf{E}, \quad \mathbf{J} = \nabla \times \mathbf{H}, \tag{1, 2}$$

$$\nabla \cdot \mathbf{B} = 0, \quad \nabla \cdot \mathbf{D} = \vartheta. \tag{3, 4}$$

Equation (1) is Faraday's law of induction; Eq. (2) is Ampère's law; Eq. (3) expresses the absence of magnetic poles; and Eq. (4) shows how free charges create **D**. Equation (2) lacks the displacement current present in full Maxwell theory, which makes it relativistically covariant.

Equation (1) shows that, if Eq. (3) holds initially, it holds for all time. By Eq. (2),

$$\nabla \cdot \mathbf{J} = 0, \tag{5}$$

which shows that the term $\partial\vartheta/\partial t$ present in the full equation of charge conservation ($\partial\vartheta/\partial t + \nabla \cdot \mathbf{J} = 0$) is negligible in prerelativistic theory; its absence represents an $O(\mathcal{V}^2/c_0^2)$ error, and errors of the same order are consistently present throughout pre-Maxwell theory.

The pre-Maxwell equations are invariant under the Galilean transformation $\mathbf{x} \rightarrow \mathbf{x}' = \mathbf{x} - \mathbf{w}t$ to a reference frame moving with a constant relative speed **w**. To see this, recall that according to pre-Maxwell theory,

$$\mathbf{B}' = \mathbf{B}, \quad \mathbf{E}' = \mathbf{E} + \mathbf{w} \times \mathbf{B}, \tag{6}$$

$$\mathbf{H}' = \mathbf{H}, \quad \mathbf{D}' = \mathbf{D} + \mathbf{w} \times \mathbf{H}/c_0^2, \tag{7}$$

$$\mathbf{J}' = \mathbf{J}, \quad \vartheta' = \vartheta - \mathbf{w} \cdot \mathbf{J}/c_0^2. \tag{8}$$

Since $\partial/\partial t = \partial/\partial t' - \mathbf{w} \cdot \nabla'$, it follows that Eqs. (1)–(5) are also satisfied in the moving frame.

Conservation of charge is as fundamental as conservation of mass, and it may at first seem strange that, according to Eq. (8), ϑ' differs from ϑ unless **J** vanishes. This apparent paradox, which is also faced by the full Maxwell theory, may seem less mysterious when the operational problem of measuring charge is considered. Clearly, the measurement of ϑ by a probe inserted at **x** would be corrupted unless **J** were zero there and if, in an attempt to prevent current flowing continuously into the probe, a small domain, of volume v, containing **x** were isolated—for example, by surrounding the domain with a thin insulating sheath—a charge distribution would be set up on the sheath to reflect the incoming current and the charge contained by v would no longer be $v\vartheta$; i.e., ϑ would be corrupted. Perhaps the clearest demonstration that pre-Maxwell theory does not conflict with charge conservation is the evaluation in both reference frames of the net charge carried by an isolated body V surrounded by an insulator. It is easily shown [see Eq. (28)] that the difference between the surface charge densities Θ' and Θ on the boundary S of V as evaluated in the two reference frames exactly compensates for the difference (8) between ϑ' and ϑ so that the net charge carried by the body is the same in both frames even though ϑ and Θ differ in each.

The pre-Maxwell equations must be supplemented by constitutive relations, i.e., relations that specify the constitution of the conductor. We assume that the conductor is isotropic so that, if we transform to a reference frame moving with the velocity $\mathbf{w} = \mathbf{V}(\mathbf{x})$ of a particular point **x** in the conductor, the

---

[a] Astrophysical quantities are given representative values which in some cases (denoted by ?) are extremely uncertain. Quantities based on turbulent transport coefficients are in parentheses.

relations between fields at $\mathbf{x}$ are isotropic and are, in fact, the well-known relations of classical em theory:

$$\mathbf{H}' = \mathbf{B}'/\mu_0, \quad \mathbf{D}' = \epsilon\mathbf{E}', \quad \mathbf{J}' = \sigma\mathbf{E}'. \tag{9}$$

We assume in Eq. $(9)_1$ and throughout that the permeability of the fluid is that of free space; the greater generality of supposing otherwise carries too high a price in added complexity. Since $c_0^2 = (\mu_0\epsilon_0)^{-1}$, where ϵ_0 is the permittivity of free space, we find from Eqs. (6)–(9) that

$$\mathbf{H} = \mathbf{B}/\mu_0, \quad \mathbf{J} = \sigma(\mathbf{E} + \mathbf{V} \times \mathbf{B}), \tag{10, 11}$$
$$\mathbf{D} = \epsilon\mathbf{E} + (\epsilon - \epsilon_0)\mathbf{V} \times \mathbf{B}, \tag{12}$$

the first two of which are especially significant. Equation (11) expresses Ohm's law in a nonrelativistically moving conductor; the term $\mathbf{V} \times \mathbf{B}$ is known as the induced emf.

1.2 Stress and Energy

The nonrelativistic approximation has further significant consequences. The force per unit volume on the conductor due to the free charges it carries is $\vartheta\mathbf{E} = O(\epsilon\mathscr{E}^2/\mathscr{L}) = O(\epsilon\mathscr{V}^2\mathscr{B}^2/\mathscr{L})$ by Eqs. (4) and (12). Through current flow, it also experiences a *Lorentz force* $\mathbf{J} \times \mathbf{B} = O(\mathscr{B}^2/\mu_0\mathscr{L})$ by Eqs. (2) and (10). The ratio of the first force to the second is $O(\mathscr{V}^2/c_0^2)$ so that, with negligible error,* we have, for the total force per unit volume,

$$\mathbf{L} = \mathbf{J} \times \mathbf{B}. \tag{13}$$

This is often conveniently thought of in terms of Faraday's equivalent stresses:

$$L_i = \nabla_j m_{ij}, \tag{14}$$

where

$$m_{ij} = B_iB_j/\mu_0 - (B^2/2\mu_0)\delta_{ij} \tag{15}$$

are the components of the (magnetic) stress tensor. It follows that

$$\mathbf{L} = \mu_0^{-1}\mathbf{B} \cdot \nabla\mathbf{B} - \nabla(B^2/2\mu_0). \tag{16}$$

The term B_iB_j/μ_0 in Eq. (15) represents a tension in (magnetic) lines of force; the last term imparts an isotropic *magnetic pressure,* which is about 4 atm for a field of 1 T.

Because $\vartheta\mathbf{E}$ could be omitted from Eq. (13), the electric stress tensor has, to the same $O(\mathscr{V}^2/c_0^2)$ inaccuracy, no part to play in the total stress tensor. In a similar way and with the same $O(\mathscr{V}^2/c_0^2)$ error, the term $\vartheta\mathbf{V}$ representing convection of free charge could be omitted from Ohm's law (11) and the contribution $\frac{1}{2}\,\epsilon E^2$ made by the electric field to the total electromagnetic energy density E_M may be ignored. Thus,

$$E_M = B^2/2\mu_0 \tag{17}$$

is the magnetic field energy density. The Poynting flux $\mathbf{S} = \mathbf{E} \times \mathbf{H}$ of em energy is the same in both relativistic and nonrelativistic theories,

$$\mathbf{S} = \mathbf{E} \times \mathbf{B}/\mu_0, \tag{18}$$

and is $O(E_M\mathscr{V})$, corresponding to the advection of E_M by $\mathbf{V}$. The momentum of the electromagnetic field is negligible in pre-Maxwell theory.

The rate per unit volume at which Ohmic resistance heats the fluid is

$$\epsilon_\sigma = J^2/\sigma. \tag{19}$$

Of the three expressions for ϵ_σ used interchangeably in the familiar em theory of stationary conductors, namely, J^2/σ, σE^2, and $\mathbf{J} \cdot \mathbf{E}$, only J^2/σ is correct in MHD. Note, however, that, by Eqs. (11) and (13),

$$\mathbf{J} \cdot \mathbf{E} = \epsilon_\sigma + \mathbf{V} \cdot \mathbf{L} \tag{20}$$

gives the em-power loss per unit volume through both Ohmic dissipation and the rate of working of the Lorentz force. Although ϵ_σ is non-negative, $\mathbf{V} \cdot \mathbf{L}$ can have either sign and, if negative, represents the generation of em energy from kinetic energy.

1.3 Induction Equation; Perfect Conductors

Equation (4) serves only to determine the charge density in the conductor once $\mathbf{E}$ has been determined by solving the remaining MHD equations. It is of little interest, although it is worth noting that ϑ is nonzero in general. In the nonconducting exterior $\hat{V}$ of the conductor, $\hat{\vartheta}$ may be known (e.g., $\hat{\vartheta} = 0$ if $\hat{V}$ is a vacuum), and Eq. (4) is then needed to determine $\hat{\mathbf{E}}$; but $\mathbf{E}$ plays such a minor role in MHD compared with $\mathbf{B}$ that one usually speaks of $\mathbf{B}$ as "the field," the adjective "magnetic" being implied. The emphasis is always to determine $\mathbf{B}$ and $\mathbf{V}$, and, once these have been found, the solution is seldom completed by the evaluation of $\mathbf{E}$ and ϑ. For this reason, we shall consider ϑ no further and eliminate $\mathbf{E}$ in favor of $\mathbf{B}$ wherever possible.

---

*Strictly speaking, before claiming this, we should also require that the Debye length be small compared with all other lengths of interest.

For example, by Eqs. (2), (10), and (11),

$$\begin{aligned}\mathbf{E} &= -\mathbf{V} \times \mathbf{B} + \mathbf{J}/\sigma \\ &= -\mathbf{V} \times \mathbf{B} + \eta\nabla \times \mathbf{B},\end{aligned} \tag{21}$$

and, substituting this into Eq. (1), using Eq. (3) and the vector identity $\nabla \times \nabla \times \mathbf{B} = \nabla(\nabla \cdot \mathbf{B}) - \nabla^2\mathbf{B}$, we obtain the *induction equation*:

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{V} \times \mathbf{B}) + \eta\nabla^2\mathbf{B}, \tag{22}$$

where η is the *magnetic diffusivity*,

$$\eta = 1/\mu_0\sigma, \tag{23}$$

which is constant because σ is constant by assumption.

A useful idealization, which will arise several times in subsequent sections, is the perfectly conducting fluid ($\sigma = \infty$; i.e., $\eta = 0$). In this case, Eqs. (21) and (22) reduce to

$$\mathbf{E} = -\mathbf{V} \times \mathbf{B}, \quad \frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{V} \times \mathbf{B}). \tag{24, 25}$$

According to Eqs. (15), (17), (18), and (24), in a perfect conductor,

$$\begin{aligned}&\mathbf{S} = \mathbf{B} \times (\mathbf{V} \times \mathbf{B})/\mu_0 \quad \text{or} \\ &S_i = E_M V_i - m_{ij} V_j,\end{aligned} \tag{26}$$

which has a clear interpretation.

1.4 Continuity Properties

To make the solutions of the electrodynamic equations unique, one must apply continuity conditions at any discontinuity in electrodynamic properties. These conditions rest on the same fundamental physical laws as do the differential equations. The laws take the form of integral statements. Equation (3) is the consequence of statement that the net flux of $\mathbf{B}$ from any closed volume is zero, and, applying this to a small "pill-box" spanning the discontinuity surface S, one finds that $\mathbf{n} \cdot \mathbf{B}$ must be continuous across S, where $\mathbf{n}$ is the unit normal to S directed from side 1 into side 2. Similarly, Eq. (4) is the consequence of the statement that the flux of $\mathbf{D}$ from a closed volume is equal to the net charge that that volume contains, and condition (28) also follows. Equation (5) follows from the demand that the net current leaving a closed volume is zero, and this also leads to conditions $(27)_2$ and (31). Equation (2) results from the requirement that the integral of $\mathbf{H}$ around any closed curve is equal to the current flowing through it. Applying this to a small rectangular loop with its long sides on either side of S, one obtains condition (30). Similarly, Eqs. (1), $(27)_3$, and (32) follow from the demand that the rate of change of magnetic flux through a closed curve is equal to the integral of $-\mathbf{E}$ around its perimeter (taken in the sense of Stokes's theorem).

If the fluid is not a perfect conductor ($\sigma \neq \infty$), $\mathbf{B}$ is everywhere differentiable, but $\nabla\mathbf{B}$, in general, is discontinuous on any surface S where the conductivity changes abruptly. One has

$$\begin{aligned}&[\![\mathbf{B}]\!] = 0, \quad [\![\mathbf{n} \cdot \mathbf{J}]\!] = 0, \\ &[\![\mathbf{n} \times \mathbf{E}]\!] = 0, \quad \text{on S},\end{aligned} \tag{27}$$

where $[\![Q]\!] = Q_2 - Q_1$ denotes the jump in a field Q across S. Although it is of no greater interest than ϑ, we may note that a free surface charge of density Θ per unit area exists on S given by

$$\Theta = [\![\mathbf{n} \cdot \mathbf{D}]\!], \quad \text{on S}. \tag{28}$$

Conditions (27) are not independent. The second follows from the first, and the third shows that, if

$$[\![\mathbf{n} \cdot \mathbf{B}]\!] = 0, \quad \text{on S}, \tag{29}$$

is obeyed initially, it will be obeyed for all time.

In a perfect conductor, $\mathbf{n} \times \mathbf{B}$ may be discontinuous, and

$$[\![\mathbf{n} \times \mathbf{H}]\!] = \mathbf{I}, \quad \text{on S}, \tag{30}$$

where $\mathbf{I}$ is a *surface current*. This is an infinitely thin sheet carrying along it a finite net current (per unit length across **I**). It may be thought of as the limit, as its thickness δ tends to zero, of a thin *current layer* in which **J** is $O(\mathcal{J}/\delta)$, i.e., very large. Continuity of charge now requires that

$$[\![\mathbf{n}\cdot\mathbf{J}]\!] = -\nabla_2\cdot\mathbf{I}, \quad \text{on S}, \tag{31}$$

where $\nabla_2\cdot$ denotes the surface divergence. Equation $(27)_3$ is also altered. Since $\mathbf{n}\times\mathbf{E}'$ is continuous in a frame moving with S, we have

$$[\![\mathbf{n}\times(\mathbf{E}+\mathbf{U}\times\mathbf{B})]\!] = 0, \quad \text{on S}. \tag{32}$$

If S separates two perfect conductors of different physical properties, then

$$V_{1n} = V_{2n} = U_n, \quad \text{on S}, \tag{33}$$

where $V_{\alpha n} = \mathbf{n}\cdot\mathbf{V}_\alpha$ and $\mathbf{V}_\alpha$ is the velocity on side α of S; Eqs. (24) and (33) reduce condition (32) to

$$B_n[\![\mathbf{V}]\!] = 0, \quad \text{on S}. \tag{34}$$

Thus, **V** is continuous when $B_n \equiv \mathbf{n}\cdot\mathbf{B} \neq 0$ on S. If, however, S is a shock, in which a material exchanges one thermodynamic state for another as it passes through S, Eqs. (33) and (34) do not hold [see Eqs. (54) and (59)].

2. FLUID MECHANICS

This section summarizes the theory governing two models of fluid behavior: the incompressible Newtonian (or linear viscous) fluid and the Euler fluid, which is compressible but inviscid; these models are generalized to the MHD context merely by the addition of the em body force **L** or the equivalent em stresses m_{ij}. Readers for whom this summary is unnecessary may wish to refer to the table of notation at the end of this article and then skip forward to Sec. 3.

2.1 The Ideal Fluid

The Euler fluid is often used to model fluid behaviors when there is reason to believe that viscous forces and thermal diffusion are insignificant. Ignoring these processes and also ignoring the possibility that the fluid is being internally heated, the equations expressing conservation of mass, momentum, and energy may be written as

$$\frac{D\rho}{Dt} = -\rho\nabla\cdot\mathbf{V}, \tag{35}$$

$$\rho\frac{D\mathbf{V}}{Dt} = -\nabla p + \mathbf{J}\times\mathbf{B} + \rho\mathbf{g}, \tag{36}$$

$$\frac{DS}{Dt} = 0, \tag{37}$$

where D/Dt stands for the motional derivative, i.e., the rate of change following the motion of the fluid:

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + \mathbf{V}\cdot\nabla; \tag{38}$$

g is an externally applied body force per unit mass, such as gravity. An alternative and useful way of writing Eq. (36) makes use of the representation (16) of $\mathbf{L} = \mathbf{J}\times\mathbf{B}$:

$$\rho\frac{D\mathbf{V}}{Dt} = -\nabla P + \frac{\mathbf{B}\cdot\nabla\mathbf{B}}{\mu_0} + \rho\mathbf{g}, \tag{39}$$

where

$$P = p + B^2/2\mu_0 \tag{40}$$

is the *total pressure*, i.e., the sum of thermodynamic and magnetic pressures.

Equation (37) excludes entropy production, such as might have arisen from dissolved heat sources (such as radioactivity) if present and would certainly arise from the diffusion of heat and momentum had we not already excluded those processes. When the Euler fluid is generalized to become the *ideal fluid* of MHD, the entropy source ϵ_σ/T, where T is the (absolute) temperature, must also be excluded from Eq. (37), and this requires that the Ohmic heating ϵ_σ, and therefore η, must be negligible; i.e., the fluid is a perfect electrical conductor. Thus, the ideal fluid is defined by*

$$\nu = \kappa = 0 \quad \text{and} \quad \sigma = \infty, \tag{41}$$

---

*Strictly, we should also add to Eqs. (41) the demand that the bulk viscosity is zero. The effects of bulk viscosity are excluded from this article.

where ν is the kinematic viscosity and κ is the thermal diffusivity.

The concept of an ideal fluid is not entirely straightforward. It is always advisable to consider Eqs. (41) as a limit: $\nu \to 0$ and $\eta \to 0$, with their ratio, the *magnetic Prandtl number,*

$$p_m = \nu/\eta = \mu_0 \sigma \nu, \tag{42}$$

held fixed. We shall recognize in Sec. 3.3 that, even though the ideal equations do not involve ν and η, their solutions may be required to depend on p_m.

The adiabatic condition (37) ensures that the entropy of each fluid element remains at its initial value, which, however, may differ from one fluid element to the next. Two alternative expressions of Eq. (37) follow from the thermodynamic relations

$$\begin{aligned} dp &= a^2 d\rho + (\gamma T/K_p C_v) dS, \\ dI &= (p/\rho^2) d\rho + T dS, \end{aligned} \tag{43}$$

where I is the internal energy per unit mass, a is the (adiabatic) speed of sound, γ is the coefficient of volume expansion, K_p is the isothermal compressibility, and C_v is the specific heat at constant volume. By Eqs. (35), (37), and (43), we have

$$\frac{Dp}{Dt} = -a^2 \rho \nabla \cdot \mathbf{V}, \tag{44}$$

$$\frac{DI}{Dt} = -\frac{p}{\rho} \nabla \cdot \mathbf{V}. \tag{45}$$

Equations (35), (36), (44), and (25), together with Eq. (2) and appropriate boundary conditions (see Sec. 2.2), suffice to determine the evolution of ρ, $\mathbf{V}$, p, and $\mathbf{B}$.

The situation is yet simpler when the system is *isentropic*, i.e., when S is the same for all $\mathbf{x}$. Then the equation of state $p = p(\rho, S)$ reduces to $p = p(\rho)$, i.e., the fluid is *barotropic*, and Eq. (36) becomes

$$\frac{D\mathbf{V}}{Dt} = -\nabla \varpi + \frac{\mathbf{J} \times \mathbf{B}}{\rho} + \mathbf{g}, \tag{46}$$

where ϖ is the *reduced pressure*:

$$\varpi(\rho) = \int_0^{\rho} \rho^{-1} dp(\rho). \tag{47}$$

Since $dH = TdS + \rho^{-1} dp$, where $H = I + p/\rho$ is the enthalpy per unit mass, we see that ϖ essentially coincides with H in an isentropic system.

The conservation laws (35)–(37) have useful alternative expressions:

$$\begin{aligned} &\frac{\partial \rho}{\partial t} = -\nabla \cdot \mathbf{M}, \quad \frac{\partial M_i}{\partial t} = -\nabla_j \Pi_{ij}, \\ &\frac{\partial E}{\partial t} = -\nabla \cdot \mathbf{Q}, \end{aligned} \tag{48}$$

where $\mathbf{M} = \rho \mathbf{V}$ is the momentum density, E is the total energy density per unit volume, Π_{ij} is the total stress tensor, and $\mathbf{Q}$ is the total energy flux. With the help of the alternative form (45) of Eq. (37), we find that

$$E = \rho(I + \tfrac{1}{2} V^2) + B^2/2\mu_0, \tag{49}$$

$$\Pi_{ij} = \rho V_i V_j + P \delta_{ij} - B_i B_j/\mu_0, \tag{50}$$

$$\mathbf{Q} = \rho(H + \tfrac{1}{2} V^2)\, \mathbf{V} + \mathbf{E} \times \mathbf{B}/\mu_0. \tag{51}$$

In deriving Eqs. (48), we have assumed that $\mathbf{g} = 0$. When $\mathbf{g} \neq 0$, not only must $\rho \mathbf{g}$ be restored to the right-hand side of Eq. $(48)_2$ but an extra term $\rho \mathbf{V} \cdot \mathbf{g}$ must be added to the right-hand side of Eq. $(48)_3$ representing the rate of working of the external forces. If, however, $\mathbf{g} = -\nabla \varphi$ is a *time-independent* conservative force, Eq. $(48)_3$ holds once again, but with E and $\mathbf{Q}$ redefined as

$$E = \rho(I + \tfrac{1}{2} V^2 + \varphi) + B^2/2\mu_0, \tag{52}$$

$$\mathbf{Q} = \rho(H + \tfrac{1}{2} V^2 + \varphi)\mathbf{V} + \mathbf{E} \times \mathbf{B}/\mu_0. \tag{53}$$

In Eq. (52), we see the sum of internal, kinetic, and em energies and the potential energy (φ) of the applied forces; in Eq. (53), we see enthalpy, kinetic energy, and external potential energy advected with the fluid motion, while em energy is transmitted by the Poynting flux. Provided no energy is being injected from outside a system (e.g., from external current-carrying coils), its total energy (the integral of E) is conserved. This forms the basis of an energy principle described in Sec. 8.

2.2 Continuity Conditions for an Ideal Fluid; Shocks

The assumptions (41) defining the ideal model permit discontinuities (including shocks) to arise at a stationary or moving surface S in the fluid. For convenience, let us transform to a reference frame in which $U_n = 0$. The integral forms of Eqs. (48) tell us that M_n, Π_{in}, and Q_n are continuous across S. The first of these gives

$$\rho_1 V_{1n} = \rho_2 V_{2n} = j, \quad \text{say}. \tag{54}$$

The second, when separated into components parallel and perpendicular to **n**, gives, by Eq. (50),

$$[\![p]\!] + j^2[\![\rho^{-1}]\!] + [\![B_H^2/2\mu_0]\!] = 0, \tag{55}$$

$$j[\![\mathbf{V}_H]\!] = B_n[\![\mathbf{B}_H/\mu_0]\!], \tag{56}$$

where $\mathbf{V}_H = \mathbf{V} - V_n\mathbf{n}$ and $\mathbf{B}_H = \mathbf{B} - B_n\mathbf{n}$. The third gives, by Eq. (51),

$$j\left[\!\!\left[H + \frac{j^2}{2\rho^2} + \tfrac{1}{2}V_H^2 + \frac{B_H^2}{\mu_0\rho}\right]\!\!\right] = B_n\left[\!\!\left[\frac{\mathbf{V}_H\cdot\mathbf{B}_H}{\mu_0}\right]\!\!\right]. \tag{57}$$

In writing Eqs. (55)–(57), we have made use of two results from Sec. 1.4: first, by Eq. (29),

$$B_{1n} = B_{2n} = B_n, \quad \text{say}; \tag{58}$$

second, by Eq. (24), continuity of $\mathbf{n} \times \mathbf{E}$ requires that

$$B_n[\![\mathbf{V}_H]\!] = j[\![\mathbf{B}_H/\rho]\!]. \tag{59}$$

When $j \neq 0$ and $B_n \neq 0$, the discontinuity is an MHD shock and Eqs. (54)–(59) are the MHD generalizations of the *Rankine–Hugoniot conditions* of classical fluid mechanics. And, as in that subject, they must be supplemented by the demand that fluid passing through the shock cannot suffer a diminution in entropy; *i.e.*,

$$j[\![S]\!] \geq 0. \tag{60}$$

Thus, the basis of Eq. (37), conservation of entropy, generally fails as fluid passes through S. This is called *shock heating*.

There are three principal types of discontinuity in which shock heating does not occur, either because $[\![S]\!] = 0$ or because $j = 0$. The former possibility arises in the so-called *rotational discontinuity* in which $[\![S]\!] = [\![\rho]\!] = 0$ so that $[\![H]\!] = [\![p]\!] = 0$. By Eq. (54), $[\![V_n]\!] = 0$ and Eqs. (56) and (59) show that

$$j = \pm\left(\frac{\rho}{\mu_0}\right)^{1/2} B_n, \qquad [\![\mathbf{V}_H]\!] = \pm\frac{1}{\sqrt{\mu_0\rho}}[\![\mathbf{B}_H]\!]. \tag{61}$$

We shall recognize in Sec. 6.2 that the rotational discontinuity is merely a finite-amplitude Alfvén wave with a discontinuous wave form.

When $j = 0$ but $B_n \neq 0$, we see from Eqs. (56)–(59) that

$$[\![p]\!] = 0, \quad [\![\mathbf{V}]\!] = 0, \quad [\![\mathbf{B}]\!] = 0, \tag{62}$$

though the values of ρ, S, T, ... may jump across such a *contact discontinuity*. Because $[\![S]\!] \neq 0$, in general, the contact discontinuity is one example of an entropy wave. The other is the *tangential discontinuity* for which $j = 0$ and $B_n = 0$. Then the values of $\mathbf{V}_H$, $\mathbf{B}_H$, ρ, S, T, ... may jump in crossing S, and we require only that

$$[\![P]\!] = 0. \tag{63}$$

We return to the topic of shock waves in Sec. 6.2.

Contact and tangential discontinuities also arise when S is a surface separating materials of different physical properties, such as two immiscible fluids of different composition. Conditions (62) or (63) apply depending on whether $B_n \neq 0$ or $B_n = 0$; interfacial tension may also have to be included. If one side of S is a rigid solid, conditions on the stresses are meaningless: a rigid solid can balance fluid-created stresses on its boundary by accelerating as a solid body and by *infinitesimal* internal deformations. Conditions $(62)_1$ and (63) then cease to apply, although the integral of the fluid stresses involved may have to be included when determining how the rigid body moves. Condition $(62)_1$ or (63) applies when one side of S is a vacuum, p then being zero in the vacuum.

2.3 The Incompressible Viscous Fluid

Using the imprecise terminology common in fluid mechanics, we say that a fluid is *incompressible* when its density is unaffected both by changing pressure and by changing temperature. Since then $D\rho/Dt = 0$, the expression (35) of mass conservation becomes

$$\nabla \cdot \mathbf{V} = 0. \tag{64}$$

Equation (64) is equivalent to assuming that the sound speed a is infinite; shocks, therefore, do not exist in an incompressible fluid, although if $\nu = 0$, discontinuities in $\mathbf{V}_H$ are allowed; if $\kappa = 0$, discontinuities in T are allowed; and if $\eta = 0$, discontinuities in $\mathbf{B}_H$ are allowed. The assumption $D\rho/Dt = 0$ only ensures that the density of each fluid element remains the same and not that the density is uniform; however, we will suppose that ρ is the same everywhere.

Approximation (64) simplifies the mathematical expressions for the viscous forces and the viscous dissipation of heat, ϵ_ν. Assuming that $\nu(\geq 0)$ is constant, conservation of momentum (36) may be written as

$$\frac{D\mathbf{V}}{Dt} = -\nabla\varpi + \frac{\mathbf{J} \times \mathbf{B}}{\rho} + \nu\nabla^2\mathbf{V} + \mathbf{g}, \tag{65}$$

where now $\varpi = p/\rho$. The rate at which kinetic energy is lost in heating the fluid through friction is

$$\epsilon_\nu = \tfrac{1}{2}\rho\nu(\nabla_i V_j + \nabla_j V_i)(\nabla_i V_j + \nabla_j V_i) \tag{66}$$

and is clearly non-negative.

Energy conservation plays a subservient role in the theory of incompressible fluids. The continuity, momentum, and induction equations can be solved for $\mathbf{V}$, $\mathbf{B}$, and p; and the energy equation may subsequently be solved if it is of interest to do so, e.g., if the temperature of the fluid resulting from viscous, Ohmic, and external heating is required. For this reason, it is unnecessary to set down the energy equation here.

If $\nu \neq 0$, $\mathbf{V}$ is everywhere continuous and differentiable, but $\nabla\mathbf{V}$ will, in general, jump in value in crossing a surface S where the material properties change abruptly. The *no-slip condition* $(62)_2$ applies both when S is the boundary of a solid and when it is an interface between two immiscible viscous fluids. In the latter case, viscous stresses must be included in condition (50) and so

$$[\![P\delta_{ij} - B_iB_j/\mu_0 - \rho\nu(\nabla_i V_j + \nabla_j V_i)]\!]n_j = 0. \tag{67}$$

If $\eta \neq 0$, so that $[\![\mathbf{B}]\!] = 0$, condition (67) simplifies to

$$[\![p\delta_{ij} - \rho\nu(\nabla_i V_j + \nabla_j V_i)]\!]n_j = 0. \tag{68}$$

Again, corrections for interfacial tension may have to be included in conditions (67) and (68).

3. STEADY PARALLEL FLOWS

It is natural to ask how the Lorentz force affects well-known and well-understood situations encountered in classical fluid mechanics. (When we use the word "classical," we imply that magnetic fields are absent so that electrical conduction is irrelevant.) The simplest examples provide the most revealing demonstrations of how drastically MHD flows can differ from classical flows. This section will exhibit this through the study of simple, steady unidirectional flows of the form

$$\mathbf{V} = V(y, z)\mathbf{e}_x. \tag{69}$$

Moreover, laboratory investigations on the flow of liquid metals, particularly mercury, have provided support for the theoretical findings. Theory and experiment have significant technological applications to power generation, plasma propulsion, and the flow of liquid metals in fast reactors and in the blankets surrounding thermonuclear reactors.

One of the simplest cases is one-dimensional (1D) *plane Poiseuille flow*, for which

$$V(y) = (k/2\rho\nu)(a^2 - y^2). \tag{70}$$

This classical solution of the Navier–Stokes equations depends on y alone and results from the application of the pressure gradient $-k\mathbf{e}_x$ to an incompressible fluid contained between fixed parallel walls, $y = \pm a$. The profile of the velocity (70) is said to be "parabolic" for obvious reasons; see the uppermost curve of Fig. 1. The mean velocity,

$$\bar{V} = \frac{1}{2a}\int_{-a}^{a} V(y)dy, \tag{71}$$

is proportional to k: it is $\bar{V}_0 = ka^2/3\rho\nu$.

The MHD flow corresponding to solution (70) arises when the fluid is an electrical conductor and a uniform magnetic field, $\mathbf{B}_0 =$

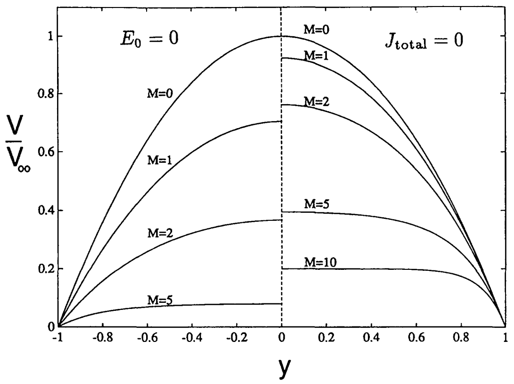

FIG. 1. Velocity profiles for Poiseulle flow ($M = 0$) and for Hartmann flow ($M \neq 0$). Velocity profiles $V(y)$ are shown for various Hartmann numbers M in two cases: $E_0 = 0$ (perfectly conducting walls) on left, and $J_{\text{total}} = 0$ (insulating walls) on right. Here, $V_{00} = ka^2/2\rho\nu$ is the velocity at $y = 0$ for $M = 0$. Note the reduction and flattening of the profiles as M, a measure of the applied field, increases.

$B_0\mathbf{e}_y$, is externally applied perpendicularly to the layer. In studying the resulting *Hartmann flow,* we shall suppose, for simplicity, that the "top and bottom walls" $y = \pm a$ are insulators.

Another very simple 1D classical solution of the Navier–Stokes equation is *plane Couette flow,* in which $k = 0$ but in which the fluid attaches to the walls $y = \pm a$, which move with velocity $\pm U\mathbf{e}_x$, so creating the velocity $\mathbf{V} = (Uy/a)\mathbf{e}_x$ between them. The corresponding MHD flow will not be studied here (e.g., see Sec. II.3 of Moreau, 1990).

3.1 Hartmann Flow

One of the most profound differences between classical and MHD flows arises from the long-range nature of em forces. For example, plane Poiseuille flow provides a good approximation to the flow far from the "side walls" $z = \pm c$ of a duct having a rectangular cross section ($-a \leq y \leq a$; $-c \leq z \leq c$) of large aspect ratio c/a (see Fig. 2). In contrast, the effect of the side walls on Hartmann flow pervades the entire duct. To see this, note that the flow (69) produces an emf, $\mathscr{E} = \mathbf{V} \times \mathbf{B} = VB_0\mathbf{e}_z$, which will, in general, create charges on the side walls and an electrostatic field $\mathbf{E}$. In the case of the 1D flow (70), $\mathbf{E}$ is parallel or antiparallel to $\mathscr{E}$, so that $\mathbf{E} = E(y)\mathbf{e}_z$. Since conditions are steady, Eq. (1) becomes $\nabla \times \mathbf{E} = 0$ so that $E(y)$ is a constant ($-E_0$, say). The value of E_0 is decided by whether the side walls are insulating or conducting and (if the latter) what electrical circuitry connects them to one another. Thus, V is *not* uniquely determined by B_0 and k (where k is now the gradient of *total* pressure in the x direction); it depends through E_0 also on the side walls. At one extreme, we shall focus on the case in which the side walls are perfect conductors that are connected together by a wire of zero resistance so that $E_0 = 0$; at the other extreme, we shall consider insulating side walls so that the net current

$$J_{\text{total}} = \int_{-a}^{a} J_z dy \tag{72}$$

carried across the duct is zero. In this case, $E_0 = \bar{V}B_0$ and a measurement of the potential difference $2cE_0$ between the side walls directly meters $\bar{V}$ noninvasively, making it a potentially interesting way of, for example, measuring blood flow in the body (see Shercliff, 1962). Perhaps the first flow meter to make use of induced currents was that of

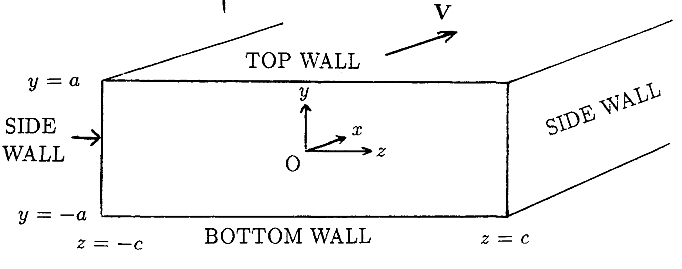

FIG. 2. The rectangular duct. When the aspect ratio c/a of the duct is large, plane Poiseuille flow ($\mathbf{B} = 0$) is a good approximation for $\mathbf{V}$ sufficiently far from the side walls. In the case of Hartmann flow (the MHD generalization of Poiseuille flow in which $\mathbf{B}_0 \neq 0$ is parallel to the side walls), the solution throughout the duct depends on the electrical properties of the side walls.

Faraday, who in 1843 measured flow in the Thames from the potential difference of its banks, an experiment which, like that of Ritchie mentioned below, demonstrated one-half of the MHD relationship and which is sometimes described as the first MHD experiment.

The general form of Hartmann flow is easily derived from the theory of Secs. 1 and 2 and will not be given here (e.g., see Sec. II.2 of Moreau, 1990). The solution depends crucially on the *Hartmann number*

$$M = (\sigma/\rho\nu)^{1/2} B_0 a, \qquad (73)$$

which measures the relative sizes of the Lorentz force $\mathbf{J} \times \mathbf{B} \approx \sigma(\mathbf{V} \times \mathbf{B}) \times \mathbf{B} \approx \sigma\mathcal{B}^2\mathcal{V}$ and the viscous force $\rho\nu\nabla^2\mathbf{V} \approx \rho\nu\mathcal{V}/a^2$; the ratio of these terms is M^2, a parameter also called the *Chandrasekhar number*. The dependence of the velocity profile on the magnetic field is illustrated in Fig. 1. When M is small, the profile differs little from profile (70), but, as M increases, the flow is increasingly suppressed, the effect being more pronounced at the $E_0 = 0$ extreme (shown on the left of Fig. 1) than at the $J_{\text{total}} = 0$ extreme (on the right). This is also illustrated in Fig. 3, where $\bar{V}$ is shown in each extreme case; here, $\bar{V}_0$ is the mean velocity for zero M (see above). Another striking feature of Fig. 1, which will be explicated in Sec. 3.2, is the way that the velocity profile flattens as M increases.

In the general case, the Poynting energy flux (per unit xz area) out of the duct through its top and bottom surfaces is

$$S = (E_0/\mu_0)[b(-a) - b(a)] = E_0 J_{\text{total}}. \qquad (74)$$

If $S < 0$, the duct converts externally provided em energy into kinetic energy; i.e., it is a pump. The applied pressure gradient, $-k\mathbf{e}_x$, can then be dispensed with, and flow is down or up the duct depending on whether E_0/B_0 is positive or negative. One example of an electromagnetic pump is sketched in Fig. 4: the annular linear induction pump. The cross section shown should be imagined rotated about the axis of symmetry. Only 12 of perhaps 30 windings are depicted; these carry ac currents that produce fields that close in the central laminated core and are phased to provide a magnetic field pattern that travels from left to right in the figure (The field directions shown apply, of course, only at one instant of time.) The induced currents flow in bands, as indicated, and the associated Lorentz force drives the liquid metal in the stainless steel pipe in the direction shown. For a recent discussion of the technology of electromagnetic pumping, see Baker and Tessier (1987). Ritchie performed an experiment in 1843 which may have been the first in which a fluid (water) was pumped electromagnetically, so demonstrating the other half of the MHD relationship.

If $S > 0$, the duct acts as a generator of electricity, i.e., a dynamo. This fact lies behind several interesting proposals for MHD generators, including a coal-fired open-cycle liquid-metal MHD energy conversion system, designed as a retrofit to a pre-existing conventional power plant. A liquid metal is mixed with the combustion gas and expanded across a transverse magnetic field. Electrical power is drawn off in the direction perpendicular to both **V** and **B**. After leaving this MHD generator (one of perhaps eight similar generators), the liquid metal is separated and purified before being returned to the mixer; the gas is directed to a conventional steam plant. The eight generators are connected in series to produce high-voltage dc, later converted to ac. Liquid copper is a good choice for the working metal, for not only is it compatible with the combustion gases but it also carries away the particulates in those gases, such as sulfur and nitrogen oxides, and the slag/ash. These can be easily and inexpensively removed so that no stack cleanup or slag/ash

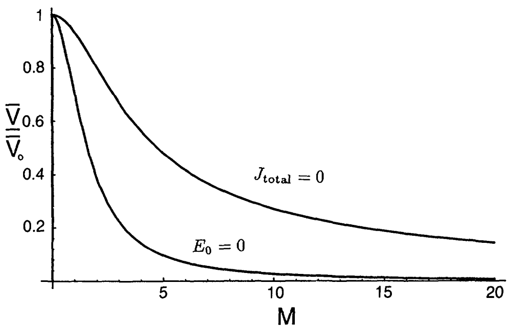

FIG. 3. Variation of mean velocity with increasing field strength in Hartmann flow. The variation of the mean flow down the duct $\bar{V}$ with Hartmann number M is shown in the two cases $J_{\text{total}} = 0$ (insulating walls) and $E_0 = 0$ (perfectly conducting walls). Here, $\bar{V}_0 = ka^2/3\rho\nu$ is the mean velocity for $M = 0$.

FIG. 4. Schematic of an annular linear induction pump. The cross section sketched should be imagined rotated about the axis of symmetry and extended further to the right and left to include perhaps 30 stator windings. The Lorentz force on the induced currents shown drives liquid metal from left to right.

removal from the boiler is required; clearly the system is environmentally clean. See Pierson *et al.* (1983). In another type of MHD generator, the air is seeded before being mixed with coal and burnt so that the gas leaving the combustor is a plasma, i.e., has a high electrical conductivity. It is expanded across a magnetic field in an MHD generator in much the same way as described above [see Jackson (1983), where earlier references will be found]. Systems that make use of solar power have also been proposed.

It is clear from these examples that the MHD concepts so clearly exemplified by Hartmann flow have significant technological applications. But the added complexities of those applications require the theory to be developed further, as we shall do in the remainder of this section.

We should note first that to confine attention to the two special cases of insulating and perfectly conducting walls would be too restrictive for many applications, but to introduce finitely conducting walls would add complications connected with their geometry and spatial extent. A commonly adopted simplification supposes that the walls are very highly conducting but extremely thin, thinner in fact than every length scale of interest (even δ_H, see Sec. 3.2). Their integrated conductivity defines a conductance $\bar{S}$ that is supposed finite; $\bar{C} = \bar{S}/\sigma a$ is called the *conductance ratio*. The currents flowing in the layer act as a current sheet of strength $\mathbf{I}_{\text{total}} = \bar{S}\mathbf{E}_H$ by Ohm's law. Also, Eq. (11) gives $\mathbf{J}_H = \sigma\mathbf{E}_H$, because $[\![\mathbf{E}_H]\!] = \mathbf{V} = 0$ on the wall. (As in Sec. 2.2, the suffix H refers to components tangential to the boundary.) It follows that $\mathbf{I}_{\text{total}}/\bar{S} = \mathbf{J}_H/\sigma$. Moreover, condition (30) gives $\mu_0\mathbf{I}_{\text{total}} = \mathbf{n} \times \mathbf{b}$, where $\mathbf{n}$ points into the duct. Here, $\mathbf{b} \equiv \mathbf{B} - \mathbf{B}_0$ is evaluated on the fluid edge of the thin conducting layer; on the other edge, it is zero. We, therefore, have

$$\mathbf{n} \times \mathbf{b} = a\bar{C}\mu_0\mathbf{J}_H, \tag{75}$$

which, in the case of parallel flow, gives $b = a\bar{C}\mathbf{n}\cdot\nabla b$, so that $b(\pm a) = \mp\bar{S}\mu_0E_0$. It follows that

$$M(k - \bar{C}\sigma B_0E_0) = (k + \sigma B_0E_0)\tanh M,$$

which determines E_0.

3.2 Flow at Large Hartmann Number

Not only are large Hartmann numbers attainable in the laboratory, they are also relevant to many technological applications. The corresponding theory is also particularly amenable to solution, by the application of asymptotic methods (see, for example, Kulikovsky, 1973). Moreover, a knowledge of flows for large M can be helpful in qualitatively interpreting situations in which $M = O(1)$. A large-M solution is pictured as a main stream and boundary layers that match it to the walls, in much the same way as is routinely done at large Reynolds numbers,

$$Re = \mathcal{V}\mathcal{L}/\nu, \qquad (76)$$

in classical fluid mechanics. The nature of the main stream (or "core flow" as it is usually called in the MHD context) and of the boundary layers for large M is, however, very different from those arising classically for $Re \gg 1$.

Hartmann flow provides an ideally simple test bed for MHD asymptotics and for explaining the flattening of the velocity profile observed in Fig. 1. For uniform $\mathbf{B}_0$ (and for $\mathbf{g} = 0$), the steady forms of Eqs. (22) and (39) are to leading order

$$\mathbf{B}_0 \cdot \nabla\mathbf{V} = 0, \quad 0 = -\nabla p + \mathbf{J} \times \mathbf{B}, \qquad (77,78)$$

the latter of which gives

$$\mathbf{B}_0 \cdot \nabla\mathbf{J} = 0. \qquad (79)$$

Equations (77) and (79) are the basis of a *two-dimensional theorem*: If $M \gg 1$ and $\mathbf{B}_0$ is uniform, the fluid velocity and electric current density are independent of the coordinate parallel to $\mathbf{B}_0$. This theorem is analogous to the classical *Proudman–Taylor theorem* of rotating fluids, which states that the slow, steady motion of inviscid fluid in a rotating fluid is two-dimensional (2D) with respect to the direction of the angular velocity $\mathbf{\Omega}$ (see Sec. 10.4 and Greenspan, 1968).

Equation (78) is the equation of magnetostatic balance. It shows that a tiny $\mathbf{J}$ arises (tiny because $\mathbf{B}_0$ is large) for the sole purpose of creating the Lorentz force necessary to offset the applied pressure gradient. The large $\mathbf{B}_0$ can generate from a very small $\mathbf{V}$ the potential differences required to produce the necessary $\mathbf{J}$. In application to Hartmann flow, Eq. (78) gives at once $J_z^{\text{core}} = k/B_0$, from which it follows by Ampère's law (2) that $B_y^{\text{core}} = -k\mu_0 y/B_0$. Consistent with Eq. (77), Ohm's law (11) then gives a y-independent V, namely, $V^{\text{core}} = (k + \sigma B_0 E_0)/\sigma B_0^2$, so accounting for the flattening of the profiles seen in Fig. 1. Clearly, if $E_0 \neq 0$, then $V^{\text{core}} = E_0/B_0$ for large M, while if $E_0 = 0$, $V^{\text{core}} = k/\sigma B_0^2$.

It is clear that V^{core} does not satisfy the no-slip conditions on $y = \pm a$. This is rectified by thin *Hartmann layers*, across which viscous stresses diminish V monotonically from V^{core} to zero. The thickness δ_{H} of these layers may be estimated by equating the viscous force $\rho\nu\nabla^2\mathbf{V} = O(\rho\nu\mathcal{V}/\delta_{\text{H}}^2)$ to $\mathbf{J} \times \mathbf{B} = O(\mathcal{J}\mathcal{B}) = O(\sigma\mathcal{V}\mathcal{B}^2)$. In this way, we obtain

$$\delta_{\text{H}} = a/M = \sqrt{\rho\nu/\sigma B_0^2}. \qquad (80)$$

The same dynamical balance can be used to relate the discontinuities $\mathbf{B}_2 - \mathbf{B}_1$ and $\mathbf{V}_2 - \mathbf{V}_1$ in field and velocity from one side of the boundary layer to the other. Let us suppose that $\mathbf{B}_2 - \mathbf{B}_1$ is in the z direction, $\mathbf{B}_0$ being in the y direction as before. According to Eq. (30), the net current carried by the Hartmann layer is then $(B_{2z} - B_{1z})\mathbf{e}_x/\mu_0$, which creates from $\mathbf{B}_0$ a Lorentz force $B_0(B_{2z} - B_{1z})\mathbf{e}_z/\mu_0$ per unit area, that acts to accelerate the entire layer in the z direction. In a steady state, this must be balanced by the difference in viscous stress at the edges of the layer, which is of order $\rho\nu(\mathbf{V}_2 - \mathbf{V}_1)/\delta_{\text{H}}$. This must therefore be in the z direction, showing that $V_{2z} - V_{1z} = O(\delta_{\text{H}} B_0/\mu_0\rho\nu)(B_{2z} - B_{1z}) = (\text{sgn}B_0)O((\eta/\mu_0\rho\nu)^{1/2})(B_{2z} - B_{1z})$. This argument is supported by precise analysis (Stewartson, 1960):

$$\frac{\mathbf{B}^{\text{core}} - \mathbf{B}^{\text{wall}}}{\sqrt{\mu_0\rho}} = p_m^{1/2}(\text{sgn}B_n)(\mathbf{V}^{\text{core}} - \mathbf{V}^{\text{wall}}), \qquad (81)$$

where $p_m = \nu/\eta$ is the magnetic Prandtl number. In condition (81), we have specialized to the duct by identifying sides 1 and 2 with the wall and core, respectively. Also, we have generalized to ducts of arbitrary cross section by replacing B_0 by B_n, the component of $\mathbf{B}$ normal to the wall and directed into the duct; each side of the n component of condition (81) vanishes separately.

If we integrate J_z^{core} across the layer, we apparently obtain a net z-current flow of $2ak/$

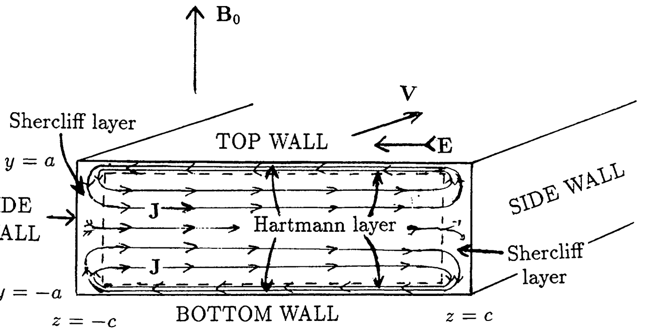

FIG. 5. An insulating rectangular duct when M is large. The Hartmann layers are shown on the top and bottom walls and the Shercliff layers on the side walls. The current generated in the core of the duct is reflected from the $z = c$ boundary and, driven by the electric field $\mathbf{E}$ generated by the free charges at the sides, returns equally along the Hartmann layers and is reflected at the $z = -c$ boundary to return to the core.

B_0, irrespective of the conductivity of the side walls, even though, in the case of insulating side walls, we know that $J_{\text{total}} = 0$. The current $2ak/B_0$ must therefore be totally reflected at the side walls and return in the Hartmann layers (see Fig. 5). Since V is much less than V^{core} in these layers, the current within them is driven primarily by $\mathbf{E} = -E_0\mathbf{e}_z$, which is indeed in the correct (negative z) direction and is of the right magnitude if $-J_z\delta_H \approx \sigma E_0 \delta_H \approx ak/B_0$. It follows that E_0 is independent of B_0 and M; in fact, $E_0 \approx ka/\sqrt{\rho\nu\sigma}$. Thus, V and $\bar{V}$ are proportional to M^{-1} for $M \gg 1$. In contrast, they are clearly proportional to M^{-2} in the case ($E_0 = 0$) of perfectly conducting side walls when (see above) $V^{\text{core}} = k/\sigma B_0^2$. This accounts for the fact that the profiles on the left side of Fig. 1 are depressed, compared with the curves for corresponding M on the right. It also explains the much smaller values of $\bar{V}$ shown in Fig. 3. In the case of the insulating duct, the Lorentz force on the return current is, in apparent contradiction to Lenz's law, in the *positive x* direction. When the current returns elsewhere, it exerts no Lorentz force on the fluid and the flow speed for $E_0 = 0$ is then $O(M^{-1})$ times smaller.

3.3 The Hartmann Layer and Applications

Hartmann layers arise when $\mathcal{B}$ is large in far more general situations than those considered in Sec. 3.2. And, even when $\mathcal{B}$ is not large, insight is gained from solutions for $M \gg 1$. A Hartmann layer forms on a wall wherever $|B_n|$ is large compared with $\sqrt{\rho\nu/\sigma\mathcal{L}^2}$. Its thickness is given by Eq. (80), with B_n replacing B_0, i.e., $\delta_H = \sqrt{\rho\nu/\sigma B_n^2}$. It is, therefore, a function of position on the walls and tends to infinity as the curves (or surfaces) on which $B_n = 0$ are approached, such as the points T_1 and T_2 shown in Fig. 6. The infinity is, however, illusory, since the Hartmann layers must themselves match to different boundary-layer structures that exist at the curves (or surfaces) where $B_n = 0$. These structures are passive and not of Hartmann layer type. They are hard to analyze, and fortunately they usually make only a small correction to the solution obtained by ignoring them.

Hartmann layers exist when all geometrical length scales $\mathcal{L}$ of interest are large compared with typical values of δ_H. They also arise in time-dependent situations and, provided that external conditions change little during the *magnetic response time* $\tau_m = \rho/\sigma\mathcal{B}^2$ and during the time scale $\nu\mu_0\rho/\mathcal{B}^2$, they can be treated as steady.

As an illustration of the usefulness of condition (81), we determine to leading order the flow in a duct with an insulating wall of arbitrary cross section but with just two points,

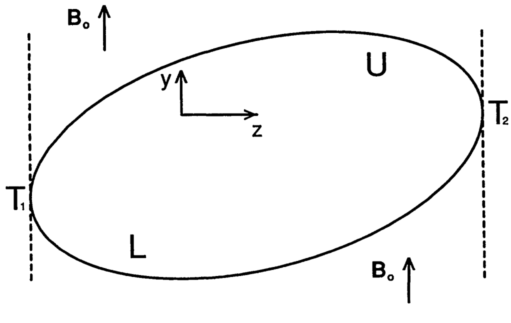

FIG. 6. Flow in a duct of arbitrary cross section. The points T_1 and T_2 where $\mathbf{B}$ is tangent to the cross section divide its perimeter into two segments: the upper part T_1UT_2, where condition (81) applies with $\text{sgn}B_n < 0$, and the lower part T_1LT_2, where $\text{sgn}B_n > 0$ in condition (81).

T_1 and T_2, at which $z = z_1$ and $z = z_2$ and $B_n = 0$ (see Fig. 6). Let the upper boundary, T_1UT_2, have the equation $y = y_1(z)$, the lower boundary, T_1LT_2, being $y = y_2(z)$. To leading order, the core is in magnetostatic balance (78) and $J_z^{\text{core}} = k/B_0$, as before. Again, $\mathbf{E}$ is predominantly created by em induction: $\mathbf{E} \approx -B_0V\mathbf{e}_z$. Since $\nabla \times \mathbf{E} = 0$, we have

$$\frac{\partial b^{\text{core}}}{\partial y} = -k\mu_0/B_0, \quad \frac{\partial V^{\text{core}}}{\partial y} = 0, \tag{82}$$

so that

$$b^{\text{core}} = -(k\mu_0/B_0)y + f(z), \quad V^{\text{core}} = g(z), \tag{83}$$

where $f(z)$ and $g(z)$ are functions that remain arbitrary until condition (81) is applied at $y = y_1(z)$ and $y = y_2(z)$. This means that the role of the Hartmann layers is decisive; they *control* the core flow. In fact, condition (81), which applies at every point on the cross section (except T_1 and T_2), requires that

$$\begin{aligned} f(z) &= \frac{k\mu_0}{2B_0}[y_1(z) + y_2(z)], \\ g(z) &= \frac{k}{2B_0\sqrt{\rho\sigma\nu}}[y_1(z) - y_2(z)]. \end{aligned} \tag{84}$$

If we set $y_1 = -y_2 = a$, we recover our earlier results for Hartmann flow at large M. If we take $y_1 = -y_2 = \sqrt{a^2 - z^2}$, we obtain the core flow for a circular duct of radius a: to leading order,

$$\begin{aligned} b^{\text{core}} &= -\frac{k\mu_0}{B_0}y, \\ V^{\text{core}} &= \frac{k}{B_0\sqrt{\rho\sigma\nu}}\sqrt{a^2 - z^2}, \end{aligned} \tag{85}$$

where the origin is on the axis of the duct. Equation $(85)_2$ provides another example of the 2D theorem (77).

If $\mathbf{B}_0$ is parallel to one of the sides of a duct of rectangular cross section, the singularities T_1 and T_2 of Fig. 6 extend along the entire side walls and boundary layers are set up along their entire length. The thickness of these *Shercliff layers* (also called "side-wall layers") is $\delta_S = M^{-1/2}a$, and within them the core flow is brought to rest in obedience to the no-slip conditions on $z = \pm c$. The corresponding flux deficit depends on the electrical properties of the walls and is not necessarily positive. Indeed, in one striking case, the side walls may make a greater contribution to $\bar{V}$ than does the entire core. This is because the current $J^{\text{core}} = k/B_0$ flowing across the duct must, when the side wall is an insulator, be deflected within the Shercliff layer toward the top and bottom walls (see Fig. 5). Being then substantially parallel to $\mathbf{B}_0$, the Lorentz force it creates is greatly reduced and is insufficient to balance the applied pressure gradient, which must therefore be offset by the viscous force. This can only happen if the velocity shear within the Shercliff layer is large. This results in a jet of fluid along the side wall of speed $O(M^{-1})$ which makes a positive $O(M^{-3/2})$ contribution to $\bar{V}$. When the top and bottom walls of the duct are perfect conductors [so that the core flow is $O(M^{-2})$], the boundary layer "deficit" is $O(aM^{1/2}/c)$ times larger than the contribution made by the core.

Side-wall layers are essentially passive shear layers that smooth out discontinuities that are permitted by the 2D theorem, i.e., those in which $\mathbf{V}(x, z)$ and $\mathbf{J}(x, z)$ are different on either side of a surface $x = x(z)$, where Oy is parallel to $\mathbf{B}_0$. They arise in more general contexts than Hartmann flow (see Sec. 4). Their theory was initiated by Braginsky (1960) and developed by Waechter (1979). The velocity profile at a shear layer usually possesses an inflection point and may therefore be subject to inertial instabilities of the type described in, for instance, Ch. 4 of Drazin and Reid (1981) (see Reed and Picologlou, 1989).

Rectangular ducts have been studied both theoretically and experimentally for a variety of different electrical wall conditions. For a more detailed account, see Ch. IV of Moreau (1990). Flow parallel to a cylinder in the presence of a transverse magnetic field is also discussed in Sec. V.V of that book.

4. STEADY NONPARALLEL FLOWS

In the situations examined in Sec. 3, the induced field $\mathbf{b}$ is everywhere parallel to the flow $\mathbf{V}$, so that it does not contribute to the emf $\mathbf{V} \times \mathbf{B}$, which is therefore $\mathbf{V} \times \mathbf{B}_0$. In the situations now described, $\mathbf{V} \times \mathbf{b} \neq 0$, so that a further field $\mathbf{b}_1$ arises which, in turn, creates another field $\mathbf{b}_2$ and so on. The ratio of successive terms is $O(|\mathbf{b}|/B_0) = O(\mu_0\sigma\mathscr{V}\mathscr{L})$, so that the sum converges rapidly if $R \ll 1$, where

$$R = \mathcal{V}\mathcal{L}/\eta \tag{86}$$

is the *magnetic Reynolds number*. In this case, all fields except $\mathbf{B}_0$ and $\mathbf{b}_1$ may usually be safely ignored.

In the situations examined in Sec. 3, the inertial term in the equation of motion $\rho\mathbf{V} \cdot \nabla\mathbf{V}$ is identically zero. In what follows, this is not the case, and the inertial force influences the flow. The ratio of this to the viscous force is of order $Re = \mathcal{V}\mathcal{L}/\nu$, the usual *(hydrodynamic) Reynolds number*. If $Re \ll 1$, the inertial term is negligible in comparison with the viscous force, and if $N \gg 1$, where $N = M^2/Re = \sigma\mathcal{B}^2\mathcal{L}/\rho\mathcal{V}$ is the *interaction parameter*, the inertial term may be discarded in comparison with the Lorentz force. In short, if $Re \ll \max(1, M^2)$, inertial forces may be ignored. The situation is then much as in Sec. 3, and, in particular, if $M \gg 1$, viscous forces may be neglected except in Hartmann or shear layers. In what follows, we shall assume that $N \gg 1$, $M \gg 1$, and $R \ll 1$, since such situations are often the simplest and most illuminating. It is worth noting, however, that, even then, inertial forces may sometimes be significant. When duct flow changes direction abruptly at an elbow joint, N is, in effect, reduced near it and inertial forces usually cannot be ignored. Also, as mentioned in Sec. 3.3, shear layers are prone to inertial instability.

As a first example (Alpher *et al.*, 1960), consider steady flow under the pressure gradient $-k\mathbf{e}_x$ between horizontally infinite top and bottom boundaries that are insulating, except for a highly conducting disk that is inset into one of them. Far upstream and far downstream of the disk, $\mathbf{E} = -E_0\mathbf{e}_z$ and $\mathbf{J} = J\mathbf{e}_z$, as in Sec. 3; but $\mathbf{E}$ and $\mathbf{J}$ are distorted near the disk, which is an equipotential. The return current takes the path of least resistance and returns (where possible) through the disk rather than within the Hartmann layers. Where this happens, the flow is reduced by the $O(M^{-1})$ factor of Sec. 3. The plug flow, therefore, passes around the cylinder whose surface touches the perimeter of the disk and whose axis is parallel to $\mathbf{B}_0$, almost as though that cylinder were solid rather than fluid (Fig. 7). This is another striking example of the two-dimensionality imposed by a large $\mathbf{B}_0$. The surface of the cylinder is not infinitely sharp but is a free shear layer of the type described in Sec. 3.3. Its thickness would be $O(\delta_S)$ ($\propto M^{-1/2}$) were it not for instabilities that create turbulence that thickens the layer (see Sec. IV.V.4 of Moreau, 1990).

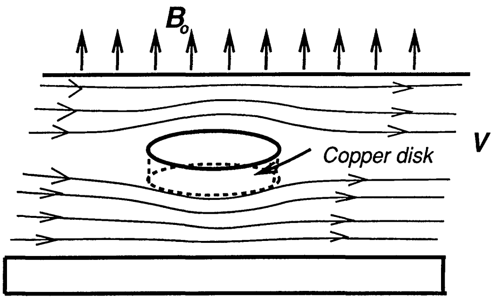

FIG. 7. Flow down an insulating rectangular duct in which the bottom wall contains a copper disk. When the applied field is strong, the flow is almost stagnant within a cylinder with axis parallel to $\mathbf{B}_0$ and passing through the perimeter of the disk, and the flow elsewhere passes around that cylinder, almost as though it were a solid obstacle.

As a second and similar example, consider flow past an insulating three-dimensional (3D) obstacle placed in an otherwise unidirectional flow between parallel insulating planes in the presence of a strong ($M \gg 1$) uniform applied field. Again, the flow is almost 2D and flows around the cylinder formed by the tangents to the obstacle that are parallel to the field, that cylinder being itself surrounded by a free shear layer that is singular on the curves of tangency. An expression for the drag on the obstacle can be derived theoretically and tested experimentally (see Sec. 5.5 of Moreau, 1990).

Numerous cases of practical importance involve ducts of varying cross section lying in spatially varying magnetic fields; e.g., $\mathbf{B}_0 = \mathbf{B}_0(x)$. Then $\mathbf{V}$, $\mathbf{b}$, and $\mathbf{J}$ also vary with x but in a way that can often be simply understood when $M \gg 1$ by applying a simple physical principle (see Sec. 6.3): Suppose that the changes in $\mathbf{B}_0$ and cross section are "abrupt" or, more precisely, that they occur over an x length short compared with $\mathcal{L}M^{1/2}$, where $\mathcal{L}$ is a cross-section dimension. Then, in the vicinity of the abrupt changes, streamlines and current lines follow *characteristic surfaces*. These are defined as surfaces composed of lines of force of $\mathbf{B}_0$ and are such that

$$\int \frac{dl}{B_0} = \text{constant}, \qquad (87)$$

where the integration is taken along the segment of the line of force lying within the duct. Each value of the constant in Eq. (87) defines a different characteristic surface.

As an application, suppose that the field applied across the circular duct considered in Sec. 3.3 depends on x. Since $\mathbf{B}_0$ is a potential field, we should not simply assume that $\mathbf{B}_0 = B_0(x)\mathbf{e}_y$; we should include a y-dependent x component in $\mathbf{B}_0$. So, for definiteness, suppose that the change in B_0 occurs in an interval $-a < x < a$ in which B_{0x} is nonzero and that $\mathbf{B}_0 = B_0(x)\mathbf{e}_y$ in $x > a$ is only half what it is in $x < -a$. The characteristic surfaces are planes of constant z in $|x| > a$. According to Eq. (87), the plane at $z = z'$ (say) for $x < -a$ becomes the plane $z = \frac{1}{2}\sqrt{3a^2 + z'^2}$ in $x > a$. Thus, the streamlines in the segment $-a < x < a$ move outward toward either T_1 (for $z' < 0$) or T_2 (for $z' > 0$); the situation in the xz plane is sketched in Fig. 8. Since the width of the characteristic surface is reduced by two, the flow speed must increase correspondingly, and the velocity profile becomes "M-shaped." The central streamline (shown dashed) splits into two streamlines, and according to Eq. (87), the fluid is stagnant between them, $\mathbf{V}$ being (weakly) singular as they are approached from the outside. In reality, since Eq. (87) is not exact, the flow is nowhere infinite and there are slowly moving trapped eddies between the streamlines. Of course, the profile must approach the solution (85), with the appropriately reduced B_0, as $x \to +\infty$; and, in fact, for a distance of order $aM^{1/2}$ both ahead of and behind the interval $-a < x < a$, there are regions of adjustment. For more details, see Ch. IV of Moreau (1990).

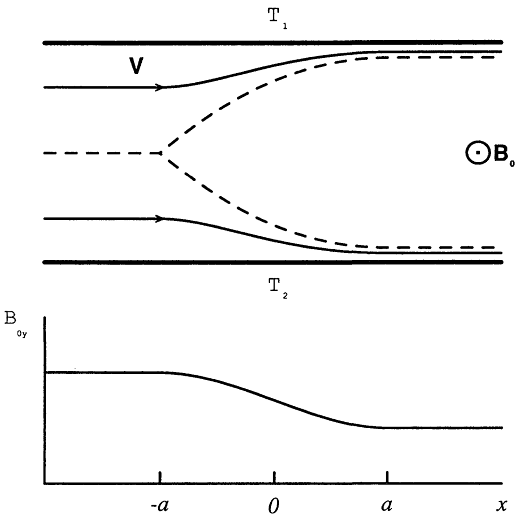

FIG. 8. Flow down a circular pipe when the applied field is halved. When the applied field is strong, the flow approximately follows the characteristic surfaces (87), and the streamlines therefore crowd toward the edges of the duct, leaving a stagnant area in the middle, so producing an M-shaped velocity profile.

5. HIGH FREQUENCIES; LEVITATION, HEATING, AND STIRRING

Suppose that current-carrying coils create in free space a nonuniform ac field, $\mathbf{B}_0 = \Re[\hat{\mathbf{B}}_0 \exp(i\omega t)]$, so that outside the coils, $\hat{\mathbf{B}}_0$ is a potential field ($\nabla \cdot \hat{\mathbf{B}}_0 = 0, \nabla \times \hat{\mathbf{B}}_0 = 0$). (In what follows, $\Re$, which stands for the real part of the expression it precedes, will be omitted but implied.) Now suppose that a solid block of material, V, is introduced. The field $\mathbf{B}_0$ will diffuse into V, and if $\omega = 0$, it will do so completely, the final field being everywhere the same as the initial field. If $\omega \neq 0$, the penetration of $\mathbf{B}_0$ will be less complete, and if $R_\omega \gg 1$, where

$$R_\omega = \omega \mathscr{L}^2/\eta \qquad (88)$$

is a new magnetic Reynolds number (sometimes called the "magnetic shielding parameter" to distinguish it from R), the field will penetrate the conductor only to a small *skin depth*,

$$\delta_\eta = (2\eta/\omega)^{1/2}. \qquad (89)$$

It is the strong induced current flowing in this skin that creates an induced field $\mathbf{b} = \tilde{\mathbf{b}} \times \exp(i\omega t)$ equal and opposite to $\hat{\mathbf{B}}_0 \exp(i\omega t)$ in V, i.e., which *expels* the applied field from V, apart from the thin skin on its surface S (see also Sec. 9.2). The component B_n of the total field $\mathbf{B} = \mathbf{B}_0 + \mathbf{b}$ normal to S is zero to a first approximation, and the tangential component $\mathbf{B}_H = \hat{\mathbf{B}}_H \exp(i\omega t)$ differs from the tangential component of $\mathbf{B}_0$. The skin currents are of order $\mathbf{J} = \mathbf{B}_H/\mu_0\delta_\eta$ and produce a field (**b**) that is comparable with $\mathbf{B}_0$ on S but that decreases with distance from V. They dissipate energy at an average rate $|\overline{J^2}|/\sigma \approx \sigma^{-1}(|\hat{\mathbf{B}}_H|/2\mu_0\delta_\eta)^2 \exp(-2z/\delta_\eta)$, and, integrated through the depth of the skin, they heat S at the rate $|\hat{\mathbf{B}}_H|^2/2\mu_0^2\sigma\delta_\eta$ per unit area.

On the outer (vacuum) side of the skin layer, the magnetic pressure is $B_H^2/2\mu_0$, and on the inner, field-free side, there is no magnetic stress. The net force per unit area on the skin, and hence on V, is therefore $B_H^2/2\mu_0$, and this has a nonzero mean: $|\hat{\mathbf{B}}_H|^2/4\mu_0$. When placed in a suitably chosen $\mathbf{B}_0$, the force can *levitate* the solid. This forms the basic idea of an almost perfect furnace, in which the metal is both levitated and heated by the field and is kept free of contamination from walls (see Fig. 9). (The composition of the atmosphere surrounding the furnace is carefully controlled.)

When the metal has been heated past its melting point, it might flow out of the levitating field and a challenging problem arises in *magnetohydrostatics*, namely, how to design the external coils and so "shape" $\hat{\mathbf{B}}_0$ that it can levitate a *fluid* conductor. This is a nontrivial free-boundary problem, i.e., to find S such that the following conditions are satisfied:

1. $\hat{\mathbf{B}}$ is everywhere tangential to S;
2. the interior V of S contains the correct volume of (incompressible) conductor;
3. the stresses across each element of S balance; i.e.,

$$\frac{|\hat{\mathbf{B}}_H|^2}{4\mu_0} + p_{\mathrm{atm}} = p_0 - \rho g z - \tilde{\gamma}\left(\frac{1}{R_1} + \frac{1}{R_2}\right). \tag{90}$$

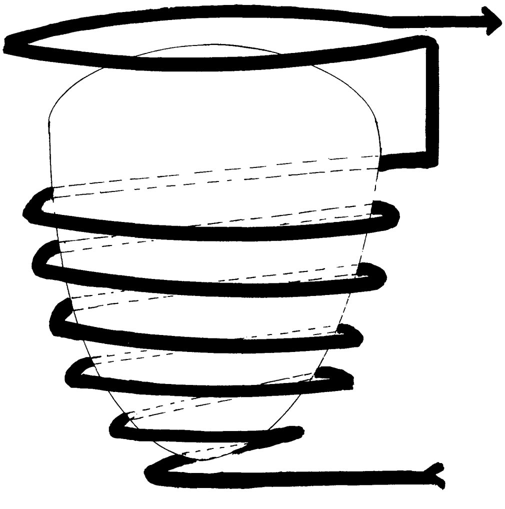

FIG. 9. Schematic of a levitated furnace. The metal is melted and supported by ac currents flowing in the lower coil and is stabilized by the current loop at the top.

Here, p_{atm} is the (constant) atmospheric pressure; p_0 is constant, $p_0 - \rho g z$ being the hydrostatic pressure in V; g is the acceleration due to gravity; z is height; $\tilde{\gamma}$ is the coefficient of surface tension; and R_1 and R_2 are the principal radii of curvature of S. Surface tension is required to prevent the metal from flowing out of the bottom of the furnace at which, since it lies on the axis of symmetry, $\mathbf{B} = 0$.

There is an equivalent, and very useful, variational way of finding S, namely, that of minimizing $W_g + W_\gamma - W_m$, where

$$\begin{aligned} W_g &= \int_V \rho g z\, dV, \quad W_\gamma = \tilde{\gamma} \oint_H dS, \\ W_m &= \int_{\hat{V}} \frac{\overline{\mathbf{B}^2}}{2\mu_0}\, dV, \end{aligned} \tag{91}$$

with the proviso that the currents in the external coils are fixed so that $\hat{\mathbf{B}}_0$ is constant. This proviso accounts for the at first surprising minus sign in the quantity to be minimized; the sources maintaining $\mathbf{B}_0$ supply energy $2W_m$, on average. Clearly, Eqs. (91) define the total gravitational, surface, and magnetic energies.

Even after S has been found, one important question should be addressed: Is the configuration stable? A similar question is even more significant in our later discussion of magnetostatic equilibria (Sec. 8).

There are two reasons why the furnace is not strictly in magnetostatic balance. First, in addition to the mean magnetic pressure that levitates V, there are fluctuating stresses that create oscillations in V of frequency 2ω. Because of the inertia of the fluid, the amplitude of these oscillations is usually small and can be safely ignored. Second, $B_n = 0$ on S only to leading order; in the next approximation, $B_n = O(\delta_\eta B_H/\mathcal{L})$. There is, then, in addition to the magnetic pressure, a smaller tangential magnetic stress of order $B_n B_H/\mu_0 \approx \delta_\eta B_H^2/\mu_0\mathcal{L}$. This stress has a nonzero average that causes slow circulations which stir the interior of the furnace (see Sec. VI.V of Moreau, 1990).

Suppose that the external coils are placed symmetrically about Oz; let the currents they carry have frequency ω but be phase shifted in such a way that a *rotating* axisymmetric $\mathbf{B}_0$ is created: i.e., $\mathbf{B}_0 = \hat{\mathbf{B}}_0(s, z) \exp[i(m\phi - \omega t)]$, where (s, ϕ, z) are cylindrical coordinates and $m > 0$ is an integer. When the body V is axisymmetric about Oz and $\delta_\eta \ll \mathcal{L}$, an electromagnetic skin again forms on S that expels $\mathbf{B}_0$ and heats V. As before, a magnetic pressure $B_H^2/2\mu_0$ acts on S, which has a nonzero average and can levitate V. In addition, there is a tangential stress that exerts a torque about Oz of order $m\delta_\eta B_H^2/2\mu_0$ per unit area of S; the rotating field imparts a rotation to V in the same sense—an example of Lenz's law. For further discussion, including reports on experiments and analyses of cases in which R_ω is not large, see Sec. VI.VI of Moreau (1990).

6. INFINITELY CONDUCTING FLUIDS

6.1 Alfvén's Theorem

At the start of Sec. 5, we noted that, if a conducting *solid* V were placed in a steady field $\hat{\mathbf{B}}_0$, that field would diffuse into V and ultimately take up its initial configuration everywhere. Suppose that the currents in the coils generating the field *subsequently* start to oscillate with frequency ω, where $R_\omega \gg 1$. The steady $\hat{\mathbf{B}}_0$ is then replaced outside V by $\mathbf{B}_0 = \hat{\mathbf{B}}_0 \exp(i\omega t)$. As in Sec. 5, an electromagnetic skin forms on S that shields the interior of V from the externally changing $\mathbf{B}_0$; i.e., the field $\hat{\mathbf{B}}_0$ present in V before the oscillation commenced is unchanged beneath the skin on S. This may also be seen from the induction equation (22) for $\mathbf{V} = 0$:

$$\frac{\partial \mathbf{B}}{\partial t} = \eta \nabla^2 \mathbf{B} = \frac{\omega \delta_\eta^2}{2} \nabla^2 \mathbf{B}. \tag{92}$$

Beneath the skin, $\nabla = O(\mathcal{L}^{-1})$. Since $\delta_\eta \ll \mathcal{L}$, Eq. (92) reduces in leading order to $\partial \mathbf{B}/\partial t \approx 0$, just as though one had formally set $\sigma = \infty$ in Eq. (22), i.e., just as though the solid were a perfect conductor.

There is another way of interpreting this result: the time scale over which the flux threading a conductor can change significantly is $\tau_\eta = \mu_0 \sigma \mathcal{L}^2$, where $\mathcal{L}$ is the length scale over which the field varies. For example (see Sec. 10.3), the field in a stationary conductor that has no sources to maintain it will disappear in a time of order τ_η. In the present case, the period of the external sources is $\tau_P = 2\pi/\omega$, and since $R_\omega \equiv 2\pi\tau_\eta/\tau_P \gg 1$, the flux of field through V has no time to change before those sources reverse.

The omission of $\nabla^2 \mathbf{B}$ from Eq. (22) for regions far from boundary layers (and other singular layers; see Sec. 9) applies more generally to a fluid, provided that $R_\omega \gg 1$ or $R \gg 1$. Equation (22) then reduces to Eq. (25); i.e.,

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{V} \times \mathbf{B}), \tag{93}$$

which is analogous to the equation of classical fluid mechanics that governs the vorticity $\boldsymbol{\omega}$ $(= \nabla \times \mathbf{V})$ in an inviscid, incompressible (or barotropic) fluid:

$$\frac{\partial \boldsymbol{\omega}}{\partial t} = \nabla \times (\mathbf{V} \times \boldsymbol{\omega}). \tag{94}$$

From Eq. (94), the *Kelvin–Helmholtz theorem* follows: vortex lines are material curves; i.e., vortex lines are "frozen" into the fluid as it moves. Similarly, *Alfvén's theorem* follows from Eq. (92): *Magnetic lines of force are frozen into an infinitely conducting fluid as it moves.* This property allows a completely new type of wave motion, one that belongs to MHD but not to classical fluid mechanics or to em theory: the *Alfvén wave,* sometimes also called the *hydromagnetic wave.*

6.2 Waves and Shocks

We recall that the Maxwell stresses associated with a field $\mathbf{B}$ consist of an isotropic (magnetic) pressure $B^2/2\mu_0$, which is for the moment irrelevant, together with a tension B^2/μ_0 along field lines. A flux tube, composed of a bundle of field lines of cross-sectional area $\mathcal{A}$, is therefore in a tension of $\mathcal{A}B^2/\mu_0$ and carries frozen within it a mass per unit length of $\mathcal{A}\rho$. Thus, like an elastic string, it can transmit a transverse wave in either direction along the tube with speed $V_{\mathrm{A}} = \sqrt{(\mathcal{A}B^2/\mu_0)/(\mathcal{A}\rho)}$, i.e., with the Alfvén velocity

$$\mathbf{V}_{\mathrm{A}} = \mathbf{B}/\sqrt{\mu_0 \rho}. \tag{95}$$

These Alfvén waves are transverse to a uniform **B** and are nondispersive. They define a new time scale, $\tau_A = \mathcal{L}/V_A$, the time taken by an Alfvén wave to cross a system of dimensions $\mathcal{L}$.

Returning now to the conductor V containing the trapped field $\hat{\mathbf{B}}_0$ and lying in the oscillatory field $\mathbf{B}_0 = \hat{\mathbf{B}}_0 \exp(i\omega t)$, where $R_\omega \gg 1$, we now suppose that V is an initially stationary *fluid* and we recognize a remarkable fact: the boundary layer on S (which is actually now a Hartmann layer) is no longer able to shield the interior of V from $\mathbf{B}_0$. News of the external variations is radiated throughout V by Alfvén waves. This radiation consists of vibrations of the field lines of the trapped $\hat{\mathbf{B}}_0$; by Alfvén's theorem, the flux threading the conductor beneath the Hartmann layer cannot change.

In a moving medium, the frequency of Alfvén waves is Doppler shifted in the obvious way. For example, the velocities of waves that ride on an *aligned flow*, i.e., one in which **V** is parallel to **B**, are $\mathbf{V} \pm \mathbf{V}_A$. If the *Alfvén number* (also called the *magnetic Mach number*), defined by

$$A = \mathcal{V}/\mathcal{V}_A, \tag{96}$$

is less than 1, one wave moves upstream and the other downstream, but if $A > 1$, both Alfvén waves travel downstream. If a body is placed in an aligned flow, it will create an upstream wake if $A < 1$ (see Sec. V.III of Moreau, 1990).

When $\mathbf{B}_0 = B_0\mathbf{e}_z$ is uniform,

$$\begin{aligned} \mathbf{V} &= \mathbf{V}(x, y, z \mp V_A t), \\ \mathbf{b} \equiv \mathbf{B} - \mathbf{B}_0 &= \mp \frac{1}{\sqrt{\mu_0 \rho}} \mathbf{V}(x, y, z \mp V_A t) \end{aligned} \tag{97}$$

satisfy the MHD equations exactly for **V** of arbitrary amplitude, provided $\nabla \cdot \mathbf{V} = 0$; their passage leaves the magnetic pressure unchanged. They correspond to waves traveling parallel (upper sign) or antiparallel (lower sign) to $\mathbf{B}_0$. Since the fluid is dissipationless, it may be assumed that **V** is discontinuous; if we then transform to a frame moving with the wave carrying the discontinuity and compare Eq. (61) with Eqs. (95) and (97), we see that the rotational discontinuity of Sec. 2.2 is merely a finite-amplitude Alfvén wave having a discontinuous profile. A linear combination of waves (97) does not satisfy the MHD equations unless the waves are of infinitesimal amplitude.

When the fluid is compressible, two further types of plane waves arise: *fast waves* and *slow waves*. Assuming that **B** and ρ are uniform and that the waves are infinitesimal, they have phase velocities

$$\begin{aligned} c_{f,s} &= \tfrac{1}{2}\sqrt{a^2 + V_A^2 + 2aV_A|\cos\theta|} \\ &\quad \pm \tfrac{1}{2}\sqrt{a^2 + V_A^2 - 2aV_A|\cos\theta|}, \end{aligned} \tag{98}$$

where a is the speed of sound, θ is the angle between **B** and the wave vector **k**, and the upper (lower) sign refers to the fast (slow) wave. Clearly, in a compressible medium, there are in addition to τ_A two further significant time scales: $\tau_f = \mathcal{L}/c_f$ and $\tau_s = \mathcal{L}/c_s$.

The fast and slow waves are dispersive. Their polarizations (defined by the direction of **V**) lie in the plane of **B** and **k**; the direction perpendicular to that plane defines the direction of polarization of the pure Alfvén wave discussed earlier, which exists unchanged in a compressible medium (since it does not affect ρ) and which is often called an *intermediate wave*; its phase speed is, as before, $V_A \times |\cos\theta| = c_f c_s/a$. This is also approximately the phase speed of the slow wave when $a \gg V_A$, and in this case, the polarizations of slow and intermediate waves are almost perpendicular to one another and to **B**. They are then essentially the Alfvén waves of the incompressible fluid, while the fast wave becomes an acoustic wave.

MHD shocks occur in many contexts. Perhaps the best known example is the bow shock, created where the solar wind encounters the magnetosphere and resembling the shock that occurs in Earth's atmosphere ahead of a supersonically moving blunt object. Figure 10 is a conceptual (overidealized) sketch of Earth's vicinity, the Dungey (1961) picture of the flow of the solar wind around the Earth in the interesting case in which the interplanetary magnetic field (IMF), generated in the Sun and carried to Earth by the solar wind, is in a direction opposite to the magnetic field of Earth. (It would be more realistic, but less clear for our purposes, to show Earth's dipole and the IMF tilted with respect to the ecliptic and to include components of **B** out of the plane shown.) The bow shock is a fast MHD shock of the type considered below. The magnetopause is the boundary of the mag-

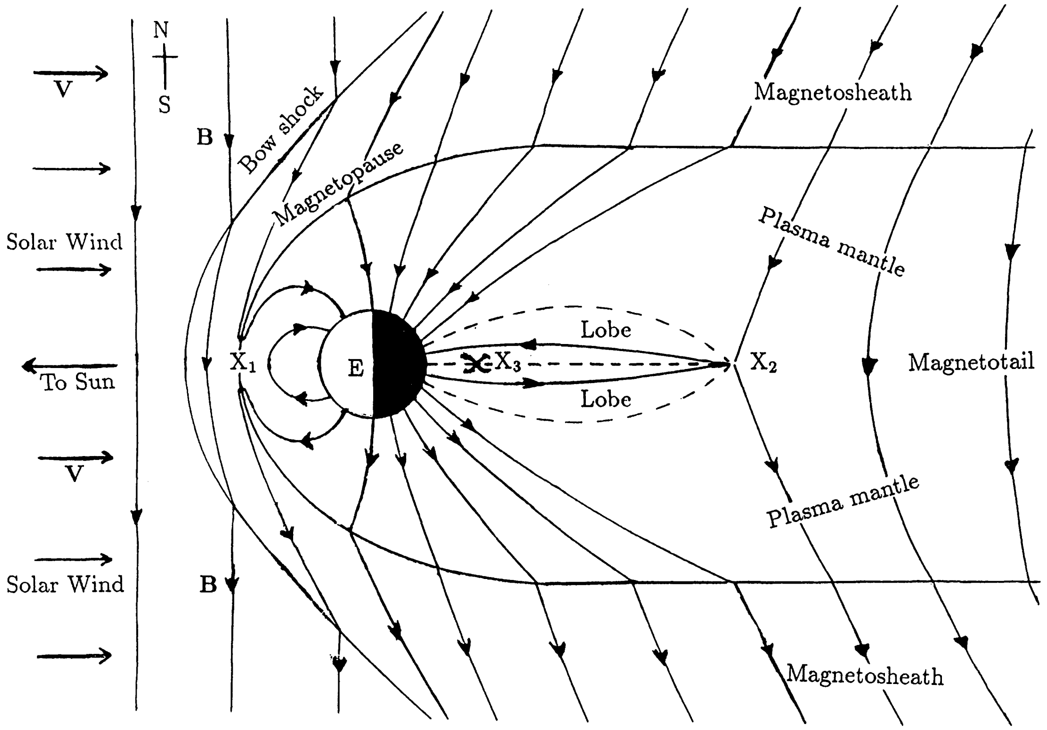

FIG. 10. Schematic of the Dungey model for the magnetic field in the vicinity of Earth (not to scale). The case in which the interplanetary magnetic field is antiparallel to the geomagnetic field is sketched. The bow shock is shown. Field line reconnection occurs at X_1 and X_2; further reconnection may take place on the neutral line between Earth (E) and X_2, as indicated by X_3 (see Sec. 9.4).

netosphere. There is little exchange of plasma across the magnetopause, and in a first approximation, one can think of the solar wind as flowing past a solid body whose boundary is the magnetopause. The shape of that body is, however, constantly altering as the MHD state of the solar wind changes. It appears that the magnetopause can be thought of as a contact discontinuity (Sec. 2.2) or, when material crosses from one side to the other, as an intermediate shock (see below). For future reference, we may observe three further features of Fig. 10. First, reconnection of field lines takes place at X_1, the head of the bow shock. Second, field line reconnection also occurs in the magnetotail, where the IMF detaches from Earth's field at a second neutral point X_2. Reconnection at these X-type neutral points is discussed in Sec. 9.3, where it is noted that slow shocks of the type described below are involved in the process of reconnection. Third, along the neutral line EX_2 of Fig. 10, there is a strong "northward" shear in the magnetic field, making it a favorable environment for tearing instabilities that create further points of reconnection, such as the one indicated by X_3 in Fig. 10 (see Sec. 9.4).

When treated as discontinuities, MHD shocks must satisfy the relations derived in Sec. 2.2. It follows from conditions (54), (56), and (59) that

$$\left(\frac{B_n^2}{\mu_0 j} - V_{n1}\right)\mathbf{B}_{H1} = \left(\frac{B_n^2}{\mu_0 j} - V_{n2}\right)\mathbf{B}_{H2}, \qquad (99)$$

so that **B** on one side of the shock lies in the plane defined by **B** and **n** on the other; conditions (56) and (59) show that **V** lies in the same plane Π on each side of the shock. In this coplanarity, MHD shocks differ fundamentally from the rotational discontinuity described in Sec. 2.2.

In categorizing MHD shocks, it has proven helpful to divide possible fluid states into four classes, differing by the normal flow speed in a reference frame in which the shock is at rest:

State 1. $V_n > c_f$;
State 2. $V_A < V_n < c_f$;
State 3. $c_s < V_n < V_A$; and
State 4. $V_n < c_s$.

Condition (60) allows six possibilities for the incoming → outgoing transitions: 1 → 2; 1 → 3; 1 → 4; 2 → 3; 2 → 4; and 3 → 4, all of which are compressive, i.e., the density of the gas is increased in passing through the shock.

The easiest transitions to understand are the first and the last, the *fast shock* and the *slow shock*, respectively; the remainder are called *intermediate shocks*. It follows from Eq. (99) that $\mathbf{B}_{H1}$ and $\mathbf{B}_{H2}$ are parallel for a fast shock and a slow shock and that they are antiparallel for intermediate shocks. Further, the strength of the transverse field is increased by a fast shock but decreased by a slow shock. Two marginal states can be approached:

1. $V_n = V_{A1}$, i.e., $1 \rightarrow (2 = 3)$, defines the "switch-on shock," so named because, by Eq. (99), $\mathbf{B}_{H1} = 0$, and
2. $V_n = V_{A2}$, i.e., $(2 = 3) \rightarrow 4$, defines the "switch-off shock," so named because $\mathbf{B}_{H2} = 0$.

See also Landau *et al.* (1984).

Situations in which the front separates states of oppositely directed $\mathbf{B}_H$ are particularly significant for reconnection processes and are, therefore, of special theoretical interest. Akhiezer *et al.* (1959), Germain (1960), and Kantrowitz and Petschek (1966) argued, from three different points of view, that intermediate shocks are unphysical and cannot arise. Consider, for example, the point of view of Germain (1960). He generalized to MHD the very successful theory of weak, non-MHD shocks [see, for example, Sec. 89 of Landau and Lifshitz (1987)]. According to this "classical" theory, it is always possible to connect two neighboring states on the same Hugoniot [i.e., related by $I_1 - I_2 + \frac{1}{2}(p_1 + p_2)(\rho_1^{-1} - \rho_2^{-1}) = 0$ and, therefore, satisfying the Rankine–Hugoniot conditions] by a thick shock front governed by the dissipative continuum equations. Although there is still no satisfactory theory of a strong shock front, it is an article of faith that solutions of the Boltzmann equation exist that similarly connect two distant states on the same Hugoniot by a shock front having a thickness of the order of a mean free path. In this way, the idea arises naturally that the discontinuity theory of shocks always gives results that can in principle arise in nature.

In the MHD case, a solution of the dissipative MHD equations can always be found to connect a state 1 to a neighboring state 2 or to connect a state 3 to a neighboring state 4. Thus, the discontinuity theory is on firm ground for weak fast and weak slow shocks. Germain (1960) proved, however, that, for *some* specifications of the transport parameters (shear and bulk viscosities and electrical and thermal conductivities), no solution of the dissipative MHD equations exists to bring about an intermediate transition (such as 1 → 3). In *these* circumstances, the discontinuity theory fails, and this led (erroneously) to the conclusion that intermediate shocks are unphysical in *all* circumstances. Rotational discontinuities were invoked to connect states where $\mathbf{B}_H$ switches direction at the front.

Recent research has led to an amusing reversal of ideas. Computer solutions for weak fronts have shown that, in situations such as those described above in which Germain (1960) had shown that no intermediate shock is possible, two or more shocks evolve, one intermediate and the other(s) fast or slow. These together effect the required intermediate transition (such as 1 → 3). It was also shown that rotational discontinuities cannot be involved in any way. Paradoxically, however, $\mathbf{B}_H$ may have a nonzero component perpendicular to Π that is confined to the interior of an intermediate shock front. The topic is one of some complexity (see Wu, 1992).

6.3 Creation of Magnetic Energy

Alfvén's theorem provides an almost indispensable aid to MHD thought: the evolution of $\mathbf{B}$ is more readily pictured in concrete terms as the motion of field lines frozen into the fluid than in abstract mathematical terms as a solution of Eq. (25).

As an example, consider two ways in which energy is converted from kinetic to magnetic forms. Imagine a tube of magnetic flux of radius a_0 and length L_0 containing a uniform field B_0 and surrounded by force-free fluid. Suppose that an inward radial motion toward the axis of the tube compresses the tube symmetrically until its radius is reduced to $a < a_0$ and the (uniform) field it contains becomes B. Since the strength κ of the tube (defined as the flux of magnetic field through any cross section) remains the same by Alfvén's theorem, $\pi a^2 B = \pi a_0^2 B_0 = \kappa$. The trapped magnetic energy per unit length of tube is increased, however, by a factor of $(a_0/a)^2$, from $\pi a_0^2 B_0^2/2\mu_0 = \kappa^2/2\pi\mu_0 a_0^2$ to $\pi a^2 B^2/2\mu_0 = \kappa^2/2\pi\mu_0 a^2$. This increase represents the work done by the motion compressing the tube against the magnetic pressure in the tube (which increases during the compression). During the compression, B/ρ does not change. (This is a consequence of Cauchy's integral in MHD.)

Magnetic energy can be increased by stretching the flux tube to a length of $L > L_0$, say. This mechanism also works in an incompressible fluid for which volume is preserved and for which the stretching requires that the cross section is reduced by a factor of L_0/L; it follows that B is enhanced by a factor of L/L_0 and the magnetic energy of the tube is increased by the factor $(L/L_0)^2$, without altering the pressure within the tube. The increase in magnetic energy is now supplied by the work done by the motion against the tension in the tube (which increases during the stretching).

The proportionality of B and L during the stretching of field lines lies at the heart of the principle invoked in Sec. 4 to explain how duct flow changes at abrupt variations in cross section or applied field. The strength of electric current in a duct at large M is dynamically determined and may be small compared with both the induced emf and **E**. Then, despite the smallness of R, the last term of Eq. (21) is negligible, Alfvén's theorem follows, and the characteristic surfaces defined by Eq. (87) become significant.

6.4 Magnetic Helicity

The topology of field lines cannot change when $\sigma = \infty$. This has attracted much theoretical interest [see, for example, Moffatt *et al.* (1992)]. One of the best known topological connections arises from the constancy of the *magnetic helicity*. This quantity, sometimes also called the "Woltjer invariant" after its discoverer, is defined by

$$H_M = \oint \mathbf{A} \cdot \mathbf{B} dV \qquad (100)$$

taken over the interior of any closed *magnetic surface*, which is a surface S such that

$$\mathbf{n} \cdot \mathbf{B} = 0, \quad \text{on S}. \qquad (101)$$

Here, **A** is a vector potential which by Eq. (25) obeys

$$\frac{\partial \mathbf{A}}{\partial t} = \mathbf{V} \times (\nabla \times \mathbf{A}) + \nabla \Phi \qquad (102)$$

for some Φ. The integral (100) is independent of the gauge chosen for the vector potential **A** of **B**, i.e., of the arbitrary gradient that can be added to **A** without disturbing the relationship $\mathbf{B} = \nabla \times \mathbf{A}$. From Eqs. (25), (101), and (102), it follows that $dH/dt = 0$; i.e., H is constant in a perfect fluid.

The topological connection can be clarified with the help of the Biot–Savart representation

$$\mathbf{A}(\mathbf{x}) = \frac{1}{4\pi} \int_{\text{all space}} \frac{\mathbf{B}(\mathbf{x}') \times (\mathbf{x} - \mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|^3} dV. \qquad (103)$$

Suppose that **B** vanishes everywhere except in the two flux tubes, of strength κ_1 and κ_2 and filling volumes V_1 and V_2, depicted in Fig. 11. Then,

$$H = H_1 + H_2 + H_{12} + H_{21}, \qquad (104)$$

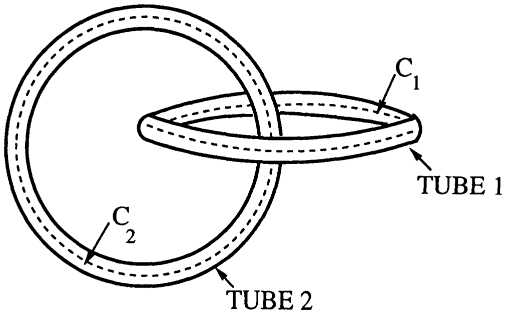

FIG. 11. Linked flux tubes with nonzero mutual helicity. In the limit in which the tubes have infinitesimal cross sections, the mutual helicity is the product of the strengths of the tubes and the winding number (here, ±1) which is Gauss' measure of topological linkage of two curves.

where

$$H_l = \frac{1}{4\pi}\int_{V_l}\int_{V_l} \frac{(\mathbf{x}-\mathbf{x}')\cdot[\mathbf{B}(\mathbf{x})\times\mathbf{B}(\mathbf{x}')]}{|\mathbf{x}-\mathbf{x}'|^3}\,dV dV' \tag{105}$$

is the self-helicity of flux tube l, where $l = 1$ or 2 and

$$H_{12} = H_{21} = \frac{1}{4\pi}\int_{V_1}\int_{V_2} \frac{(\mathbf{x}_1-\mathbf{x}_2)\cdot[\mathbf{B}(\mathbf{x}_1)\times\mathbf{B}(\mathbf{x}_2)]}{|\mathbf{x}_1-\mathbf{x}_2|^3}\,dV_1 dV_2 \tag{106}$$

is their mutual helicity.

Now suppose the flux tubes to be of infinitesimal cross section, surrounding the closed field lines C_1 and C_2. Then, Eq. (106) reduces to

$$H_{12} = H_{22} = \kappa_1\kappa_2 N_{12}, \tag{107}$$

where

$$N_{12} = \frac{1}{4\pi}\oint_{C_1}\oint_{C_2} \frac{(\mathbf{x}_1-\mathbf{x}_2)\cdot(d\mathbf{x}_1\times d\mathbf{x}_2)}{|\mathbf{x}_1-\mathbf{x}_2|^3}\,dC_1 dC_2 \tag{108}$$

is the "winding number," first isolated by Gauss, who showed that $|N_{12}|$ is an integer equal to the number of times C_1 threads C_2 before closing. If the field lines are disconnected, $|N_{12}| = 0$; in the topology of Fig. 11, $|N_{12}| = 1$.

Ohmic dissipation causes magnetic helicity to dissipate at a rate proportional to $\mathbf{B}\cdot\mathbf{J}/\sigma$ per unit volume, which may be compared with the rate of dissipation of magnetic energy $\epsilon_\eta = J^2/\sigma$. In a turbulent conductor, in which $\mathcal{J} = O(\mathcal{B}/\mu_0 l)$, where the correlation length l of the turbulence is small compared with $\mathcal{L}$, the scale of the system, the rate of dissipation of H_M is much smaller than that of E_M (see Sec. 9.3).

6.5 The Lundquist Number

Despite the usefulness of Alfvén's theorem in visualizing MHD processes, it is wise to bear constantly in mind that, in reality, σ is not infinite, that field lines diffuse relative to the fluid at a rate proportional to η, and that the frozen-field picture may be seriously misleading if applied over time scales comparable with τ_η, or perhaps even shorter (see Sec. 9.4).

Alfvén waves are damped by Ohmic resistance and by viscosity. In a frame moving with the wave, they decay on a time scale of $\tau_D = \mathcal{L}^2/(\nu + \eta)$, where $\mathcal{L}$ is their wavelength. Often, $p_m \ll 1$ and we may therefore replace τ_D by τ_η. The waves then travel a distance of $\mathcal{V}_A\tau_\eta$ through a conductor V before dissipating. An important parameter is clearly the *Lundquist number*:

$$S = \mathcal{V}_A\tau_\eta/\mathcal{L} = \tau_\eta/\tau_A = p_m^{1/2}M = \mathcal{V}_A\mathcal{L}/\eta, \tag{109}$$

where $\mathcal{L}$ is the scale of V. Thus, S resembles the magnetic Reynolds number (86), but with $\mathcal{V}$ replaced by $\mathcal{V}_A$. If $S \gg 1$, Alfvén waves cross V in an *Alfvén time*, $\tau_A = \mathcal{L}/\mathcal{V}_A$, short compared with τ_η and are, therefore, scarcely attenuated; if $S \ll 1$, they are damped out after traveling only a small fraction of $\mathcal{L}$. Although large M can be attained in liquid-metal facilities, it is more difficult to make S large since $p_m \ll 1$ for most available fluids. Large S can be attained in plasma experiments. Usually $S \gg 1$ in geophysical and astrophysical systems because of their enormous scale $\mathcal{L}$ (see Sec. 10).

7. MAGNETOHYDROSTATICS

7.1 Balancing Nonzero Pressure Gradients

A conducting fluid is in magneto(hydro) static equilibrium when Eq. (78) holds. The fluid is unaccelerated and either is stationary or, as in Sec. 3.2, moves so slowly that inertial forces are negligible, the dynamical balance being between the pressure gradient, the Lorentz force, and externally applied forces such as gravity, if any. In the simplest case of no external forces,

$$\mathbf{J}\times\mathbf{B} = \nabla p. \tag{110}$$

If such an equilibrium is disturbed, it will respond on the dynamic time scales of the three types of waves introduced in Sec. 6.2: $\tau_A = \mathcal{L}/V_A$, $\tau_f = \mathcal{L}/c_f$, and $\tau_s = \mathcal{L}/c_s$. The result may, or may not, be an instability that takes the system far from its initial configuration during these time scales (see Sec. 8). Equation (110) expresses a dynamical balance over the three time scales and in particular over τ_A. Clearly, such a balance has little meaning if **B** has evolved during that time through Ohmic diffusion. It is, therefore, implicitly assumed in the study of magnetostatics that $\tau_A \ll \tau_\eta$, i.e., that $S \gg 1$. Here and in Sec. 8, the fluid is assumed to be perfectly conducting: $S = \infty$.

The left-hand side of Eq. (110) is at most $O(\mathcal{B}^2/\mu_0\mathcal{L})$, and the right-hand side is $O(p/\mathcal{L})$, where p is a typical pressure *difference* within the system. It follows that

$$\beta = \mu_0 p/\mathcal{B}^2 \tag{111}$$

is $O(1)$ at most, but it may be zero, as when **B** and **J** are parallel; **B** is then a *force-free field* and

$$\mathbf{J} \times \mathbf{B} = 0. \tag{112}$$

In fusion-reaction technology, where the aim is to promote as many reactions as possible during a "confinement time" in which Eq. (110) approximately holds, it is desirable to design a magnetic bottle that has as large a β as possible, and β is in fact one of the *figures of merit* by which a design is judged. Unfortunately, the larger the β, the more prone the device is to instability. A compromise is necessary, and in practical devices, β generally lies between 0.01 and 0.1. For other figures of merit, see Freidberg (1987).

According to Eq. (110), the lines of force and current lines lie on isobaric magnetic surfaces, which are necessarily multiply connected and which, in 2D plasma configurations, may resemble the axisymmetric set of nested surfaces sketched in Fig. 12. The surfaces surround a single degenerate toroid (the dotted circle shown). The magnetic field has *poloidal* and *toroidal* components, and their sum produces a field that spirals around each isobaric surface without, in general, closing; it is "ergodic." The current lines similarly fill each magnetic surface.

Insight into these *toroidal equilibria*, especially those of large aspect ratio, R/a (see Fig. 12), can be gained from studies of "1D equilibria" such as the *cylindrical equilibria* ($R \rightarrow \infty$) of which the *screw pinch* depicted in Fig. 13(a) is the general case. The word "pinch" refers to the compression of the fluid (or plasma) by the magnetic stresses. The fluid (or plasma) pressure p increases toward the axis $s = 0$, both because of the increase in magnetic pressure $B^2/2\mu_0$ away from the axis and because the poloidal field lines, which girdle the cylinder like hoops around a barrel, exert a *hoop stress* B_ϕ^2/μ_0.

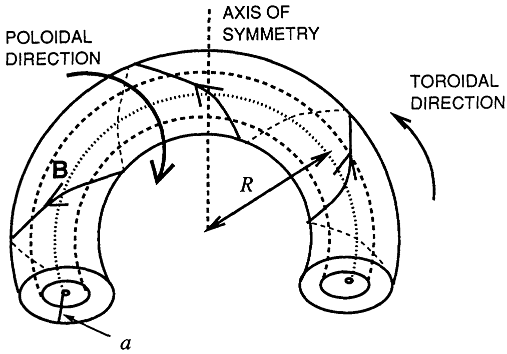

FIG. 12. A toroidal magnetostatic equilibrium. The magnetic surfaces are a set of nested toroids, on which the pressure is constant and about which the lines of force and current lines wind ergodically. Two surfaces are shown (full lines and dashed lines) as well as the degenerate surface (the dotted curve) forming the center of the nest.

Two special cases of the screw pinch have received particular attention in the field of controlled thermonuclear research: the θ

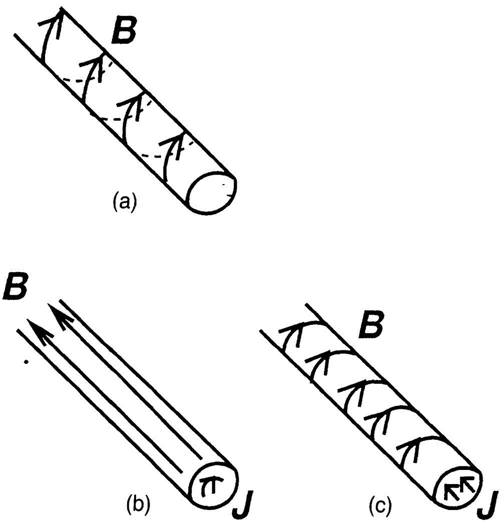

FIG. 13. The general screw pinch and two limiting cases. (a) The general cylindrical pinch, which has nonzero toroidal and poloidal fields. (b) The θ pinch, which has no poloidal field or toroidal current. (c) The Z pinch, which has no toroidal field or poloidal current.

pinch, in which B_ϕ and J_z are zero [Fig. 13(b)], and the Z pinch, in which $B_z = J_\phi = 0$ [Fig. 13(c)]. The latter is the 1D analogue of Ohmically heated Tokomaks, such as ITER (pronounced ē'ta, as in Greek), proposed as the way to controlled thermonuclear fusion in the future. The design envisages a blanket of liquid metal around the reaction chamber, both to remove heat and breed tritium [see Fig. 14 and, for example, Malang *et al.* (1991)]. Such a blanket operates on the same physical principles as those described in Secs. 3 and 4, and, in this sense, the technology of ITER spans MHD more broadly than does the MHD usually encountered in plasma physics.

Also of interest are 3D configurations such as the stellarator, which has no symmetry about an axis and which will not be described here (see Freidberg, 1987).

7.2 Force-Free Fields

In a low-density fluid (such as the solar magnetosphere; see Sec. 10), the pressure gradient can be neglected in comparison with the Lorentz force, and the internal energy density is negligible compared with the magnetic energy density. To a good first approximation, $\beta = 0$. Equation (112) then holds so

FIG. 14. Schematic of ITER (the International Thermonuclear Experimental Reactor). The sketch shows a cross section of the tokomak including the oval reaction chamber and the arrangement of segments of the water-cooled lead-lithium blanket that breeds tritium. (After Malang *et al.*, 1991.)

that, for some field α,

$$\nabla \times \mathbf{B} = \alpha \mathbf{B}. \tag{113}$$

Operating on this with $\nabla\cdot$ using Eq. (3), we see that

$$\mathbf{B} \cdot \nabla \alpha = 0; \tag{114}$$

i.e., α is constant on each line of force. The lines of force and current lines lie on magnetic surfaces of constant α on which they are usually ergodic; i.e., $\alpha = \alpha(v)$, where v is some label for a magnetic surface, e.g., the volume v it contains.

If α is constant in a volume, then the lines of force and current lines will in general be chaotic in that volume, i.e., they will usually be space-filling rather than surface-filling. Such fields, for which

$$\nabla \times \mathbf{B} = \alpha \mathbf{B}, \quad \alpha = \text{constant}, \tag{115}$$

are known as *Beltrami fields*.

A simple Cartesian example illustrating both magnetostatic and force-free (Beltrami) fields was given by Fadeev *et al.* (1965):

$$\mathbf{B} = \frac{B_0}{\cosh kz + \epsilon \cos kx} [\sinh kz, \alpha_0 \sqrt{1 - \epsilon^2}, \epsilon \sin kx], \tag{116}$$

where B_0, k, α_0, and $\epsilon (<1)$ are constants. This is force-free if $\alpha_0 = \pm 1$ and is hydrostatic otherwise, with

$$p = p_\infty + \frac{B_0^2 (1 - \alpha_0^2)(1 - \epsilon^2)}{2\mu_0 (\cosh kz + \epsilon \cos kx)^2},$$

where p_∞ is the pressure at $z = \pm\infty$. Field lines projected onto the xz plane are sketched in Fig. 15. The $\epsilon = 0$ field, $B_0 = B_0 (e_x \tanh kz + \alpha_0 e_y \operatorname{sech} kz)$, is prone to instability through a resistive instability, known as the "tearing mode" (see Sec. 9.4). This instability reconnects the field lines of $\mathbf{B}_0$, and the final result might be a steady state that could be modeled by Eq. (116) with $\epsilon \neq 0$. It has been shown, however, that state (116) is itself prone to a coalescence instability (see Sec. 9.4).

Force-free fields have useful variational properties. We mention two, to which we return in Sec. 9.

7.2.1 First Variational Property Let V be a simply connected volume bounded by a surface S over which B_n is specified. By a well-known theorem of potential theory, the field for which the magnetic energy contained in V is a minimum is harmonic: $\nabla \times \mathbf{B} = 0$ (and as always $\nabla \cdot \mathbf{B} = 0$). Now suppose that, through every point inside V, a line of force passes that meets S in two "footpoints." Suppose not only that B_n is specified over S but also that the correspondence between every such pair of footpoints is fixed; i.e., we envisage that each line of force crossing V can move, but only between fixed end points on S. It can then be shown that the field of minimum magnetic energy is force-free. Thus, if a perfectly conducting fluid is started from an arbitrary initial state and evolves consistently with the constraints, and if the fluid has a dissipation mechanism available such as viscosity, then it will equilibrate to a force-free configuration satisfying Eqs. (113) and (114) for some $\alpha(v)$. Clearly, the constrained minimum energy of the force-free field cannot be less than the unconstrained minimum of the harmonic field. The difference between the two is significant (see Sec. 10.2).

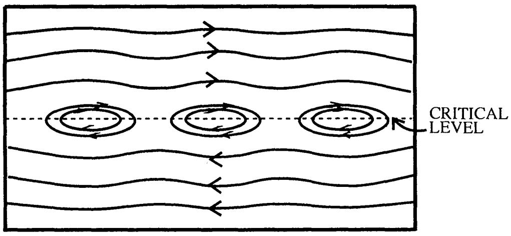

FIG. 15. An example illustrating both magnetostatic and force-free equilibria. This example (Fadeev *et al.*, 1965) has both closed and open field lines. The former, called cat's eyes or magnetic islands, may have been produced by the tearing instability of the sheared field (open field lines) as described in Sec. 9.4.

7.2.2 Second Variational Property Suppose V is not simply connected and that its boundary S is a magnetic surface. For example, the magnetic field configuration might initially resemble that shown in Fig. 12, with the outermost toroid a perfectly conducting wall. The initial configuration is not force-free and will evolve in time, but each magnetic surface possesses a magnetic helicity $H_M(v)$, which, for a perfectly conducting fluid, is conserved during the evolution (see Sec. 6.4). The variational property is this: the state of minimum (magnetic) energy that preserves $H_M(v)$ for each surface is force-free. Thus, if the fluid has a dissipation mechanism available such as viscosity, it will equilibrate to a force-free configuration satisfying Eqs. (113) and (114) for some $\alpha(v)$. But this is not the minimum energy state that it can reach if the constraints are partially lifted. The difference between the two is significant (see Sec. 9.3).

8. IDEAL INSTABILITIES

8.1 Approaches to Stability

It is of vital importance in fusion reactor technology to design stable field configurations that will confine a plasma for a sufficiently long time for a significant number of thermonuclear reactions to take place. A configuration may be unstable through MHD processes or through microscale processes beyond the scope of this review. The most obvious MHD processes are ideal instabilities that can destroy the equilibria discussed in Sec. 7 in a time of order τ_A, which is too short for them to be interesting as potential reactors. Less obviously, a configuration may be threatened by resistive instabilities; i.e., it may seem to be stable when diffusive processes are ignored but is in fact unstable for $\eta \neq 0$. Resistive modes will be discussed in Sec. 9.4. Here, we suppose that

$$\eta = \nu = \kappa = 0. \tag{117}$$

The first step is to study the linear stability of the configuration. It is supposed that the equilibrium state, in which ρ, p, $\mathbf{B}$, ... are denoted by ρ_0, p_0, $\mathbf{B}_0$, ..., is perturbed. As a result, a new state is created in which

$$\rho(\mathrm{x}, t) = \rho_0(\mathrm{x}) + \delta\rho(\mathrm{x}, t), \ldots \tag{118}$$

and which is governed by the ideal MHD equations. This system is *linearized* by supposing that $\mathbf{V}$, $\delta\rho$, δp, $\delta\mathbf{B}$, ... are so small that their squares and products are negligible. The resulting equations can be reduced to a single equation governing the vector displacement $\boldsymbol{\xi}(\mathbf{x}, t)$ of the fluid element originally situated at $\mathbf{x}$:

$$\rho_0 \frac{\partial^2 \boldsymbol{\xi}}{\partial t^2} = \mathbf{F}(\boldsymbol{\xi}), \tag{119}$$

where $\mathbf{F}$ is linear in ξ and its gradients and depends on the equilibrium fields, but not explicitly on t. We shall confine attention to two cases in which the operator $\mathbf{F}$ is self-adjoint:

$$\int_v \boldsymbol{\xi}_1 \cdot \mathbf{F}(\boldsymbol{\xi}_2) dV = \int_v \boldsymbol{\xi}_2 \cdot \mathbf{F}(\boldsymbol{\xi}_1) dV. \tag{120}$$

This happens in a number of cases of interest, including the following:

1. when the fluid conductor V is confined by infinitely conducting boundaries S; and
2. when S is a free surface separating V from a nonconducting exterior $\hat{\mathrm{V}}$ free of sources of energy such as current-carrying coils.

An investigation of linear stability consists of solving the initial-value problem, i.e., of solving Eq. (119) and appropriate boundary conditions starting from arbitrary initial $\boldsymbol{\xi}$ and $\partial\boldsymbol{\xi}/\partial t$. If the solution remains bounded for all time, the configuration is linearly stable; if any solution grows without bound, it is unstable. (Of course, in reality, no solution can grow without bound; it can grow only until its amplitude violates the assumed smallness of ξ, and nonlinear interactions become significant in limiting its growth.)

The initial-value problem is rarely easy to solve. An attractive, but seldom useful, alternative is to seek normal-mode solutions in which $\boldsymbol{\xi} \propto \exp(i\omega t)$ and for which Eq. (119) becomes

$$-\omega^2 \rho_0 \boldsymbol{\xi} = \mathbf{F}(\boldsymbol{\xi}), \tag{121}$$

which, together with the boundary conditions, poses an eigenvalue problem for ω^2. When Eq. (120) holds, ω^2 is real. If the spectrum of ω^2 of the normal modes is discrete and complete, which is rarely the case, the arbitrary initial state can be expanded as an infinite sum over the eigenfunctions. If one or more of these ω^2 is negative, the system is unstable; if all are positive, it is linearly stable.

Equation (118) and the relevant boundary conditions may possess only a finite number of discrete eigenvalues or perhaps none at all; the remainder belong to a continuous spectrum. For example, consider the result of perturbing an infinite ocean of perfectly conducting fluid $z < 0$ lying under gravity ($\mathbf{g} =$

$-g\mathbf{e}_z$) and permeated by a uniform vertical field $\mathbf{B}_0 = B_0\mathbf{e}_z$. It is obvious on physical grounds that the system is stable; surface waves are damped as Alfvén waves radiate their energy to $z = -\infty$, and this may be confirmed by solving the (non-self-adjoint) initial-value problem. There are, however, no discrete normal modes whatsoever.

Although the unstable modes are usually found in a finite discrete spectrum, there is no general theorem that makes this invariably true; the unstable modes may in principle lie in the continuous spectrum. To solve for the continuous spectrum adds complications; its existence also makes the already difficult task of solving the initial-value problem even harder (see Lifschitz, 1989). For this reason, energy methods are often employed for their relative simplicity.

8.2 The Energy Method

In the configurations **1** and **2** described above, the total energy is conserved; i.e., $K + W$ is constant, where K is the kinetic energy and W is the potential energy of the system (see Sec. 2.1). The situation then resembles that of a ball rolling on a surface. A stable configuration is shown in Fig. 16(a), one that is stable for small displacements but not large is sketched in Fig. 16(b), and an unstable equilibrium is shown in Fig. 16(c). The possibilities shown in Figs. 16(a) and (b) cannot be distinguished in a linear stability analysis, in which K and δW are quadratically small:

$$K = \frac{1}{2}\int_V \rho_0 \left(\frac{\partial \boldsymbol{\xi}}{\partial t}\right)^2 dV,$$

$$\delta W = -\frac{1}{2}\int_V \boldsymbol{\xi}\cdot\mathbf{F}(\boldsymbol{\xi})dV, \qquad (122)$$

where the integrations are over the unperturbed equilibrium configuration, $\delta W = W - W_0$ and W_0 is the equilibrium potential energy. If *any* displacement $\boldsymbol{\xi}$ can be found that satisfies the boundary conditions and for which $\delta W < 0$, that potential energy is transformed into an increase in kinetic energy; i.e., the system is unstable. If $\delta W > 0$ for *all* $\boldsymbol{\xi}$ satisfying the boundary conditions, the system is (linearly) stable.

For displacements that deform S, the evaluation of δW from Eq. (122) is hampered by the need to choose only those $\boldsymbol{\xi}$ satisfying boundary conditions on S, such as Eq. (29) and either Eq. (62) or (63). In a celebrated reformulation of Eq. $(122)_2$, Bernstein *et al.* (1958) showed how to rewrite δW in such a way that only Eq. (29) had to be enforced; we may call such $\boldsymbol{\xi}$ "eligible." For further details, see Freidberg (1987).

In the simplest cases (e.g., Secs. 8.2.1–8.2.3), it is comparatively easy to guess an eligible $\boldsymbol{\xi}$ for which $\delta W < 0$ and so prove instability. In other cases (e.g., Sec. 8.2.4), it is necessary to appeal to the calculus of variations to find the minimum of δW and to deduce stability or instability from its sign.

8.2.1 The Flowers–Ruderman Mechanism

This mechanism was advanced in an attempt to explain certain perplexing data from pulsars (Flowers and Ruderman, 1977). The idea is illustrated in Fig. 17. Two identical bar magnets are side by side and free to rotate about a common pivot through their centers; initially their N poles are adjacent, as are their S poles [Fig. 17(a)]. This configuration is unstable. One magnet swings relative to the other to bring the N pole of one next to the S pole of the other [Fig. 17(b)].

Now suppose that, instead of bar magnets, we have two hemispheres of a magnetic "star" V, containing an axisymmetric field which in the exterior, $\hat{\mathrm{V}}$, of V is a potential field of dipole type. If one hemisphere rotates relative to the other through 180° about an axis through the equator, the dipole moment is reduced and a quadrupole moment is increased. The magnetic energy $\hat{W}_M$ of $\hat{\mathrm{V}}$ is less for the quadrupole than for the dipole, and the magnetic energy W_M of V is unaltered. Indeed, further motions on S may, by rearranging the areas where magnetic flux enters and leaves V, reduce the energy of the configuration even more by the destruction of the lower harmonics of $\mathbf{B}$ and the creation of higher harmonics. Such motions may, however, increase the distortion of $\mathbf{B}$ within V and so offset the reduction in $\hat{W}_M$ by an even greater increase of W_M. Moreover, if V is rotating, such motions may be inhibited by Coriolis forces. Nevertheless, the general point is made: $\hat{W}_M$ can be reduced by suitable surface motions, and this may suffice to make the configuration unstable.

8.2.2 The *Z* Pinch The *Z* pinch shown in Fig. 13(c) is vulnerable to an axisymmetric

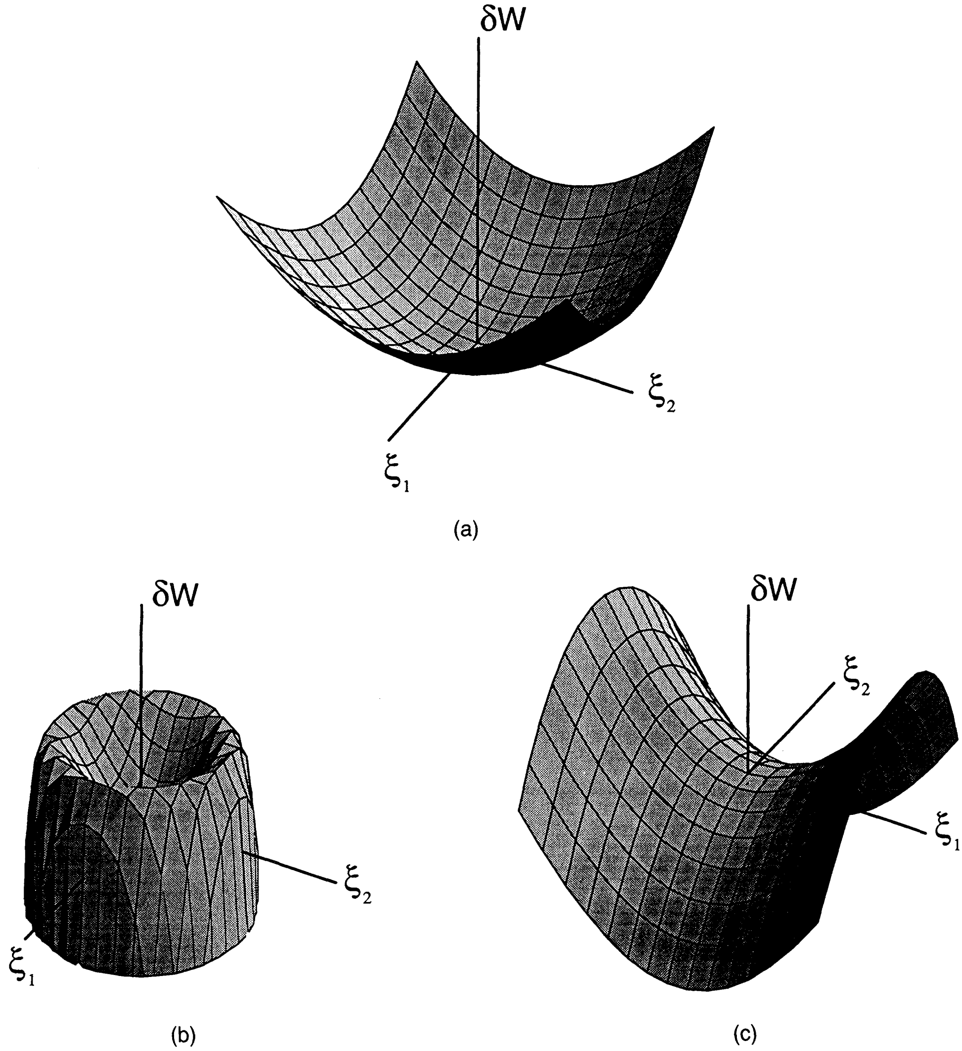

FIG. 16. Schematic explanation of the energy principle. These depict an analogy with the motion of a particle over a smooth surface under gravity: (a) a stable state in which $\delta W > 0$ for all displacements **gj**; (b) a state that is stable for all sufficiently small $\boldsymbol{\xi}$ but is unstable for larger $\boldsymbol{\xi}$; (c) the saddle, an unstable case in which δW is positive for some $\boldsymbol{\xi}$ but negative for others.

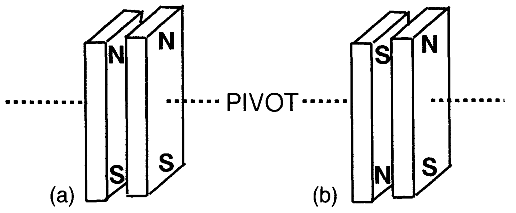

FIG. 17. (a),(b) The Flowers-Ruderman instability of two bar magnets. The configuration on the left is unstable to a displacement that carries it into the configuration on the right.

perturbation $\boldsymbol{\xi}$ that deforms its surface, $s = a$, into something vaguely resembling a string of sausages (see Fig. 18). Such a mode is sometimes called a "sausage" or "necking" instability.

We consider the simplest case ($\mathbf{B}_0 \equiv 0$) of a field-free plasma V, carrying a uniform surface current $\mathbf{I} = I\mathbf{e}_z$ that has been induced by the sudden creation of an external field $\hat{\mathbf{B}} = aI\mathbf{e}_\phi/\mu_0 s$ in the vacuum $\hat{\mathrm{V}}$ surrounding V. The net surface current along the pinch is

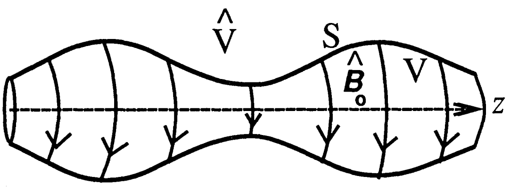

FIG. 18. Necking instability of the Z pinch.

not altered by the axisymmetric $\boldsymbol{\xi}$, so that $\hat{\mathbf{B}}$ is unchanged. The areas of maximum (minimum) surface displacement from Oz, therefore, are areas of reduced (enhanced) field and magnetic pressure. By choosing ξ_z so that $\nabla \cdot \boldsymbol{\xi} = 0$, we ensure that ρ and p are also unchanged in V, and so the unbalanced forces on the areas of maximum and minimum displacement act to increase the displacement further.

Necking instability can be inhibited by setting up a field B_{0z} in V prior to inducing the surface current on S. The compression of this field, by the $\boldsymbol{\xi}$ considered above, opposes the formation of necks. Thus, the general screw pinch shown in Fig. 13(a) is less prone to this particular kind of instability. It may, however, be prone to a *kink instability*. This is the $m = 1$ case of the general displacement $\boldsymbol{\xi} \propto \exp[i(m\phi + kz)]$, where m is a positive or negative integer. (Necking instabilities are axisymmetric: $m = 0$.) In the kink (or "Shafranov") instability, the central axis of the cylinder is displaced from Oz and winds about it as a helix. The instability resembles the one that creates loops on the cord of a telephone handset when it is twisted.

8.2.3 Interchange Instability We consider the field-free plasma more generally, supposing it is confined by a field $\hat{\mathbf{B}}_0$ in the surrounding vacuum $\hat{V}$ (see Fig. 19). A *local stability criterion* can be developed which decides whether the configuration is unstable or (linearly) stable at a particular point P on S. More precisely, displacements are envisaged that vanish everywhere except in a small neighborhood of P, which is then shrunk to zero. If $\delta W > 0$ for all such $\boldsymbol{\xi}$, the configuration is locally stable at P; if $\delta W < 0$ for any $\boldsymbol{\xi}$, it is locally unstable. Local instability is enough to establish overall instability, but local stability establishes very little; it is always possible that a global $\boldsymbol{\xi}$ might make $\delta W < 0$ even when the configuration is everywhere locally stable.

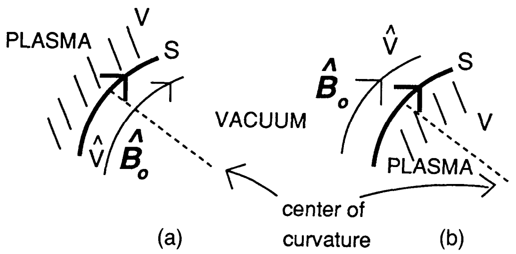

FIG. 19. Instability of a current-free plasma contained in a magnetic bottle. (a) Points on the plasma surface where $\hat{\mathbf{B}}_0$ is concave to the surface of the plasma are locally stable, but (b) points where it is convex are unstable.

It may be shown that a configuration in which $\hat{\mathbf{B}}_0$ is concave to the plasma, i.e., in which the center of curvature of the field line through P lies in the vacuum [Fig. 19(a)], is locally stable; if $\hat{\mathbf{B}}_0$ is convex to the plasma [Fig. 19(b)], it is unstable. The deformation $\boldsymbol{\xi}$ that establishes local instability is said to be of *interchange* type. The situation is sketched in Fig. 20. The displacement "corrugates" S near P along the direction of $\hat{\mathbf{B}}_0$ and so tends to raise and depress the field lines while bending them only slightly. Bending entails a positive contribution to δW that is stabilizing.

8.2.4 Screw Pinch; Suydam's Criterion So far we have considered instabilities that require S to be deformed. We now consider one that is local within V and that, therefore, exists even when S is undisplaced. It is again of interchange type, and it threatens the sta-

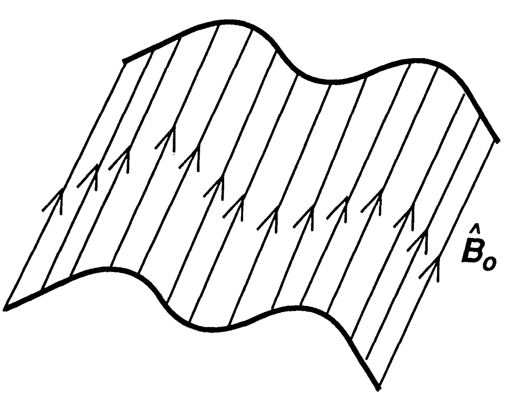

FIG. 20. Interchange instability. The displacement is dangerous for the stability of a system, because it moves the field lines with little bending and therefore wastes little in increasing the magnetic energy.

bility of the general screw pinch shown in Fig. 13(a). The putative instability involves a singular surface, S_0, within the plasma. The word "singular" is especially significant when the stability of the configuration is studied by the normal-mode method: S_0 corresponds to a singularity of the differential equation governing ξ_s (see Sec. 9.4). In the energy method, the instability is studied by the calculus of variations, and S_0 corresponds to a singularity of the Euler–Lagrange equation governing the minimizing ξ_s.

The displacement envisaged has the form $\boldsymbol{\xi} \propto \exp[i(m\phi + kz)]$, and the singular surface S_0 is defined by $F = 0$, where

$$F = kB_{0z} + mB_{0\phi}/s; \qquad (123)$$

$F = 0$ means that the pitch, $s\zeta = B_{0\phi}/B_{0z}$, of the helix defined by $\mathbf{B}_0$ on S_0 coincides with the pitch, $-ks/m$, of the helix on which the phase of displacement is constant, i.e, the perturbation moves the field lines on S_0 without bending them. The perturbation also bends them very little in a singular layer surrounding S_0 (see Sec. 9). The larger the shear, $d\zeta/ds$, the thinner the singular layer and the more stable the equilibrium. A variational argument reveals that the level s is unstable to the modes $\boldsymbol{\xi} \propto \exp[i(m\phi + kz)]$ for which $F = 0$ if *Suydam's criterion* is satisfied:

$$-\frac{dp_0}{ds} > \frac{s}{8\mu_0}\left[\frac{B_{0z}}{\zeta}\frac{d\zeta}{ds}\right]^2. \qquad (124)$$

9. RESISTIVE EFFECTS

Magnetic flux is "frozen" to a perfect conductor according to Alfvén's theorem, but finite resistivity ($\eta \neq 0$) allows flux to drift relative to the moving conductor at a speed of order $\mathcal{V}_d = \eta/\mathcal{L}$. The topology of field lines cannot be altered in a perfect conductor, but a finite resistivity allows the field lines to be severed and reconnected in new ways that change the field-line topology. Not unexpectedly, both these phenomena are very significant over the τ_η time scale. What is more surprising is that they can also be significant over periods of much shorter duration.

It may be recalled here that τ_η was defined to be $\mathcal{L}^2/\mathcal{V}$, where $\mathcal{L}$ was, somewhat vaguely, said to be "a length characteristic of the field." The central idea was that $\mathcal{B}/\mathcal{L}$ should be of the order of the field gradient $\nabla\mathbf{B}$ so that $1/\tau_\eta$ is a good estimate of the diffusion term $\eta\nabla^2\mathbf{B}$ in the induction equation (22). Similarly, the magnetic Reynolds number, $R = \mathcal{V}/\mathcal{V}_d$, involves $\mathcal{V}$, "a velocity characteristic of the flow," the central idea being that it should measure the relative sizes of the induction and diffusion terms in Eq. (22).

Portmanteau descriptions, such as τ_η and R, cannot reliably describe a system in detail, simply because no single $\mathcal{L}$ can represent the spectrum of length scales it possesses and no single $\mathcal{V}$ can reflect the range of $|\mathbf{V}|$ present. For example, rapid fluid motions can generate high field gradients by sweeping together fluid carrying similarly directed flux, so creating flux tubes or flux sheets (see Secs. 9.1 and 9.2); similarly, by bringing differently directed fields together, they can create regions where flux is destroyed or reconnected (see Secs. 9.1 and 9.3). The field gradients may be large in some parts of the system but comparatively small in others, and em diffusion will proceed rapidly in the former but comparatively slowly in the latter. In regions where $\mathcal{V}$ is large, the field will be swept along with the flow, much as envisaged by Alfvén's theorem, but where $\mathcal{V}$ is small, the diffusion of field will be more significant than its advection. Qualitatively, we may regard R, τ_η, and $\mathcal{V}_d$ as functions of position $\mathbf{x}$. Depending on their values, there may be considerable diffusion and rearrangement of magnetic flux in some parts of the system, but virtually none elsewhere. And the influence of the diffusively dominated regions may be far reaching.

9.1 Flux Concentration and Destruction

We consider here two simple but illuminating examples in which the steady flow

$$\mathbf{V} = \zeta(-x\mathbf{e}_x + y\mathbf{e}_y), \qquad \zeta = \text{constant} \qquad (125)$$

maintains a steady unidirectional magnetic field $\mathbf{B} = B(x)\mathbf{e}_y$. Equation (21) gives

$$\eta\frac{dB}{dx} + \zeta xB = E_0, \qquad (126)$$

where $E_0\mathbf{e}_z$ is a (constant) electric field. The steady equation of motion (39) is also obeyed (for $\mathbf{g} = 0$), with

$$p = p_0 - \tfrac{1}{2}\rho V^2 - \frac{B^2}{2\mu_0}, \quad p_0 = \text{constant}. \tag{127}$$

In the first example, we suppose as in Sec. 3 that the implied distant walls, $z = \pm c$, are perfectly conducting and shortcircuited; i.e., $E_0 = 0$. Then Eq. (126) shows that

$$B = B_0 \exp(-x^2/l^2), \quad B_0 = \text{constant}, \tag{128}$$

where $l = \sqrt{2\eta/\zeta}$. This solution describes a *flux sheet* of thickness l created by inflow of fluid toward $x = 0$, the inward advection of flux being equal but opposite to the outward diffusion of flux relative to the conductor. As in Sec. 6.3, magnetic energy is created from kinetic energy by the compression of the flux sheet, this energy being dissipated by Ohmic resistance. In a similar way, the motion $\mathbf{V} = \zeta(-s\mathbf{e}_s + 2z\mathbf{e}_z)$ can steadily maintain the *flux rope*, $\mathbf{B} = B_0\mathbf{e}_z \exp(-s^2/l^2)$.

In the second example, we take $E_0 = \eta B_0/l$. Equation (126) gives

$$B = B_0 e^{-x^2/l^2} \int_0^{x/l} e^{\xi^2}\, d\xi. \tag{129}$$

Clearly, $B(0) = 0$, and the field is oppositely directed on each side of $x = 0$. It is advected toward $x = 0$, where the oppositely directed fields cancel each other out mostly in a layer of thickness l surrounding $x = 0$. Again, the Poynting flux is everywhere directed toward $x = 0$. Again, the overall Ohmic dissipation is made good by the rate of working of the fluid against the Lorentz forces, but now this is not true in detail: the Lorentz forces are driving for $x < 0.925l$. A similar phenomenon will be met in Sec. 9.3.

9.2 Flux Expulsion

Suppose that space is filled with a solid conductor that contains a spherical inclusion, of radius $\mathcal{L}$, in perfect electrical contact with its surroundings; initially, a uniform field $\mathbf{B}_0 = B_0\mathbf{e}_y$ is present. At $t = 0$, the sphere starts to rotate with angular velocity $\boldsymbol{\omega} = \omega\mathbf{e}_z$, where $R\omega \gg 1$. An observer sitting on the surface of the sphere would see the applied field as oscillating with frequency ω, and (as in Sec. 5) that field would eventually only penetrate into the conductor to a depth $O(\delta_\eta)$. The field initially present within the sphere has been *expelled*.

The rotating conductor need not be solid; it could equally be a circulation in a fluid, such as a convection cell. If the overturning time of the cell is short compared with τ_η, any flux that threaded the cell initially, before overturning commenced, would be swept out of the cell, to its sides, corners (if any), and (in the case of hexagonal cells) center. There are many examples of such *flux expulsion* in MHD; one 2D case is shown in Fig. 21. This solution of the induction equation (22) illustrates what happens in a convection roll of square cross section (side d) to a uniform applied field when a circulation is "switched on" at $t = 0$; the value of the magnetic Reynolds number, $R = Ud/\eta$, based on the vertical velocity U at the center of the cell, is 1000. It may be seen that, during the evolution of $\mathbf{B}$ shown, the field lines sever and reconnect (see Sec. 9.3). By time $t = 4d^2/\eta$, the flux originally threading the cell has been concentrated by the flow into sheets confined to boundary layers on the surfaces $x = \pm\frac{1}{2}d$. It has been totally expelled from the interior of the cell. It is by such processes of flux expulsion that a magnetic field becomes *intermittent* when R is large. Such intermittency is observed in the turbulent solar wind.

Fluid motions can also expel field from a fluid into an insulator. Imagine, for example, an ocean $y < 0$ lying beneath a solid insulator $y > 0$ and suppose that a field $\mathbf{B}_0 = -\zeta y\mathbf{e}_x$ is initially present in the fluid (ζ = constant), with $\mathbf{B} = 0$ in $y > 0$. Now, let a steady upwelling of fluid start that presses lines of force near $x = 0$ against the interface $y = 0$; see Fig. 22(a), where streamlines of this $\mathbf{V}$ and the initial field $\mathbf{B}_0$ are indicated. If the fluid is perfectly conducting, the field is unable to detach itself from the fluid and pass into the insulator. If $\eta \neq 0$, however, the field near $y = 0$ will diffuse into the insulator, as sketched in Fig. 22(b). It has been proposed that such a mechanism carries magnetic flux generated in Earth's core into Earth's mantle. In the case where $y > 0$ is free space, there is a second possibility: even if $\eta = 0$, the inertia of the upwelling fluid will carry it, and the trapped flux it contains, above $y = 0$. Gravity now drains the raised field lines of fluid, which returns to the ocean, leaving the flux tube evacuated. In this way, field is carried into

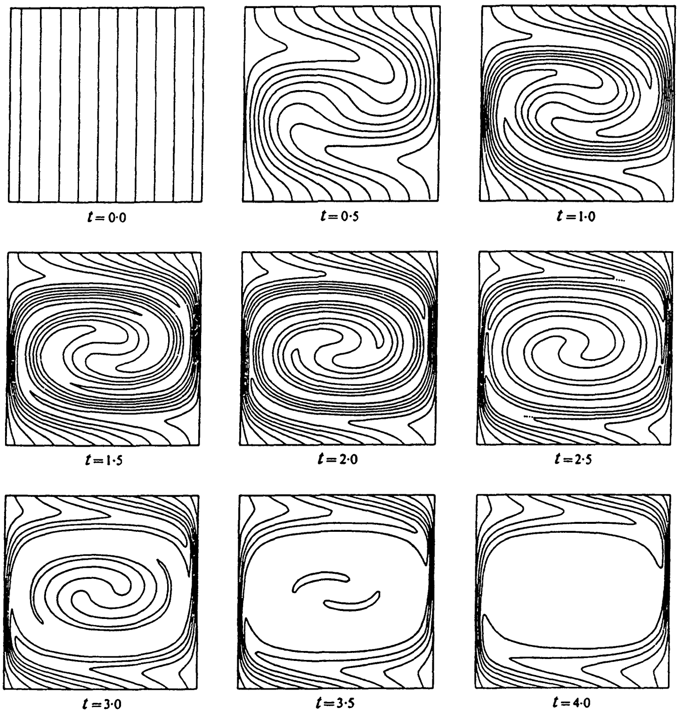

FIG. 21. Flux expulsion from a convective roll. The flow $\mathbf{V} = (\partial\psi/\partial y, -\partial\psi/\partial x, 0)$ is assumed as a model of flow in a convection roll parallel to $\mathbf{e}_z$, where Ox and Oz are horizontal and Oy is vertically upward. The cell is defined by $-\frac{1}{2}d < x < \frac{1}{2}d$, $-\frac{1}{2}d < y < \frac{1}{2}d$, and $-\infty < z < \infty$, and the externally applied field $B_0\mathbf{e}_y$ is vertical. The flow, $\psi = -(U/\pi d)(d^2 - 4y^2)^4 \cos(\pi x/d)$, is switched on at $t = 0$. The subsequent evolution of $\mathbf{B}$ is shown at equally spaced intervals of time, made dimensionless by division by d^2/η. The magnetic Reynolds number $R = Ud/\eta$ is 1000. (Figures courtesy of N. O. Weiss.)

the vacuum where no field previously existed. A similar process is thought to accelerate significantly the rise (due to magnetic buoyancy; see Sec. 10.1) of magnetic flux in the solar convection zone and to explain how it bursts out of the solar surface into its atmosphere.

9.3 Field-Line Reconnection

One of the most celebrated examples of field-line reconnection and its consequences is the so-called "stretch-twist-fold" mechanism sketched in Fig. 23. Three steps (a)–(c) are performed so rapidly that diffusion has

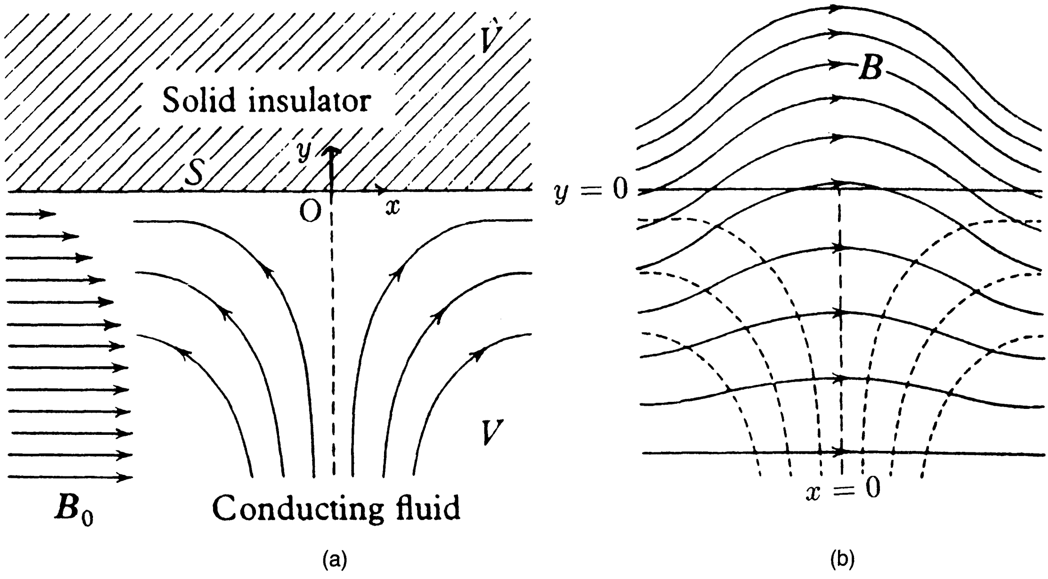

FIG. 22. Flux expulsion from a fluid into an insulator. (a) The initial field and flow; and (b) the final steady field.

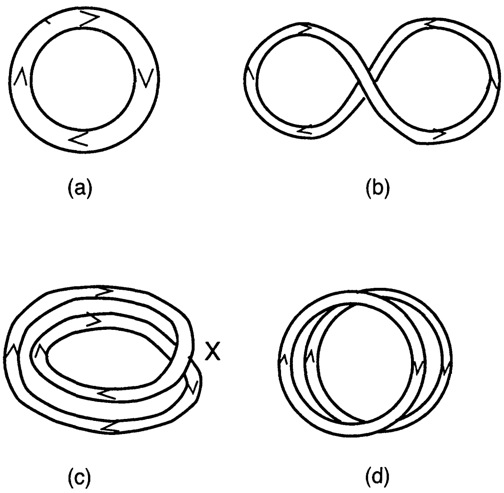

FIG. 23. The stretch-twist-fold process. The process described in the text creates, from one flux tube, two flux tubes, each of twice the energy. The loop (a) is stretched and twisted to form (b). The figure eight (b) is then folded over to produce (c). The field gradients are then high near X, and rapid field diffusion severs and reconnects the field lines near X to produce (d), i.e., two loops like (a).

no time to operate and Alfvén's theorem applies. The flux tube shown in (a) is stretched to double its length and four times its magnetic energy (see Sec. 6.3); one-half of it is twisted through 180°, as illustrated in (b). Then, like closing an open book, one-half is folded over onto the other, as shown in (c). The two halves of the loop are still connected at X on panel (c), where the field gradients are large and diffusion operates rapidly. It is plausible that, through diffusion, the two halves of the loop will separate from one another at X, so creating two flux tubes (d), each of twice the energy of the starting loop (a) (see also Sec. 10.3).

Processes of reconnection are significant in plasma physics and astrophysics (see Secs. 6.2 and 10.2). They are often completed during a time short compared with τ_η, as defined by the dimension $\mathscr{L}$ of the large-scale field structures. Indeed, it may take a time not much longer than $\tau_A = \mathscr{L}/V_A$, independent of η. This is because reconnection can be confined to regions small compared with $\mathscr{L}$, as the 2D Petschek mechanism sketched in Fig. 24 illustrates. This is a model of field-line reconnection in an incompressible fluid in the neighborhood of an X-type neutral point (or more precisely a line, Oz, of X-type neutral points). Flow toward the origin O from the right and left is so rapid that diffusive effects are at first negligible, and the oppositely directed flux is swept with the fluid toward O where it creates such large field gradients that diffusion can no longer be ignored. The field lines are reconnected in a region symbolized by the dashed rectangle. In their new configuration (above and below O in Fig. 24), they are highly bent and, in straightening, they catapult the fluid out in the general directions of $y = \pm\infty$ and at the same time generate a suction that assists new flux to be drawn in from $x = \pm\infty$.

The rapidity of reconnection in Petschek's mechanism arises from the Lorentz forces, which (as for the second model of Sec. 9.1) drive the fluid motions but which (unlike the second model of Sec. 9.1) cannot be balanced by a pressure gradient. They accelerate the outgoing fluid to Alfvénic speeds, i.e., $A \sim 1$, while the ingoing fluid is almost in magnetostatic balance. The inflow and outflow regions are separated by *Alfvén lines*, OA$_i$ (i = 1–4), defined as curves through O to which

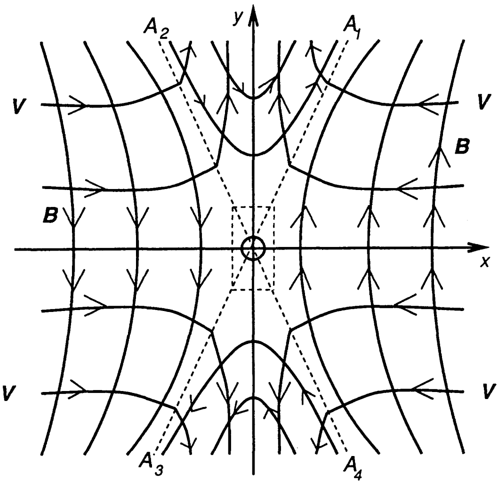

FIG. 24. The Petschek mechanism of field line reconnection at an X-type neutral point. The 2D flow is from the right and left toward the reconnection region (indicated by the dashed rectangle). The reconnection results in Lorentz forces that propel the fluid outward, toward the top and bottom of the figure. The tangential velocity is discontinuous along the Alfvén lines, OA_i (i = 1–4).

$\mathbf{V} - \mathbf{V}_A$ are tangential. The field direction changes rapidly across these slow "shocks." The current densities are large within them, and Joule losses are therefore significant (see Sec. 10.2).

The Petschek mechanism has been very thoroughly analyzed, not only for incompressible but also for compressible fluids, in which the discontinuities arise at slow shock fronts. See Soward (1982), where earlier references may be found. Slow shocks have been detected in the vicinity of the neutral point X_2 in the magnetotail of Earth (Fig. 10), suggesting that the Petschek mechanism is operating there.

The phenomenon of field-line reconnection has a bearing on the variational properties of force-free fields. It was remarked in Sec. 7.2.1 that, when the correspondence between the points of entrance and exit of field lines crossing a volume V is specified, along with B_n everywhere on S (the boundary of V), the state of minimum energy is force-free but that minimum is greater than the unconstrained minimum possible when B_n alone is given. The addition of resistivity opens up the possibility that, by reconnecting field lines, the system can release magnetic energy and evolve toward the lower energy state of the potential field (see Sec. 10.2).

In Sec. 7.2.2, a field confined within a volume V bounded by a perfectly conducting surface S was considered, such as that shown in Fig. 12. It was remarked in Sec. 6.4 that the rate of dissipation of magnetic helicity is much smaller in a turbulent conductor than the rate of dissipation of magnetic energy. It is reasonable to suppose that the *net* helicity, H_{total}, of the entire volume V is approximately conserved during the time that the system takes to reach its minimum-energy state. The field having the least magnetic energy subject to specified H_{total} is a Beltrami field [i.e., a force-free field of constant α; see Eq. (115)], and its energy is smaller than that of the more constrained minimum, discussed in Sec. 7.2.2, in which $H(v)$ is preserved on every magnetic surface in V; the addition of Ohmic dissipation permits field-line reconnection, and the system can release magnetic energy and evolve toward the Beltrami state. This possibility, often called "Taylor relaxation," is significant in thermonuclear research for the formation and stability of the so-called "reversed-field pinch"; see Taylor (1986) and Sec. 9.5.7 of Freidberg (1987). For an astrophysical application, see Aly (1992).

9.4 Resistive Instabilities; Tearing and Coalescence

The sheet pinch provides one of the simplest examples of a resistive instability, the *tearing mode*. The fluid is incompressible and inviscid and is confined between two perfectly conducting planes $z = 0$ and $\mathcal{L}$. Magnetostatic equilibrium prevails in a field of

$$\mathbf{B}_0 = B_{0x}(z)\mathbf{e}_x + B_{0y}(z)\mathbf{e}_y, \tag{130}$$

which alters its direction as z changes; see, for example, the field (116) when $\epsilon = 0$. As in Sec. 7, it is supposed that the Lundquist number S is large.

The field (130) is ideally stable, and its instability relies on field-line reconnection. The growth rate λ of the instability must therefore tend to zero as $\eta \rightarrow 0$; i.e., it must be much less than $O(\tau_A^{-1})$, which is the growth rate of the dynamical instabilities discussed in Sec. 8. But the equilibrium (130) will itself evolve through Ohmic diffusion during a time of order τ_η. It is found (see below) that $\lambda^{-1} \ll \tau_\eta$, and it is therefore permissible to treat $\mathbf{B}_0$ as constant in time. In short: because the instability develops over a length scale δ small compared with $\mathcal{L}$, λ is intermediate between τ_A^{-1} and τ_η^{-1}.

The linear stability of the state (130) is determined by studying nontrivial perturbations proportional to $\exp(ik_xx + ik_yy + \lambda t)$; it is found that the relevant λ are real. The key to the instability is a diffusive layer (of thickness δ, say), which surrounds a *critical level* and in which lines of force are detached from the fluid and reconnected. A critical level arises at any z where $\mathbf{B}_0$ is perpendicular to the wave vector $\mathbf{k} = k_x\mathbf{e}_x + k_y\mathbf{e}_y$. It marks a singularity of the ideal stability equations (121) for $\omega = 0$. The reconnection creates a string of *magnetic islands* (or cat's eyes), as illustrated in Fig. 15, where the lines of force of the components of $\mathbf{B}$ lying in the plane defined by Oz and $\mathbf{k}$ are shown. By contracting, the closed field loops can release magnetic energy to fuel the instability.

The growth rate of the instability is partly decided by the rate at which field lines can detach and reconnect themselves from fluid in the critical layer. This depends on the field gradient, δ^{-1}, in the layer, rather than on $\mathcal{L}^{-1}$. Thus, $\lambda \approx \mathcal{L}/\mathcal{V}_d$, where $\mathcal{V}_d \approx \eta/\delta$. At the critical level, the perturbation lifts lines of force bodily, i.e., it is of interchange type. The emf that balances magnetic diffusion in the layer is therefore generated by the small component of field, of order $B_0\delta/\mathcal{L}$, perpendicular to **k** in the critical layer. This emf is of order $\mathcal{V}(B_0\delta/\mathcal{L})$ rather than $\mathcal{V}B_0$. Since Ohmic diffusion destroys flux at the rate η/δ^2, the velocity perturbation must be of order $\eta\mathcal{L}^2\mathcal{B}/B_0\delta^3$, where $\mathcal{B}$ is the field perturbation. Similarly, the Lorentz force is of order $\mathcal{B}(B_0\delta/\mathcal{L})/\mu_0\mathcal{L}$ rather than $\mathcal{B}B_0/\mu_0\mathcal{L}$. Setting this against the inertial force $\lambda\rho\mathcal{V} \approx \eta\rho\mathcal{V}/\mathcal{L}\delta \approx \eta^2\rho\mathcal{L}/B_0\delta^4$, we obtain

$$\delta \approx (\tau_A/\tau_\eta)^{2/5}\,\mathcal{L} = S^{-2/5}\,\mathcal{L}, \tag{131}$$

$$\lambda \approx \mathcal{L}/\tau_\eta\delta = S^{2/5}\tau_\eta^{-1} = S^{-3/5}\tau_A^{-1}. \tag{132}$$

The effects of nonlinearities are considered in the review of White (1983). It might be expected that the linear instability of state (130) results in a new magnetostatic state of finite amplitude that depends on x and y. For example, it might seem plausible that, after an infinitesimal perturbation of the state (116) with $\epsilon = 0$ grew to finite amplitude, it would equilibrate to a configuration resembling state (116), but of finite ϵ. This does not necessarily seem to be the case. A study of state (116) has shown that it too is unstable to a *coalescence instability*, in which cat's eyes merge together to form one larger eye. Despite the implied severing and coalescence of field lines, the time scale of this instability appears scarcely greater than τ_A. It has been suggested that this instability operates in the magnetosphere and explains the presence of giant "plasmoids" that have been observed in the magnetotail, structures that consist of loops of closed field lines and hot plasma [see Fig. 10 and Richard *et al.* (1989)]. In a steady state, the rate at which the lines of force of the interplanetary magnetic field detach at X_1 must equal the rate at which they reconnect in the magnetotail. The speed of the reconnection is limited by the efficiency of the Petschek mechanism, and, if a surge of additional flux in the IMF is brought to X_1 and detached, it will, while waiting to be reconnected at X_2, cause a large increase in the S → N field gradient near the central neutral sheet joining E to X_2, so promoting instabilities of tearing type and further neutral points, such as the one indicated by X_3 in Fig. 10. These both enhance the rate at which the IMF reconnects and explain the observed plasmoids.

Other types of resistive instabilities can also arise in the sheet pinch, notably *rippling modes*, which depend on spatial variations in σ; *g* modes, which depend on the existence of a gravitational field in the $-z$ direction and a density gradient in the $+z$ direction but which ignore the diffusion of density differences; and *convective modes*, which restore density diffusion to the *g* modes, with dramatically different results. An important class of resistive instabilities arises from the curvature of the field lines of $\mathbf{B}_0$ in the cylindrical pinch, i.e., instabilities that occur even when Suydam's criterion would indicate stability. Detailed discussions of some of the associated linear stability problems may be found in Lifschitz (1989).

10. MHD IN THE LARGE

The physics of the Earth, planets, Sun, stars, and galaxies provide a rich fabric in which MHD phenomena are deeply woven. While it would be inappropriate in an encyclopedia devoted to applied physics to enter into these topics in depth, a brief discussion of a few of them supplies not only illustrations of the ideas developed in preceding sections of this article but also deeper insights into MHD processes. For further reading about the topics adumbrated below, see, for example, Parker (1979) and Priest (1982).

10.1 Sunspots; Magnetoconvection; Formation of Flux Tubes

Sunspots are the signatures of a large zonal field in the Sun. It is thought that flux tubes are generated deep within the Sun and that they rise toward the surface; a segment breaks through the surface approximately along a line of latitude and gives rise to two dark areas where it leaves and re-enters the Sun. How are the flux tubes created? Why do they rise? Why are sunspots dark?

Flux tubes rise through *magnetic buoyancy*. Radiative transfer of heat is highly efficient in the Sun except near its surface; i.e., the thermal diffusivity κ is large and the temperature within a flux tube is that of its surroundings. Likewise, mechanical equilibrium ensures that the *total* pressures $P = p + B^2/2\mu_0$ inside and outside the tube are almost the same. But the field within the tube is larger than the field outside, so that the magnetic pressure is greater and the kinetic pressure is less. Since the temperature is the same, the density is less, by the gas law. The tube, therefore, is buoyant. It rises and breaks through the solar surface in the way indicated at the end of Sec. 9.2.

Near the solar surface, radiative transfer is ineffective and heat is transported by thermal convection. Magnetic fields tend to suppress convection, and less heat per unit area is carried out of the Sun through a sunspot than elsewhere on the solar surface. The sunspot therefore appears dark.

A simple example illustrates the inhibiting effect of a magnetic field on convection: the Rayleigh–Bénard problem. This employs a theoretical idealization, the Boussinesq fluid, that avoids inessential complications while preserving the essence of the buoyancy mechanism. The density of this fluid is independent of the pressure but decreases slightly with increasing temperature T, i.e., $d\rho/dT = -\gamma\rho$, where γ, the coefficient of volume expansion, is assumed to be positive and constant. An unbounded horizontal layer, $0 < z < \mathscr{L}$, is filled with Boussinesq fluid, and the temperature of its lower wall ($z = 0$) exceeds that of its upper wall ($z = \mathscr{L}$) by ΔT. A linear stability analysis shows that, if ΔT is increased quasistatically from zero, convection first occurs, as a horizontally tessellated pattern of infinitely weak convection cells, when the *Rayleigh number*,

$$Ra = g\gamma\Delta T\mathscr{L}^3/\nu\kappa, \tag{133}$$

attains a critical value, which is $Ra_c \approx 1707.76$ if $z = 0$ and $z = \mathscr{L}$ are no-slip walls.

If the fluid is electrically conducting and a strong vertical magnetic field, $\mathbf{B}_0 = B_0\mathbf{e}_z$, is present, that field will try to enforce the two-dimensionality of Sec. 3.2. But motions $\mathbf{V} = \mathbf{V}(x, y)$ independent of z can only be horizontal; they cannot carry heat across the layer. A convective circulation must necessarily depend on z. To achieve that three-dimensionality, a larger temperature gradient is needed to defeat the putative two-dimensionality. Thus, $Ra_c(M)$ increases with M and, when $p_m < 1$, it may be shown that $Ra_c \sim \pi^2M^2$ for $M \gg 1$. Evidently, the magnetic field delays the onset of convection.

This model of magnetoconvection may also be used to demonstrate that the shortcomings of linear stability theory are no less severe in MHD than in other sciences. It was already noted in Sec. 8.1 that a state judged stable on linear theory might nevertheless be unstable when perturbed with finite amplitude. When Ra sufficiently exceeds $Ra_c(M)$, the convective circulations are so rapid that the magnetic flux passing through a cell is expelled to the sides, corners, and center of the cell (see Sec. 9.2). Once removed from the interior of a cell, the magnetic field is no longer present to inhibit convection, which can therefore continue even if Ra is reduced far below $Ra_c(M)$; i.e., the layer is *subcritically unstable.*

This gives a second, dynamical reason why intermittency is prevalent in turbulent fluids when R is large: the "preferred" mode of magnetoconvection is one in which the available magnetic flux is concentrated rather than being smoothly spread out.

10.2 Current Sheets; Solar Flares

The atmosphere of the Sun is light and highly conducting. We may expect, therefore, that its magnetic field will be approximately force-free. Matters raised in Secs. 7.2.1 and 9.2 assume a new significance. We are dealing, however, with a domain that is essentially infinite, and a line of force leaving the Sun need not return, being blown away, in effect to infinity, by the solar wind (see Fig. 10). Where a correspondence between footpoints on the solar surface exists, the field is continually modified as the footpoints are moved over the surface of the Sun by convective motion. This motion enhances the energy of the magnetic field in the atmosphere, but that field also continually evolves toward lower energy states by the processes described in Sec. 9.3, dissipating its energy to heat as it does so through the formation of current sheets and electrical discharges, known as solar flares. These processes are even more active in so-called "flare stars."

10.3 Fluid Dynamos

In Sec. 10.1, we asked how the magnetic field associated with sunspots is generated, and we may wonder similarly what the source of the main magnetic fields of the Sun is, to what some stars and planets owe their magnetism, and where the magnetic fields of galaxies originate. This is the provenance of dynamo theory, one of the largest and most rapidly growing branches of MHD, but one that is beyond the scope of this review, although an experiment is currently being constructed.

The geomagnetic field emanates from Earth's core but, if that core were a solid, the field would disappear in a time of order $\tau_\eta \sim$ 14 000 years. Motions in the core must act as a self-excited dynamo. Self-excited dynamos exist; conceptually, the simplest is the homopolar dynamo sketched in Fig. 25. The emf created by a sufficiently rapid rotation of the disk in the magnetic field created by the current in the wire loop generates this current; when the seed field initially necessary to start the regeneration is removed, the induced and inducing field are the same. The energy dissipated Ohmically in the circuitry (and in any external load, indicated by the light bulb in Fig. 25) is made good by the rate of working of the power source maintaining the motion of the disk against the opposing Lorentz force.

If a homogeneous mass of fluid V is to act as a dynamo, the magnetic Reynolds number of the motions within it must be sufficiently large. Since the ratio of the induced field to the inducing field is $O(R)$, it is necessary (but not sufficient) that $R \geq O(1)$. This condition is very hard to satisfy in laboratory conditions but may be attained in the flow of liquid sodium in the cores of fast reactors where $R \approx 50$ (see, for example, Bevir, 1973). Fortunately for the safety of the reactors, no dynamos have yet been excited in their operation, probably because the flow within them has been insufficiently helical. The point here is the following.

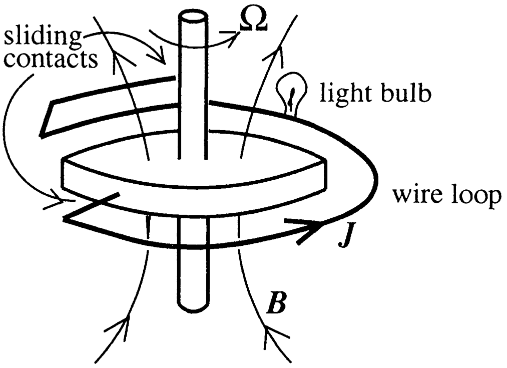

FIG. 25. The homopolar dynamo. The dynamo is self-excited. A magnetic field is created by the current flowing in the almost complete wire loop and that current is created by em induction through the rotation of the disk in the magnetic field. The device does not violate energy conservation: the current flowing between the axis and the perimeter of disk, together with the field produced by the wire loop, produces a Lorentz force that opposes the motion of the disk, and a source of energy is needed to maintain the rotation of the disk against that force.

The homopolar dynamo is man-made and highly asymmetric in structure, but the homogeneous masses of conducting fluid encountered in nature are generally highly symmetric (e.g., spherical). For these to regenerate field, the motions within them must, by *their* asymmetry, make good the lack of asymmetry of the container. Helical motions possess an asymmetry conducive to field generation. These are defined as motions of nonzero *kinetic helicity* H_K, where

$$H_K = \mathbf{V}\cdot\nabla\times\mathbf{V} = \mathbf{V}\cdot\boldsymbol{\omega}. \tag{134}$$

Beltrami motions [in which $\boldsymbol{\omega}$ and $\mathbf{V}$ are parallel; see Eq. (115)] provide some of the simplest models of working fluid dynamos; e.g., the ABC flow (Arnold–Beltrami–Childress),

$$\mathbf{V} = (C\sin z + B\cos y, A\sin x + C\cos z, B\sin y + A\cos x), \tag{135}$$

is the basis of an efficient dynamo. Other dynamos make use of the stretch-twist-fold process sketched in Fig. 23 and the kink instabilities discussed in Sec. 8.2.2. For a recent review of dynamo theory, see Roberts and Soward (1992).

10.4 RMHD

RMHD stands for "Rotating MHD", i.e., the MHD of rotating fluid conductors. Most large naturally occurring bodies are rapidly rotating, in a sense to be made more precise below, and rotating MHD therefore finds significant applications in astrophysics and planetary physics. The importance of Coriolis forces on the dynamics of Earth's fluid core explains why the magnetic compass needle points approximately North–South over

Earth's surface. Their action within the Sun explains why sunspots appear in pairs approximately along one line of latitude (Sec. 10.1). Compared with the classical MHD of nonrotating fluids, RMHD exhibits strange and sometimes almost paradoxical behaviors, even when the working fluid is of constant density and incompressible, as we shall suppose here. For example, consider again the Rayleigh–Bénard convection problem of Sec. 10.1, but now suppose that the configuration rotates rapidly about the vertical. One might have expected a priori that, since rotation is also associated with two-dimensionality (the Proudman–Taylor theorem stated in Sec. 3.2), Ra_c would be increased even beyond the $O(M^2)$ value imposed by the MHD 2D theorem. This is not the case. The magnetic field "breaks the constraint" of the Proudman–Taylor theorem (or alternatively we could say that rotation breaks the constraint of MHD two-dimensionality), and Ra_c is smaller than it would be if either rotation or magnetic field were absent.

Rotating systems are usually most simply described in a frame of reference rotating with a constant angular velocity $\mathbf{\Omega}$ characteristic of the conductor as a whole; $\mathbf{V}$ and $\partial/\partial t$ are now measured in the rotating frame but $\mathbf{B}$ and D/Dt are the same as in the inertial frame; the induction equation, therefore, is unaltered, but the equation of motion (65) becomes

$$\begin{aligned}\partial\mathbf{V}/\partial t + \mathbf{V}\cdot\nabla\mathbf{V} + 2\mathbf{\Omega}\times\mathbf{V}\\ = -\nabla\mathbf{\Pi} + \mathbf{J}\times\mathbf{B}/\rho + \nu\nabla^2\mathbf{V} + \mathbf{g}.\end{aligned} \qquad (136)$$

Here, $2\rho\mathbf{\Omega}\times\mathbf{V}$ is the so-called "Coriolis force"; the centrifugal force, $-\rho\mathbf{\Omega}\times(\mathbf{\Omega}\times\mathbf{r})$, can be expressed as $\nabla[\frac{1}{2}\rho(\mathbf{\Omega}\times\mathbf{r})^2]$ and included in the gradient of the pressure $\rho\Pi$.

The theory of rotating but nonconducting fluids is a well-developed and important branch of fluid mechanics, with applications to atmospheric and ocean physics (see, for example, Greenspan, 1968). Two nondimensional measures of Ω are particularly significant, the *Ekman number Ek* and the *Rossby number Ro,* that measure, respectively, the viscous and inertial forces against the Coriolis force:

$$Ek = \nu/\Omega\mathcal{L}^2, \qquad Ro = \mathcal{V}/2\Omega\mathcal{L}. \qquad (137)$$

When $Ek \ll 1$ and $Ro \ll 1$, steady flow is almost two-dimensional with respect to the direction of $\mathbf{\Omega}$. This is the Proudman–Taylor theorem referred to in Sec. 3.2. When a magnetic field is present, two other dimensionless groupings arise, the *magnetic coupling parameter C* and the *Elsasser number Λ*:

$$C = V_A^2/2\Omega\mathcal{L}\mathcal{U}, \quad \Lambda = \sigma\mathcal{B}^2/2\Omega\rho = RC. \qquad (138)$$

The former is the ratio of Lorentz force to Coriolis force, with $\mathbf{J}$ estimated as $\mathcal{J} = \mathcal{B}/\mu_0\mathcal{L}$; the latter appeals to Ohm's law and uses instead $\mathcal{J} = \sigma\mathcal{V}\mathcal{B}$.

Rotation mixes the two transverse polarizations of the Alfvén wave, and two different types of wave motion replace the Alfvén wave of Sec. 6. In the simplest case in which the wave vector $\mathbf{k}$ is parallel to both $\mathbf{\Omega}$ and $\mathbf{B}_0$, the frequencies of these waves are $\pm\omega_{F,S}$ where

$$\omega_{F,S} = \sqrt{\Omega^2 + V_A^2k^2} \pm \Omega. \qquad (139)$$

The subscripts F and S refer particularly to the often relevant, "highly rotating" case in which $\Omega \gg V_Ak$ and for which $\omega_F \approx 2\Omega \gg \omega_S \approx V_A^2k^2/2\Omega$. The fast wave is then essentially an inertial oscillation, of the type much studied in the classical theory of rotating fluids, that arises from the vibration of vortex lines that (as seen in the inertial frame) fill the system (see, for example, Greenspan, 1968). Greater interest centers on the slow waves, which have a phase speed of

$$c_S \approx V_A^2/2\Omega\mathcal{L}, \qquad (140)$$

where $\mathcal{L} = 1/k$. This defines a new dynamic time scale $\tau_S = \mathcal{L}/c_S$, and many mechanisms that work on the Alfvén time scale τ_A in a nonrotating fluid (see Sec. 8) operate in a highly rotating fluid on the time scale τ_S instead. (The resistive instabilities studied in Sec. 9.4 are similarly retarded.) The Elsasser number, $\Lambda = \tau_\eta/\tau_S$, is the analogue for the rotating system of the Lundquist number, $S = \tau_\eta/\tau_A$.

RMHD has a particular significance in the studies of Sec. 10.3. Rotation imparts kinetic helicity to a rotating fluid, which is beneficial for dynamo action. Consider, for example, a sinking plume of hot plasma in a rotating star. This plume will be compressed as it moves into higher pressure environments, and, in attempting to conserve its angular momentum, it will start to spin about the vertical, i.e., it will acquire vertical vorticity and therefore nonzero kinetic helicity; the same sense of helicity would be associated with an ascending, expanding plume. By Alfvén's theorem, the helicity of either plume would tend to twist the zonal field of the star into meridian planes, and many such plumes would create a general stellar meridional field, which (Alfvén's theorem again) would be stretched out into the zonal direction by differential rotation in the interior of the star, so recreating the zonal field. If the magnetic Reynolds number is sufficiently large, the dynamo cycle is complete, and the star maintains a permanent magnetic field.[*]

ACKNOWLEDGMENTS

This review has benefited from the advice of Stanislav Braginsky, Andrew Soward, Mark Tillack, Ray Walker, Cheng Chin Wu, and (for the Encyclopedia) George Trigg. I am also grateful to four postgraduate students, Weijia Kuang, Sikun Lan, Neil Morley, and Martin St. Pierre, for acting as guinea pigs and to Maureen Roberts for preparing PostScript[†] files for most of the figures.

NOTATION

a is the speed of sound (m s^{-1})

$\mathbf{A}$ is vector potential for magnetic field (T m)

$\mathbf{B}$ is magnetic field (T)

$\hat{\mathbf{B}}$ is magnetic field in $\hat{\mathrm{V}}$

$\mathcal{B}$ is a characteristic magnetic field strength

c_0 is the speed of light in vacuo (m s^{-1})

C_v and C_p are the specific heats at constant volume and pressure (J kg^{-1} K^{-1})

$\mathbf{D}$ is electric displacement (C m^{-2})

$\mathbf{e}_c$ is a unit vector in the direction of c increasing

E is the total energy density per unit volume (J m^{-3})

E_M is the (electro)magnetic energy density per unit volume (J m^{-3})

$\mathbf{E}$ is electric field (V m^{-1})

$\mathbf{g}$ is the externally applied body force per unit mass, such as gravity (m s^{-2})

$\mathbf{H}$ is magnetizing force (A m^{-1})

H is the enthalpy per unit mass (J kg^{-1})

I is the internal per unit mass (J kg^{-1})

$\mathbf{I}$ is surface current (A m^{-1})

$\mathbf{J}$ is electric current density (A m^{-2})

$\mathbf{k}$ is wave vector; k is wave number (m^{-1})

K is the kinetic energy of a system (J)

K_p is the isothermal compressibility (Pa^{-1})

$\mathbf{L} = \mathbf{J} \times \mathbf{B}$ is the force per unit volume exerted by the (electro)magnetic field on a conductor (N m^{-3})

$\mathcal{L}$ is a characteristic length (m)

m_{ij} is the (electro)magnetic stress tensor (N m^{-2})

p is kinetic pressure (Pa)

$P = p + B^2/2\mu_0$ is the total pressure (Pa)

$p_m = \nu/\eta$ is the magnetic Prandtl number

S is specific entropy (J kg^{-1} K^{-1})

$\mathbf{S} = \mathbf{E} \times \mathbf{B}/\mu_0$ is the em-energy flux (W m^{-2})

t is time (s)

T is temperature (K)

$V = 1/\rho$ is specific volume (m^3 kg^{-1})

V is the volume occupied by conducting fluid

$\hat{\mathrm{V}}$ is the exterior of V, usually assumed insulating

$\mathbf{V}$ is fluid velocity (m s^{-1})

$\mathcal{V}$ is a characteristic flow speed (m s^{-1})

$\mathcal{V}_A = \mathcal{B}/\sqrt{\mu_0\rho}$ is a characteristic Alfvén speed (m s^{-1})

W is the total energy of a system (J), i.e., the integral of E

$\mathbf{x}$ is position (m)

β is the ratio of kinetic pressure to magnetic pressure, i.e., $\mu_0 p/\mathcal{B}^2$

γ is the coefficient of volume expansion (K^{-1})

$\tilde{\gamma}$ is the coefficient of surface tension (kg s^{-2})

δ is boundary layer thickness (m)

ϵ is the permittivity of a material (F m^{-1})

ϵ_ν is the rate of viscous heating per unit volume (W m^{-3})

$\epsilon_\sigma = J^2/\sigma$ is the rate of Ohmic dissipation per unit volume (W m^{-3})

$\eta = 1/\mu_0\sigma$ is magnetic diffusivity (m^2 s^{-1})

Θ is surface charge density (C m^{-2})

ϑ is volume charge density (C m^{-3})

κ is thermal diffusivity (m^2 s^{-1})

λ is growth rate (s^{-1})

μ is the permeability of a material (H m^{-1}); taken to be μ_0 everywhere in the text

---

[*] Recent research indicates that this is not a viable explanation of the Sun's magnetic field e.g., see Krause *et al.* (1993).

$\mu_0 = 4\pi 10^{-7}$ H m^{-1} is the permeability of free space

ν is kinematic (shear) viscosity (m^2 s^{-1})

$\boldsymbol{\xi}$ is fluid displacement (m)

ϖ is the reduced pressure (m^2 s^{-2}); for a uniform density fluid, this is p/ρ; for a barotropic fluid, for which $p = p(\rho)$, it is $\varpi = \int \rho^{-1} dp$

ρ is (mass) density (kg m^{-3})

σ is electrical conductivity (S m^{-1})

τ is a characteristic time scale (s)

Φ is electrostatic potential (V)

φ is the potential energy per unit mass (m^2 s^{-2}), when $\mathbf{g} = -\nabla\varphi$ is conservative

$\boldsymbol{\omega} = \nabla \times \mathbf{V}$ is vorticity (s^{-1})

Ω is angular velocity (s^{-1})

GLOSSARY

Alfvén Number: See **Mach numbers.**

Alfvén's Theorem: The magnetic field lines in a fluid that is a perfect electrical conductor ($\sigma = \infty$; $\eta = 0$) are carried with it in its motion, as though they were frozen to it.

Alfvén Velocity/Speed: The velocity, $\mathbf{V}_A = \pm\mathbf{B}/\sqrt{\mu_0\rho}$, with which an Alfvén wave moves relative to a fluid conductor; the wave speed, therefore, is $V_A = |\mathbf{V}_A| = B/\sqrt{\mu_0\rho}$.

Alfvén Wave: A wave moving with the Alfvén velocity, relative to a conducting fluid. It travels along, and is transverse to, the magnetic lines of force.

Beltrami Field: A vector field that is a constant multiple of its curl. It is an important special case of the **Force-Free Field.**

Chandrasekhar Number: The square of the **Hartmann number.**

Couette Flow: Flow that is set up in viscous fluid contained between two coaxial, differential rotating cylinders and is everywhere zonal with respect to the common axis of the cylinders; see also **Plane Couette Flow.**

Cylindrical Pinch: An infinitely long circular cylinder of plasma through which passes an axisymmetric magnetic field having a zero component perpendicular to the axis of the cylinder. Also called "the general screw pinch," special cases of which are the **Theta Pinch** and the **Z Pinch.**

Electromagnetic Diffusion Time: The characteristic time, $\tau_\eta = \mathcal{L}^2/\eta$, in which a magnetic field of scale $\mathcal{L}$ in a stationary conductor of magnetic diffusivity η disappears through Ohmic losses.

Ekman Number: A dimensional number, $Ek = \nu/\Omega\mathcal{L}^2$, measuring the relative importance of viscous and Coriolis forces in a rotating fluid.

Elsasser Number: A dimensional number, $\Omega = \sigma\mathcal{B}^2/2\Omega\rho$, measuring the relative importance of Lorentz and Coriolis forces in a rotating fluid.

Field Lines: See magnetic lines of force.

Force-Free Field: A magnetic field that exerts no Lorentz force on a conductor; i.e., $\mathbf{J} \times \mathbf{B} = 0$. Thus, $\mathbf{B}$ is parallel to its curl, but (unlike the Beltrami field) the constant of proportionality can differ from one field line to another.

Hartmann Flow: Flow in a viscous, electrically conducting fluid contained between two stationary parallel planes, driven by a pressure gradient parallel to those planes, in the presence of a magnetic field applied perpendicularly to those planes. It is the MHD generalization of **Plane Poiseuille Flow.**

Hartmann Layer: A boundary layer that may exist at the edge of an MHD flow when the Hartmann number is large; its thickness is of order $(\rho\nu/\sigma B_n^2)^{1/2}$, where B_n is the component of the magnetic field perpendicular to the boundary.

Hartmann Number: A dimensionless measure, $M = (\sigma/\rho\nu)^{1/2}\mathcal{B}\mathcal{L}$, of the strength of the magnetic field.

Helicities: Pseudoscalars measuring the lack of mirror symmetry of fields and defined as the scalar products of the fields with their curls; thus, $\mathbf{V}\cdot\boldsymbol{\omega}$ is kinetic helicity; magnetic helicity is $\mathbf{A}\cdot\mathbf{B}$, where $\mathbf{A}$ is a vector potential for the magnetic field $\mathbf{B} = \nabla \times \mathbf{A}$.

Interaction Parameter: A dimensionless measure, $N = \sigma\mathcal{B}^2\mathcal{L}/\rho\mathcal{V}$, of the relative importance of Lorentz and inertial forces.

Interchange Instability: A mode of instability characterized by the local displacement of magnetic field lines without bending them significantly.

Intermittency: A characteristic of turbulence, in which vorticity and/or magnetic field are concentrated into comparatively small fractions of the fluid volume, so that measurement of these quantities at a fixed point is highly intermittent in time, being large only while the concentrations pass through that point.

Lundquist Number: A dimensionless number measuring the ratio, $S = \tau_\eta/\tau_A = \mathcal{V}_A\mathcal{L}/\eta$, of the electromagnetic diffusion time $\tau_\eta =$

$\mathcal{L}^2/\eta$ and the time scale $\tau_A = \mathcal{L}/\mathcal{V}_A$ of Alfvén wave propagation.

Mach Numbers: Dimensionless ratios of the characteristic flow speed $\mathcal{V}$ and wave speeds. The magnetic Mach number or Alfvén number, $A = \mathcal{V}/\mathcal{V}_A$, differs from the hydrodynamic Mach number, $M_a = \mathcal{V}/a$, by the replacement of the sound speed a by a characteristic **Alfvén Speed,** $\mathcal{V}_A$.

Magnetic Buoyancy: The tendency of magnetic flux tubes, in thermal and mechanical balance with their surroundings, to rise in a gravitational field because of their lower density.

Magnetic Diffusivity: The diffusivity $\eta = 1/\mu_0\sigma$ that determines the rate at which electric currents decay through the finite electrical conductivity σ of a material.

Magnetic Flux Tube: A volume composed of a bundle of magnetic lines of force. The net flux of magnetic field across any cross section, the strength of the tube, is the same for every cross section. The surface of a flux tube is a **Magnetic Surface.**

Magnetic Lines of Force: Curves that are everywhere tangential to the direction of the magnetic field **B**; also called "(magnetic) field lines".

Magnetic Pressure: The pressure $B^2/2\mu_0$ exerted on a conductor by the magnetic field **B** it contains.

Magnetic Response Time: The characteristic time $\tau_m = \rho/\sigma\mathcal{B}^2$ for fluid flow to respond to the Lorentz forces created by the currents it induces from the prevailing magnetic field.

Magnetic Surface: A surface composed of magnetic field lines; i.e., one on which the normal component B_n of the magnetic field is everywhere zero and which therefore contains its own flux. A particular form of a magnetic surface is the **Magnetic Flux Tube.**

No-Slip Condition: The statement that a viscous fluid in contact with a solid wall moves with the same velocity as that wall.

Pinch: An electrically conducting gas compressed by magnetic forces and commonly modeled in one dimension as either a sheet pinch or a **Cylindrical Pinch** and in two dimensions as a toroidal pinch.

Plane Couette Flow: Flow set up in a viscous fluid contained between two parallel planes moving relative but parallel to one another.

Plane Poiseuille Flow: Flow in a viscous fluid contained between two stationary parallel planes and maintained by a pressure gradient parallel to those planes.

Plasma: A partially or completely ionized gas that is therefore a conductor of electricity.

Prandtl Numbers: Dimensionless measures of relative diffusion rates. The magnetic Prandtl number $p_m = \nu/\eta$ differs only from the originally defined hydrodynamic Prandtl number $p_r = \nu/\kappa$ by the replacement of the thermal diffusivity κ by the **Magnetic Diffusivity** η.

Proudman–Taylor Theorem: The slow, steady motion of an inviscid rotating and nonelectrically conducting fluid is two-dimensional with respect to the axis of rotation.

Rayleigh Numbers: Dimensionless measures of the importance of buoyancy forces, such as $g\alpha\Delta T\mathcal{L}^3/\nu\kappa$, where g is the acceleration due to gravity and ΔT is the temperature contrast across the system.

Reduced Pressure: The ratio $\varpi = p/\rho$ in a fluid of constant density; in a barotropic fluid $[p = p(\rho)]$, it is $\varpi = \int dp/\rho$; in isentropic conditions ($\nabla S = 0$), it is the enthalpy H.

Reversed-Field Pinch: A **Cylindrical Pinch** in which the magnetic field parallel to the axis of the cylinder is in opposite directions at different distances from that axis.

Reynolds Numbers: Dimensionless measures of the relative importance of the advection of fields by motion and their dissipation through diffusive loss. The magnetic Reynolds number, $R = \mathcal{V}\mathcal{L}/\eta$, differs only from the originally defined hydrodynamic Reynolds number, $Re = \mathcal{V}\mathcal{L}/\nu$, by the replacement of the kinematic viscosity ν by the **Magnetic Diffusivity** η.

Rossby Number: A dimensionless number, $Ro = \mathcal{V}/2\Omega\mathcal{L}$, measuring the relative importance of inertial and Coriolis forces in a rotating fluid.

Shear Layer: A layer in which the fluid velocity tangential to it changes rapidly.

Shercliff Layer: A boundary layer that may exist at the edge of an MHD flow when the **Hartmann Number** is large and when the magnetic field has no component normal to the boundary; also known as a "side-wall layer"; its thickness is of order $(\rho\nu\mathcal{L}^2/\sigma\mathcal{B}^2)^{1/4}$.

Suydam's Criterion: A local criterion for the stability of a general screw pinch, i.e., a cylindrical pinch in which the magnetic field has components both parallel to the axis of the cylinder and zonally about it.

Tearing Mode: An instability of a magnetic configuration that is resistive, i.e., that owes its existence to finite electrical conductivity, which allows field lines to sever and reconnect in ways disallowed by Alfvén's theorem and so to release magnetic energy to power the instability.

Theta Pinch: A **Cylindrical Pinch** in which the electric current is everywhere parallel to the axis of the cylinder so that the magnetic field is everywhere zonally directed with respect to that axis.

Total Pressure: The sum of kinetic pressure p and **Magnetic Pressure.**

Z Pinch: A **Cylindrical Pinch** in which the magnetic field is everywhere parallel to the axis of the cylinder.

HISTORICAL INTRODUCTION

Magnetospheric physics has its origins in the study of geomagnetic variations, the polar aurorae, and the ionosphere of the Earth and is also closely connected with solar physics—in particular, sunspots, prominences, flares, and the solar wind (e.g., Chapman, 1967). With the advent of the space era, there has been a dramatic advance in our knowledge and understanding of the subject, which is of key importance since the magnetosphere of the Earth, in particular, is the most accessible natural "laboratory" for the study of collisionless plasmas in an astrophysical context.

Transient geomagnetic variations were first discovered in 1722 by Graham, and their association with the appearance of aurora was first noted in 1741 by Celsius. In 1858, Broun discovered a tendency for geomagnetic disturbances to recur after about 4 weeks, an effect later rediscovered by Maunder who associated it with solar rotation. A short-lived brightening on the Sun was observed by Carrington and Hodgson in 1859, and this was found to have been associated with one of the greatest episodes of geomagnetic activity (i.e., a geomagnetic "storm") to be observed in the 19th century. Such solar "flares" were not seen again until the introduction of the spectroheliograph in 1910 by Hale. The more frequent observations which then became possible showed that flares are often followed within a day or so by a geomagnetic storm with a sudden commencement (SC). Hale also discovered that sunspots are associated with magnetic fields, which are a crucial component of the flare phenomenon.

Following his observations of a great aurora which occurred over northern Europe in 1716, Halley made the suggestion that it was produced by "magnetic particles" moving along geomagnetic field lines. In contrast, in the second edition of his book on aurorae (1754), de Mairan argued that the cause of the phenomenon lies on the Sun and that it is the result of the extended solar atmosphere, as indicated by the zodiacal light, interacting with the atmosphere of the Earth. De Mairan argued that, on this basis, aurorae should be

seen also in the southern hemisphere, as was ultimately confirmed by Cook in 1773. The auroral "zone" was drawn first by Loomis in 1860 and showed that the frequency of occurrence of aurorae is maximum in a belt which cuts across northern Scandinavia and decreases markedly in more polar regions. The fact that there is a similar auroral zone in the southern hemisphere and that both are located roughly symmetrically with respect to the geomagnetic axis was not established until much later. Eventually it was also found that auroral and associated geomagnetic disturbances tend to occur simultaneously in both hemispheres, in a manner consistent with the hypotheses of Halley and de Mairan.

The properties of the geomagnetic quiet-day solar variation (Sq), discovered in 1722 by Graham and studied in greater detail by Gauss and his successors, are such that Stewart concluded in 1882 that the associated electric currents must flow mainly in the upper atmosphere, which he inferred to be electrically conducting. The need for such a conducting layer at moderately high altitudes was demonstrated by the first long-distance radio-wave propagation experiments of Marconi, which showed that the waves were somehow refracted so that they could propagate around the curved surface of the Earth. The "ionosphere" (*q.v.*), as we now know it, was first detected directly in 1925 by the experiments of Appleton and Barnett in England and Breit and Tuve in the United States, using sounding techniques. Since that time, the ionosphere has been investigated in great detail and has been shown, in particular, to exhibit diurnal variations that are associated with the Sq geomagnetic variations and also irregular variations in the polar regions. The latter are associated with the occurrence of aurorae and polar geomagnetic disturbances.

Since the early 1950s and with the development of the space age, there has been an extraordinary growth in our understanding of all of the phenomena described above. It was shown by Storey, using low-frequency "whistler" waves generated by atmospheric lightning discharges, that the plasma environment of the Earth extends from its base in the ionosphere out to distances of at least several Earth radii and exists in a region which we now term the "plasmasphere." At still greater distances, experiments carried on spacecraft launched by the USSR and the United States around 1960 showed that interplanetary space is indeed filled with the rapidly expanding atmosphere of the sun. This had been proposed by Biermann on the basis of observations of the behavior of comet tails and termed the "solar wind" by Parker. De Mairan's hypothesis concerning the origin of the aurora therefore can be regarded as being correct, although the component of the zodiacal light to which he referred was certainly associated with interplanetary dust rather than the solar wind.

The region surrounding the Earth in which the geomagnetic field has a dominant role in controlling the dynamics of the plasma and the more energetic particles is now called the "magnetosphere," following a suggestion by Gold (1959). The magnetosphere was investigated in great detail by many early spacecrafts, notably in 1964 by the first Interplanetary Monitoring Platform (IMP 1), which provided a rather complete survey of the main features of the structure of the magnetosphere. Earlier, Van Allen (1987), with the aid of the first U.S. Earth satellites, had made the startling discovery that the magnetosphere contains zones of relatively energetic particles which were termed the "radiation belts." The so-called "inner" belt is rather stable and contains mainly protons with energies in the range 1–100 MeV. The "outer" belt contains highly variable fluxes of electrons and ions, mainly in the range 1–1000 keV, which are associated with the aurora and also with the electric currents which produce the various classes of geomagnetic storm effects. The latter include the "ring current," which causes the main-phase global depression of the field strength observed at the Earth during geomagnetic storms, and the auroral zone "electrojet" currents, associated with transient "substorms," which lead to the injection and energization of magnetospheric plasma and cause the growth of the ring current.

In the following, we provide a summary of our knowledge of the magnetosphere of the Earth and our understanding of the main processes involved in determining its behavior. Ionospheric phenomena are included where they are an essential component of the magnetosphere, and comparisons are made with the magnetospheres of other planets that have been investigated in some detail during the past 20 years.

1. THE CONFIGURATION OF THE EARTH'S MAGNETOSPHERE

The overall configuration of the Earth's magnetosphere is shown in Fig. 1. The first point is that the magnetosphere is bounded, as a consequence of the confining pressure of the solar wind. That is, the external pressure of the solar-wind plasma and magnetic field balances the internal geomagnetic field pressure at the interface (called the magnetopause). Thus, approximately,

$$nmV^2 = B^2/2\mu_0 \qquad (1)$$

where n is the number density of ions in the solar-wind plasma, m is their mean mass, V is the speed of the wind, and B is the magnetic induction just inside the magnetopause. This simple relation, which was first given by Chapman and Ferarro (1931), provides an estimate for R, the distance to the magnetopause at the subsolar point: taking $n = 5 \times 10^6$ m^{-3}, $V = 4 \times 10^5$ m/s, and $B = 2B_0(R_e/R)^3$, where $B_0 = 0.3$ gauss $= 3 \times 10^{-5}$ T is the equatorial magnetic induction at the surface of the Earth ($R = 1R_e \approx 6.4 \times 10^6$ m), we find that $R \approx 10R_e$. In fact, the various parameters involved vary considerably with time so that R may vary by as much as 50% from this value depending on conditions in the interplanetary medium.

It is possible to generalize the above result and thus produce an approximate but quite satisfactory model for the shape of the magnetopause by replacing V with $V \cos^2 \theta$, where θ is the angle between the mean solar-wind direction and the local normal to the magnetopause, and iteratively solving for the magnetic field so that it has no normal component. This is the so-called "Newtonian" approximation, which is reasonably good provided that θ is not close to $\pi/2$ and neglected components of the pressure inside and outside the magnetosphere are indeed negligible. The approximation works well because the solar wind at the orbit of the Earth is highly supersonic (the Mach number is usually of the order of 10 or more). Since the magnetosphere constitutes an obstacle in the solar-wind flow and waves with wavelengths comparable to the scale of the magnetosphere are ordinary Alfvén and magnetoacoustic waves, a bow shock with thickness

usually of the order of the ion gyroradius (100–1000 km) is formed upstream (Onsager and Thomsen, 1991). The shock plays only a secondary role in the interaction of the solar wind with the magnetosphere, but it is important in accelerating particles in much the same way that is presumed to occur in supernova remnants where the result is the production of cosmic rays.

1.1 The Polar Cusp

A feature of the idealized model of the magnetopause described above is the "polar cusp," which is connected to the day side of the Earth at geomagnetic latitudes between 65° and 75°, depending on interplanetary conditions (Hoffet and Egeland, 1984; Crooker and Burke, 1991). Ideally, the cusp is a single geomagnetic field line in each hemisphere which splits on encountering the magnetopause and covers the entire surface. This implies that a particle which becomes attached to the surface should eventually find its way to the ionosphere in one hemisphere or the other. In fact, this is an oversimplification resulting from the assumption that the geomagnetic field is completely confined within the magnetopause and the interplanetary magnetic field completely excluded. Some interconnection between these two magnetic fields at the magnetopause cannot be avoided as a consequence of the process of magnetic "reconnection" which would normally tend to occur over the forward side of the magnetopause. Thus, the polar cusp consists, in general, of a bundle of magnetic field lines in each hemisphere which intersect the Earth in small regions surrounding the idealized Chapman–Ferarro cusp positions. These are strongly confined in local time and geomagnetic latitude; the field lines connect with the interplanetary field so that there is always a small normal component of the field at the magnetopause allowing the escape or entry of plasma across the interface. This normal component plays an important role in the interaction of the solar wind with the magnetosphere, since it implies the existence of a tangential stress at the magnetopause that results in the exchange of energy and momentum as well as plasma.

1.2 The Magnetotail

A direct consequence of reconnection between the interplanetary and geomagnetic fields is the formation of an extended tail to the magnetosphere ("magnetotail") comprised of two bundles of oppositely directed field lines (Liu, 1989; Birn, 1991). These are connected to the polar caps of the Earth at latitudes greater, approximately, than the latitudes of the cusps. A large fraction of the magnetic flux in the magnetotail is linked with the interplanetary field rather than connecting the two polar cap regions of the Earth. This "openness" of the magnetic field at high latitudes permits terrestrial plasma to escape into interplanetary space and allows moderately energetic interplanetary particles (solar-flare particles and low-energy cosmic rays) direct access to the Earth's polar caps. The open field regions, called the "lobes," contain little plasma and to maintain pressure balance with the external interplanetary medium have field strengths of the order of 10 nT at the orbit of the Moon, for example. The total amount of magnetic flux contained in each tail lobe is about (5–10) × 10^{16} Mx, since the width of the magnetotail at this distance is about (30–40)R_e. This is roughly the same as the flux intersecting the polar caps of the Earth at latitudes greater than about 70–75°.

The region separating the two tail lobes is often called the "neutral sheet," since the main component of the magnetic field (tailward in the northern lobe and earthward in the southern lobe) reverses its sign. In fact, the neutral sheet is not strictly neutral but contains a small normal component that partly links the two lobes so that, in magnetically quiet times, the field lines involved are connected at both ends to the Earth. The magnetic field around the neutral sheet consists, therefore, of highly stretched dipole-like field lines containing about 10^{16} Mx. This field connects with the auroral zones of the Earth, which are at most about 5 degrees of latitude wide in each hemisphere, and contains plasma with a pressure approximately equal to the magnetic pressure in the lobes of the magnetotail. Assuming that the mean energy of the ions is roughly the same as in the solar wind, it is easily estimated that the density of these ions is about 10^4–10^5/m^3 and the electron flux (assumed >200 eV) about 10^{12}/

m^2 s, as observed. Obviously, the plasma sheet is intimately connected with the auroral phenomenon (Sec. 1.7), which requires that the electron component be accelerated further to 1–10 keV and be, to a large extent, precipitated into the upper atmosphere in the auroral zones where it produces visible radiation and considerable heating. No good explanation as to why a (small) component of the auroral particle precipitation should be highly localized, producing spectacular features such as arcs and rays, has yet been produced. Very probably, such features are a reflection of corresponding features in the outer magnetosphere and, in particular, the inner edge of the plasma sheet, which is often quite sharply defined.

1.3 Convection

The ionosphere forms the base of the magnetosphere and is a source of plasma for the outer regions as well as providing, at low altitudes (<130 km), an electrical short circuit perpendicular to the geomagnetic field which acts to discharge electric fields of external origin unless they are maintained in some way. At altitudes below about 200 km, the ionosphere is largely controlled by a balance between (solar) photoionization and local recombination (Van Zandt, 1967; Rishbeth and Garriott, 1969). At higher altitudes, the plasma may be transported over relatively large distances before recombining, provided the speed of transport is sufficiently great. This speed follows from

$$\mathbf{E} + \mathbf{V} \times \mathbf{B} = 0 \qquad (2)$$

where the electric field **E** is determined by magnetospheric processes or by tidal and other large-scale motions of the neutral atmosphere in the so-called "dynamo" region at 100–120 km altitude. These are usually called "convective" motions, and they pervade the entire magnetosphere since Eq. (2) holds good for low-energy plasma in the magnetosphere provided the time scales involved are long (Axford, 1969). A good example of convective effects on the ionosphere is the "equatorial anomaly"; this is the result of the electric fields associated with the Sq geomagnetic variations causing an upwelling of plasma near the geomagnetic equator during the day in association with a tendency of the plasma to drop under the influence of gravity. The overall effect is for the ionospheric plasma density to have maxima on either side of the equator in the afternoon and early evening (Cohen, 1967). A second example is the transport of plasma from the sunlit side of the Earth over the polar caps to the night side as a consequence of convection associated with auroral and polar cap magnetic disturbances.

1.4 The Polar Wind

In addition to convection perpendicular to the local magnetic field direction, as implied by Eq. (2), ionospheric plasma can move freely along the field lines, being influenced only by gravity. Thus, on field lines that are closed, the ionosphere may extend far out into space, being filled from either end by upwelling plasma composed mainly of the lightest species available, namely, protons, until hydrostatic equilibrium is reached. Such an equilibrium prevails in the plasmasphere discovered originally by Storey. Observations, however, show that the plasmasphere usually has an outer boundary, the "plasmapause" at about $4R_e$, beyond which the plasma density suddenly drops to levels of the order of $10^6/\text{m}^3$. Beyond the plasmasphere, on field lines that are empty of plasma or are directly open to interplanetary space (i.e., the tail lobes), the ionosphere continues to supply plasma from below, but there is no equilibrium on a given field line until it is finally filled. The lack of hydrostatic equilibrium on closed field lines is a consequence of the convection of plasma to the outer parts of the magnetosphere where it may eventually find itself on open field lines and so escape into space. The existence of the plasmapause, which was discovered by direct spacecraft measurements as well as by the whistler technique around 1960, can be taken as an indication that such convective and loss processes are indeed important in the magnetosphere.

The upwelling of ionospheric plasma described above is termed the "polar wind" (Banks, 1978). It is a supersonic flow, somewhat analogous in its characteristics to the solar wind, and should be prevalent above most of the polar ionosphere at geomagnetic latitudes greater than about 60°. The polar wind is responsible for controlling the amount of helium in the Earth's atmosphere, since it provides an efficient escape mechanism capable of balancing the rate at which fresh helium is emitted from the Earth's crust as a result of radioactive processes. As described so far, the polar wind is a thermal process associated with photoionization and heating of the plasma by photoelectrons. Stronger heating processes are available, however, notably those resulting from cyclotron heating which favor heavier species—in particular, helium, oxygen, and even molecular ions. These play a significant role in forming the plasma sheet and the outer radiation belt following modest acceleration to the ~10-keV range (Axford, 1970; Cornwall and Schulz, 1979).

1.5 The Exosphere

While helium escapes from the Earth via the polar wind, hydrogen escapes in neutral atomic form as a result of Jeans (thermal) escape; that is, the atoms are placed on escape trajectories by collisional processes at the base of the exosphere where the mean free path for collisions begins to exceed the scale height of the distribution. The exosphere is quite extensive, depending on the phase of the solar cycle, which determines the temperature at its base, and neutral hydrogen may have a significant density out as far as $10R_e$. This cloud of neutral hydrogen surrounding the Earth's exosphere can be detected from scattered solar Lyman-alpha radiation and is usually dense enough to be optically thick in this line in its inner regions. The exosphere is important, as charge exchange of energetic protons with hydrogen atoms is a significant loss mechanism for the outer radiation belt and may determine the rate of decay of the associated ring current (Williams, 1983). Charge transfer with other species also leads to changes in their charge state distribution which can now be measured.

1.6 The Radiation Belts

The outer radiation belt has its origin mainly in transient events in which the plasma sheet is pushed close to the Earth and the energetic plasma becomes trapped. The same process, which can be regarded as temporarily enhanced convection, erodes the plasmasphere and hence, at the time it occurs, places the inner edge of the newly introduced hot plasma at the plasmapause. Since the pressure of the plasma is not insignificant, the magnetic field is inflated, and the result is observable within the plasmasphere and, in particular, on the Earth, as a ring current. Initially, this ring current may be asymmetric, but after a while, it settles down and becomes reasonably symmetrical when the magnetic field depression can be calculated from

$$\mathrm{grad}P = \mathbf{j} \times \mathbf{B} \tag{3}$$

with $\mathbf{j} = (1/\mu_0)$ curl $\mathbf{B}$ and P a given (symmetrical) distribution of plasma pressure. It has been shown by Dessler, Parker, and Sckopke (see Williams, 1983) that this leads to a simple relation for the field depression ΔB at the Earth:

$$\Delta B/B_e = -2E/3E_m \tag{4}$$

where $B_e = 30{,}000$ nT is the horizontal component of the geomagnetic field at the equator, E is the total energy of the trapped particles, and $E_m = 8 \times 10^{17}$ J is the total energy in the geomagnetic field outside the Earth. In a large geomagnetic storm, ΔB may be of the order of 300 nT so that the total energy of the plasma producing the ring current effect is about 10^{16} J. Typical particle energies are 1 keV–1 MeV. The inner radiation belt is quite different in its characteristics from the outer belt. The particles are much more energetic (100 keV–10^3 MeV), the distribution of particles does not vary greatly with time, and the ions seem to be mainly protons. The main source of energetic particles appears to be the decay of neutrons produced by cosmic rays interacting with the Earth's upper atmosphere, and this is consistent with the observed predominance of protons. Nevertheless, there may be an external source, possibly initiated by energetic solar particles, such that the particles diffuse slowly inward from an injection region around $4R$, the diffusion resulting from an interaction of drift motions in the inhomogeous geomagnetic field and fluctuations in the convection fields associated with magnetospheric substorms.

1.7 Auroral Phenomena

The most spectacular aspect of magnetospheric physics is the polar aurora, which, in magnetically disturbed periods, is a highly structured and often rapidly changing fluorescence of the upper atmosphere resulting from excitation by electrons with energies in the range 1–20 keV. The most important visible emissions are those of atomic oxygen (green λ 5577, red λ 6300) and nitrogen molecules (blue λ 3914, λ 4278). In addition, there is very strong infrared emission from molecular oxygen (λ 12 700), which is heavily absorbed in the atmosphere. Protons, with energies in the range 1–100 keV, also produce weak Balmer lines, which can be detected from the ground (e.g., red λ 6563) with Doppler shifts indicating downward-moving particles, as well as Lyman lines which are absorbed or scattered into space. Most of these emissions are produced at altitudes of 100 km and higher. High-energy electrons (>50 keV) produce x rays that can be detected at balloon altitudes (20–40 km) and that lead to low-altitude ionization detectable by radiowave diagnostic techniques. (For a detailed discussion of auroral emissions, see Omholt, 1971; Bone, 1991; Meng *et al.*, 1991; and Meng and Mauk, 1991).

Most aurora is produced in zones 5–10° wide surrounding both polar caps at magnetic latitudes of about 65–70°, corresponding to the "feet" of magnetic field lines which connect to the plasma sheet in the magnetosphere. There is, however, another class of aurora which occurs at lower latitudes, namely, the midlatitude or "subauroral red arcs." These are observed during large geomagnetic storms and are spatially associated with the plasmapause. The energy input to the normal aurora ranges from, typically, 10^{-3} J/m^2 s, for subvisual quiet-time conditions, to 1 J/m^2 s for bright, active aurora seen during disturbed periods. The midlatitude arcs, which appear to be produced by low-energy (10–100 eV) electrons, are faint and involve perhaps only 10^{-3}–10^{-2} J/m^2 s. The total power associated with the production of aurora is of the order of 10^8–10^{11} J/m^2 s depending on the level of magnetic activity. In addition, the electric currents that are associated with the aurora (the electrojet) and that produce the geomagnetic variations may involve a total of as much as 10^6 A. The resulting ionospheric Joule heating power is of the same order as that of direct particle heating. The heating results in considerable atmospheric upwelling and, together with the $\mathbf{j} \times \mathbf{B}$ forces, launches atmospheric gravity waves, the effects of which can be observed at low latitudes.

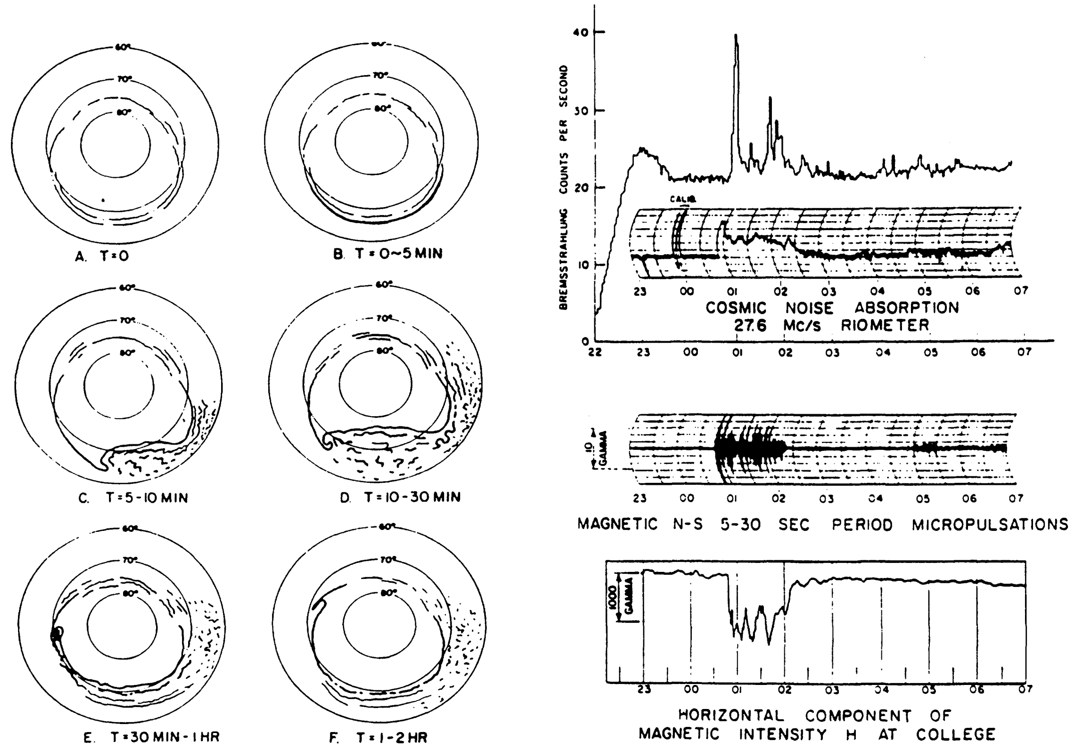
The most striking features of the visible aurora are the structures that are commonly observed, namely, arcs, rays, coronae, and so on. The arcs are often found to be many thousands of kilometers in length but are only a few kilometers wide. As magnetic activity increases, the arcs tend to fold and assume a rayed structure. The folded arcs may seem to break up into isolated rays which, on passing overhead, appear as "coronae." These features may be very dynamic, moving with speeds of the order of several kilometers per second, changing in form and often pulsing in brightness with periods of the order of 10–20 s. The pattern of auroral motions corresponds roughly to that of magnetospheric convection at ionospheric levels as confirmed by radar Doppler backscatter measurements and direct measurements of drifts and electric fields in situ. There are, however, motions in auroral patterns which do not correspond straightforwardly to Eq. (2) but are instead associated with the motion of disturbances moving across geomagnetic field lines (i.e., waves and reconnection as described in Sec. 2.1 and 2.2). It should be noted that, despite their prominence as far as visible observations are concerned, auroral structures are not dominant in terms of the total energy deposited in the atmosphere. The human eye, for example, is most sensitive to the bright features but fails to register the more ubiquitous diffuse emissions that fill much of the sky in the auroral zone during periods of high activity.

There is a certain amount of auroral activity associated with the polar cusp and occurring also in the polar cap. This aurora is evidently produced on open geomagnetic field lines to a large extent and has different characteristics from that occurring in the auroral zone. In particular, it becomes bright and active in the early phases of a geomagnetic storm, suggesting that it is activated by the enhanced dayside magnetic reconnection taking place at such times (see Sec. 3.1).

Major disturbances in the aurora, the associated electrojet, and other related phenomena were formerly called "polar elementary storms" or "magnetic bays" and are now known as substorms (see Sec. 3.2). The auroral disturbance, sometimes called "breakup," has a particular pattern, which was first clearly described by Akasofu (1977) and which is shown in Fig. 2(a). It is important to note that the poleward motion of the bright arc depicted here does not correspond to convection, which, in fact, tends to have the opposite sense. A typical example of the magnetic disturbance occurring at such times is shown in Fig. 2(b).

The cause of most auroral emissions is the precipitation from the plasma sheet of moderately energetic electrons by wave scattering or anything that leads them to interact with the atmosphere. In addition, there are strong indications for acceleration of particles in the few-keV range associated with anomalous electrical resistivity affecting magnetospheric currents. These currents flow out of the ionosphere into the magnetosphere as a consequence of the stresses induced in the system by plasma pressure, interaction with the solar wind, and ionospheric convection drag. The anomalous resistivity results in the formation of plasma turbulence involving small-amplitude electrostatic waves, which provide an integrated electric potential drop of a few kilovolts and a corresponding "monoenergetic" feature in the spectra of the incoming electrons.

In general, the aurora exhibits geomagnetic conjugacy to a surprising degree of detail. There is, however, a tendency for the patterns observed in the two hemispheres to be displaced in longitude by many hundreds or even thousands of kilometers, depending on the level of activity. It is suggested that this is the direct result of magnetic reconnection in the magnetotail, since reconnection need not involve conjugate magnetic field lines, as defined from the internal field of the



(a) (b)

FIG. 2. (a) The pattern of development of auroral arcs and activity associated with a magnetospheric substorm as seen from above the north geomagnetic pole. The rapid northward movement (C, D) does not correspond to the direction of magnetospheric convection at the time. (From Akasofu, 1977.) (b) The simultaneous occurrence of x-ray bursts, cosmic radio noise absorption, micropulsations in the geomagnetic field, and the negative magnetic disturbance associated with the auroral electrojet during a magnetospheric substorm observed in Alaska (From Akasofu, 1977.)

Earth. The component of the interplanetary field perpendicular to the geomagnetic axis skews the two lobes of the tail, thus leading to a systematic longitudinal shift of conjugacy. Small-scale nonconjugate reconnection can be relieved by the propagation of Alfvén waves, which remove the tangled component of the field as they are dissipated at low altitudes by ionospheric resistivity. Accordingly, there is a great deal of micropulsation activity associated with the aurora and detectable from ground-based observatories, directly and via fluctuations in luminosity; it may also be detected in space where the amplitudes of the waves may be very large.

2. THE DYNAMICS OF THE EARTH'S MAGNETOSPHERE

2.1 Magnetic Reconnection

The most important single process occurring in the magnetosphere is magnetic field reconnection, which is depicted schematically in Fig. 3. In general, Eq. (2) provides an accurate description of the relationship between the bulk plasma velocity and the electromagnetic field. When combined with Faraday's law, it yields

$$\frac{\partial B}{\partial t} + \operatorname{curl}(\mathbf{V} \times \mathbf{B}) = 0, \tag{5}$$

which can be shown to require that plasma elements on a common magnetic field line at one instant in time remain on a common field line thereafter and that a closed loop which moves with the plasma always encloses the same amount of magnetic flux (Sonnerup, 1979; Axford, 1984). This "frozen field" theorem is valid provided additional terms neglected in Eq. (2), such as might be associated with the finite electrical conductivity of the plasma, do not cause a breakdown of any significance. Such effects are usually negligible except in the vicinity of "neutral" points in the magnetic field where $\mathbf{V} \times \mathbf{B}$ vanishes locally and $\mathbf{E} \cdot \mathbf{B}$ is not zero. If a neutral point exists, the property of "connection" between plasma elements implied by the frozen-field theorem need not be preserved. As a consequence, magnetically connected plasma elements may become disconnected if their common magnetic field line intersects a neutral point somewhere between them, as illustrated in Fig. 3.

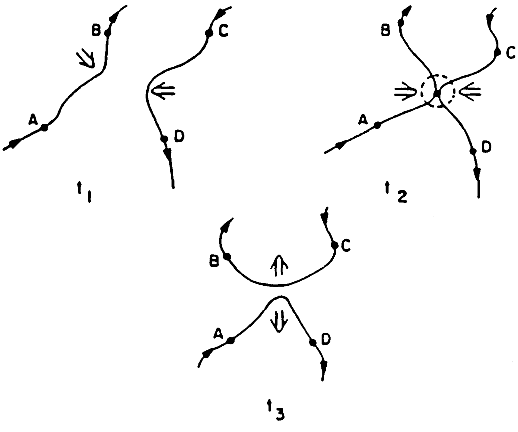


FIG. 3. At time t_1, the magnetic field line defined by plasma elements A and B approaches an oppositely directed field line defined by elements C and D. At time t_2, the two field lines touch at some point intermediate between A and B and C and D. At time t_3, the connection between A and B and between C and D is broken and the field line defined by A and D moves away from the field line defined by B and C. (Axford, 1984).

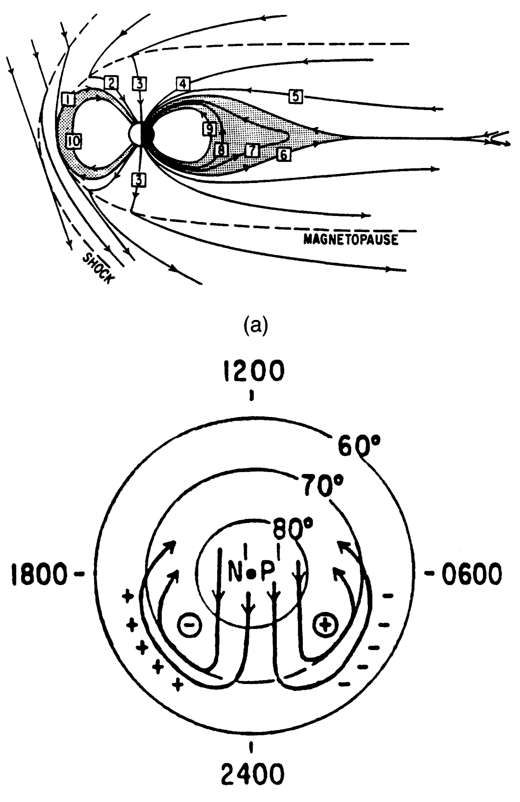
The manner in which reconnection permits linkage between the interplanetary and magnetospheric fields is shown schematically in Fig. 4(a). The numbers indicate the successive positions of a geomagnetic field line following reconnection with interplanetary field (1) and subsequently reconnection between field lines in the geomagnetic tail (6). Between positions (1) and (6), the feet of the field lines move across the polar ionosphere from the dayside to the nightside and the field lines are open ended, allowing magnetospheric plasma to escape into interplanetary space. Between positions (6) and (9), the field lines and the plasma move toward the Earth from the night side (their feet move toward the equator); between positions (9) and (10), the motion is around the Earth (out of the plane of the paper); and from (10) back to (1), the feet move poleward. The pattern of flow seen at ionospheric levels is also shown in Fig. 4(b). This pattern is consistent with what is observed on average by radar backscatter techniques and satellite-borne electric field probes and is the dominant component of magnetospheric convection in the outer magnetosphere.



(a)

(b)

FIG. 4. (a) Steady convection as seen in the noon-midnight meridian with reconnection occurring at positions (1) and (6). Between points (9) and (10), the convection is out of the plane of the paper, going around the Earth at latitudes corresponding to the auroral zones. (b) Motion of the feet of the geomagnetic field lines at ionospheric levels, shown schematically. If the Hall conductivity is dominant, the streamlines also represent current flow lines if the direction of the arrows is reversed.

2.2 Magnetospheric Substorms

The above description of reconnection is purely kinematic. In fact, there are limits on the "rate" of reconnection, that is, on the electric field strength along the neutral points shown in Figs. 3 and 4. Depending on external conditions, this lies between 0 and $V_A B$, where V_A and B are the Alfvén speed and magnetic field strength characterizing the plasma outside the reconnection region, respectively. In effect, the rate is determined by the rate at which mass can be ejected from the reconnection region to make room for further reconnection to take place, the ejection resulting from the "catapult" effect of the magnetic stresses in the strongly curved field lines in the narrower parts of the "X." Since these stresses can be counteracted by pressure gradients in the plasma, the rate of reconnection can be controlled by the degree to which such pressure gradients build up and, indeed, can be brought to a halt if the plasma on reconnected field lines is unable to escape. On examining Fig. 4, it can be seen that, on the upstream side of the magnetosphere where the solar-wind plasma flow is determined to a first approximation by externally induced pressure gradients, reconnection may proceed on a more or less continuous basis, whereas in the magnetotail, where the inner magnetosphere may block the flow, reconnection may be stopped almost entirely until the blockage is somehow overcome. The plasma that produces the blockage is the plasma sheet, and the nonlinear instability that results in its disruption and a reconfiguration of the magnetotail corresponds to the magnetospheric substorm phenomenon (Fig. 2). This kind of instability, which has been termed a "gross resistive" or "reconfigurational" instability, also plays a role in solar flares.

The precise details of substorm initiation are not completely understood at present. However, it is clear that the whole process involves growth of the magnetotail, in both size and magnetic field strength, followed by a collapse associated with reconnection beginning in the existing plasma sheet, the injection of energetic particles into the ring current region in the inner magnetosphere, and the cutting off of a large piece of the magnetotail, which is carried away downstream where it eventually merges with the interplanetary medium (Fig. 5). As a consequence of a series of such substorms, the ring current grows in strength over a period of several hours and ultimately decays again as the substorm activity declines and the losses of ring current plasma to charge exchange with the exospheric neutral hydrogen and precipitation into the atmosphere are able to restore order (see Akasofu, 1977; Kan *et al.*, 1991; Birn, 1991).

Dayside reconnection at the magnetopause is not constrained in the same way as it is in the magnetotail, since the reconnected plasma and field can easily escape (Smith, 1991). Accordingly, periods in which the interplanetary magnetic field is strong and

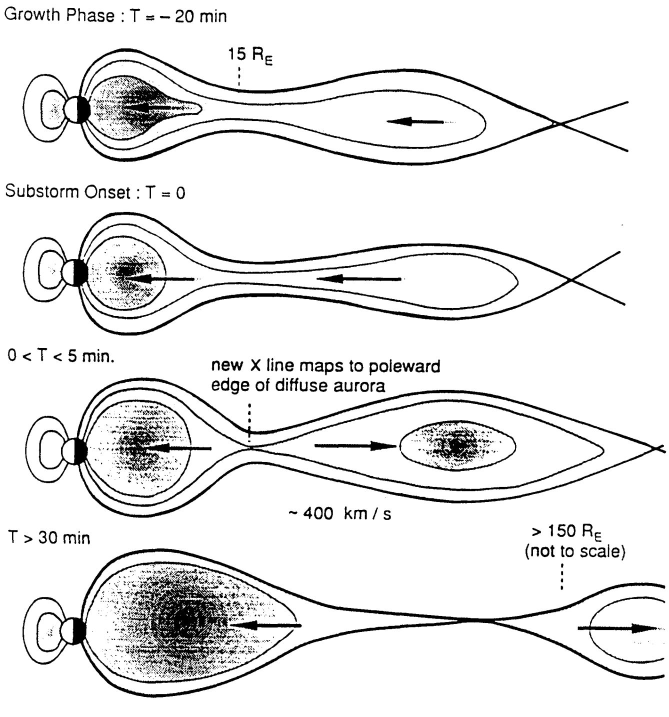


FIG. 5. Schematic diagram of the changes taking place in the plasma sheet and magnetotail during the various phases of a magnetospheric substorm. (From Kan *et al.*, 1987.) A second reconnection (X) line is formed close to the Earth, and a plasmoid is detached and moves down the magnetotail away from the Sun.

directed southward are also periods in which rapid erosion of magnetic flux from the dayside of the magnetosphere can be expected, perhaps episodically ("flux transfer events"). As a consequence of rapid flux transfer, the magnetotail grows and substorms and a geomagnetic storm must follow. The events are also associated with strong poleward convection in the high-latitude dayside ionosphere and the presence of bright and active aurora in this region.

2.3 Energy Budgets

A summary of the magnetospheric energy budget at varying levels of geomagnetic activity is given in Table 1. The average efficiency for energy transfer between the solar wind and the magnetosphere is only about 10^{-3}, but this does not include the stored magnetotail energy lost downstream. This may be much greater than that trapped in the inner regions of the magnetosphere and dissipated in the form of auroral-zone particle precipitation and Joule dissipation of ionospheric electric currents. It is interesting to note that the efficiency of capture of solar-wind plasma is quite low and may be less than the 10^{-4} quoted, since the plasma sheet and the lower-energy ring-current particles contain a significant component of ionospheric origin, notably in the form of singly ionized helium and oxygen but also, occasionally, as molecular ions such as NO^+ (Moore, 1991). Nevertheless, it seems possible that capture from the solar wind may be an important source of the atmospheric ^3He isotope, for example.

The rate of energy transfer to the magnetosphere from the solar wind, as a consequence of reconnection at the magnetopause, is of the order of $VB_tB_nA/2\mu_0$, where V is the solar-wind speed, B_t and B_n are the components of the magnetic field tangential and normal to the magnetopause, respectively, and A is the effective area of the magnetopause. Since $B_nA \approx \phi_p$, the total "open" magnetic

Table 1. Magnetospheric energy budget.

Incident solar wind flux	3×10^{12}–10^{15} J
Ring current particles	3×10^{14}–10^{16} J
Ring current injection rate	3×10^{9}–10^{12} J/s
Ring current loss rate	3×10^{9}–10^{11} J/s
Auroral particle precipitation	3×10^{9}–10^{11} J/s
Auroral Joule dissipation	3×10^{9}–10^{11} J/s
Total injection rate	10^{10}–10^{12} J/s
Efficiency	$\sim 10^{-3}$

flux intersecting the polar caps of the Earth, then, taking $V = 10^6$ m/s and $B_t = 10$ nT and assuming that the geomagnetic field above 70° latitude is open, we find that the rate of energy transfer is about 10^{13} J/s. This easily accounts for the total injection rates given in Table 1, and it is presumed that any excess is lost again to interplanetary space in the form of detached magnetized "plasmoids," following reconnection in the magnetotail.

2.4 Particle Acceleration

The violent release of electromagnetic energy associated with magnetic field reconfiguration during substorms leads to the acceleration of particles in the magnetosphere as a result of at least six distinct processes (Chang, 1986).

1. The most important acceleration process in the magnetosphere in terms of total energy conversion is associated with the convection. The process is effectively adiabatic and is a consequence of the compression and expansion of magnetic flux tubes as they move deep into and out of the magnetosphere. It can also be thought of as the result of particle drift across the equipotentials of the convection electric field, and this immediately implies that the maximum energy achievable is of the order of 100 keV/charge under conditions of strong convection. All of the plasma participates, in particular, the ions that produce the ring-current effect and the electrons that give rise to the bulk of the auroral precipitation.
2. Electric fields associated with nonsteady convection, which includes nonconservative fields, can affect particles of higher energies, especially in giving rise to radial diffusion with an associated acceleration if the diffusion is inward. The diffusion may be relatively slow, since it depends very much on the component of time-varying electric fields resonant with the particle drift period around the Earth. However, very high energies are achievable provided that losses are not important; consequently, this process may constitute a major source for the inner radiation belt.
3. The reconnection process itself can give rise to a localized but very striking acceleration, especially of ions that have large gyroradii in the weak fields near the neutral point. These are able to experience much of the available inductive voltage drop before exiting along the magnetic field lines intersecting the neutral point. When reconnection occurs on tail-lobe field lines, the voltage drop may be as large as $V_A BL$ for a short period. With $V_A = 3 \times 10^6$ m/s, $B = 20$ nT, and $L = 3 \times 10^7$ m, the voltage drop can exceed 10^6 volts, which is much greater than that associated with ordinary convection.
4. Large-amplitude waves, with their wave normals almost perpendicular to the magnetic field, are capable of producing substantial electric fields parallel to the magnetic field and can, therefore, accelerate electrons very efficiently. This may occur very close to the neutral point, where $\mathbf{E} \cdot \mathbf{B} \neq 0$ in general, and also when strong compressional waves are produced in the inner magnetosphere, as may occur when the inner magnetotail collapses toward the Earth in association with the onset of a substorm.
5. Resonant wave damping can be a very efficient heating process, but, of course, it is limited by the amount of wave energy available at suitable frequencies. A very important example is cyclotron heating of ionospheric ions in the auroral zones, which produces He^+, O^+, and even molecular ions with energies of the order of several keV. These ions escape into the outer magnetosphere where they provide a source for the ring current and are subject to further acceleration by other processes.
6. The stresses exerted by the plasma and magnetic field in the outer magnetosphere are, to some extent, taken up by the ionosphere where the plasma is held as a result of collisions with the neutral atmosphere. The communication of such stresses involves a strongly localized "shear" in the magnetic field, for example, at the boundary between open and closed field lines. This magnetic shear is associated with a field-aligned electric current which, if it is sufficiently strong, can result in plasma instabilities that produce fluctuating parallel electric fields and cyclotron waves as described above. These electric fields may be important in accelerating electrons to moderate energies. They are the result of "anomalous" elec-

trical conductivity and are not to be confused with the hypothesized "double layers," which do not appear to exist with large, stationary potential drops.

3. OTHER MAGNETOSPHERES

3.1 Magnetospheres of Nonmagnetized Bodies

All solar system bodies that have no intrinsic magnetic fields and no atmospheres have a minimum interaction with the solar wind or whatever plasma environment that may exist. The surface layers of such objects, of which the Moon is a typical example, have such a low electrical conductivity that they may be considered as being insulators through which magnetic field lines can pass unhindered. The only interactions are associated with absorption of the solar wind or other plasma, leaving a void in the wake that slowly fills in from the sides and a weak effect associated with the emission of secondary ions and neutral atoms as a result of sputtering and other processes. The objects that behave in this manner are the Earth's Moon, Phobos, Deimos, asteroids, comets at large distances from the Sun, the icy satellites of the outer planets (interacting mostly with magnetospheric plasma), and possibly the Pluto–Charon system if no atmospheres are involved.

Objects that have atmospheres but negligible intrinsic magnetic fields interact strongly with external flowing plasma and can "capture" the magnetic field of the external medium producing a kind of "induced" magnetosphere. The important components of the interaction are the ionospheres produced by collisional or photoionization and the mass loading of the more distant external plasma as a consequence of the pickup of ions from the exosphere of the body. The case of Venus (Hunten *et al.*, 1983; Luhmann, 1991) is rather special, because the ionosphere normally has enough pressure to withstand the ram pressure of the solar wind. This flows around the effective obstacle, being affected mainly by a rather strong contribution from pickup ions and the fact that the size of the obstacle is not large compared with the ion gyroradii. The interface between the topside ionosphere and the external plasma (the "ionopause") is often clearly defined, but it is liable to instabilities associated with the unfavorable curvature of the external magnetic field, especially when pushed inward as a result of a sudden increase of the external pressure; in such circumstances, magnetic field lines can be trapped in the ionosphere, forming "flux ropes" which may be relatively long lived. Mars is rather similar to Venus, but it appears that the ionosphere is not usually capable of withstanding the external pressure and hence the magnetic field lines become fully imbedded and constitute a kind of trapped or induced magnetosphere (Blamont, 1991). It is also uncertain as to whether or not Mars has a very weak (<50 nT) intrinsic field that complicates matters further. Both Venus and Mars lose material to interplanetary space as a consequence of their interactions with the solar wind, and in the case of Mars this may have played a significant role in the evolution of the atmosphere.

Comets have certain similarities to Mars and Venus but differ in that the parent bodies are negligibly small and, especially in the case of large comets such as Halley, have enormously extended atmospheres when close to the sun. As a consequence of plasma pickup, these atmospheres constitute correspondingly large effective obstacles to the solar-wind flow. At 1 a.u. from the Sun, the shock wave produced by Comet Halley was about 10^9 m from the nucleus and within 10^8 m the plasma flow was dominated by the presence of cometary ions with the magnetic field accordingly draped around the nuclear region much as it is around Venus but on a much smaller scale. The most interesting features of the interaction are the strong turbulence induced by the unstable distribution of fresh pickup ions, which in turn leads to the acceleration of some particles to several hundred keV and the formation of an "ionopause" close to the nucleus where the magnetic field is held off by the friction between the dense outflowing neutral gas and plasma contained in the field. (Ip and Axford, 1990; Johnstone, 1991; Gombosi, 1991).

The situation with regard to satellites with atmospheres, such as Triton, Io, and Titan, is rather similar to that of Venus and Mars except that the external magnetic field is much stronger and the flow need not be supersonic in every sense. Plasma lost from these bodies has an important role in supplying the magnetospheres of the host planet with heavy ions, which form a plasma torus at the orbit of the satellite concerned. Io is particularly interesting in that its atmosphere is very thin and almost entirely controlled by the vapor pressure of sulfur dioxide ice that has been deposited on the surface by volcanic activity.

3.2 The Magnetosphere of Mercury

It was something of a surprise to discover in 1974 that Mercury has a magnetic field (with a dipole moment of about 5×10^{12} T m^3, surface field ~ 400 nT), in view of the small size and slow rotation of the planet (Vilas *et al.*, 1990). The field is sufficiently strong to cause the solar wind to stand off from the surface of the planet by a few tenths of a planetary radius in most circumstances. As a consequence of its smallness and lack of a significant atmosphere, the magnetosphere is very active. The plasma in the magnetosphere must be mainly comprised of photoelectrons, sputtered ions from the surface, and such solar-wind plasma as can enter; sodium is very prominent in the spectrum of the atmosphere and is presumably sputtered from the surface. With magnetic field strengths of the order of 30–100 nT, the Alfvén speed in the magnetotail is accordingly very high, and, even with the small scales involved, it is to be expected that, for brief periods during unstable reconnection events, the voltage drops available are 10^5–10^6 V. Bursts of particles with the corresponding energies have been observed. The small size also implies that there should be rapid tail growth so that substorms recur with a time scale of a few minutes (Siscoe and Slavin, 1979).

3.3 The Magnetosphere of Jupiter

Jupiter is remarkable as far as its magnetosphere is concerned in that the planet has a large magnetic moment, large surface fields (~3.2–14.3 G, dipole field 4.3 G at the equator), rapid rotation (period 9.9 hours), a massive atmosphere and substantial ionosphere, and, most important, a satellite in the inner magnetosphere (Io) that has a partial atmosphere comprised mainly of SO_2 (Gehrels, 1976; Dessler, 1983; McNutt, 1991; Bagenall, 1992). Plasma "picked up" from the ionosphere and exosphere of Io together with the rapid rotation of the planet combine to produce a magnetosphere that is almost completely dominated by internal processes rather than by the solar wind. The net result is that a dense plasma torus is produced in the vicinity of Io's orbit, comprised mostly of ions formed from SO_2 and its daughter products and lost ultimately by being "centrifuged" into the outer magnetosphere and eventually into space (Fig. 6). This involves the magnetic field being stretched so that the plasma is contained in a disk roughly perpendicular to the axis of rotation, the field lines being almost parallel to the disk on either side and the field at higher latitudes having the character of a monopole rather than a dipole. The plasma is eventually lost to interplanetary space by magnetic reconnection and the formation of plasmoids that escape along the magnetotail away from the Sun.

This, of course, is a gross oversimplification of the situation, but it contains the most essential aspects as far as the energy and particle budgets are concerned. The solar wind plays a role mainly in shaping the more distant parts of the magnetosphere and constraining the magnetotail to the downwind direction. There is, nevertheless, evidence for sources of energetic particles other than the atmosphere of Io, namely, the ionosphere of the planet itself, since energetic H_2^+ and H_3^+ ions are observed, and also the interplanetary medium (either the solar wind or solar-flare particles), since the outer magnetosphere contains energetic ions with typical solar abundances and charge-state distributions. The inner magnetosphere is characterized by a very energetic population, presumably produced by inward diffusion resulting from time-varying convective motions, which, as far as the electron component is concerned, are sufficiently energetic to produce synchrotron radiation in the GHz range. Particles escaping from the magnetotail include intense fluxes of electrons with energies in the MeV range, which are a major contributor to the interplanetary population even near the Earth. These particles maintain a 10-hour periodicity at large distances from the planet, suggesting that their escape is controlled by rotation in some manner.

The environment of the satellite Io is especially interesting, because the plasma it supplies to the magnetosphere in the form of pickup ions has a high temperature. It is dense enough to permit reasonably rapid energy

transfer to the electrons, which, in turn, lose energy by collisional excitation of S^+ and other ions. It is noteworthy that the pickup energy is about 17 eV/amu and that some 10^{28}–10^{29} ions/s must be produced in order to account for the observed emission from the plasma torus. The source of the material is obviously dominated by the thin SO_2 atmosphere of the satellite, in which ions are produced by photoionization and electron impact, and also by sputtering from the surface, which must be partially unprotected from direct impact. The surface is partly covered by SO_2 frost, but there must be sufficient rocky material to account for the relatively large amounts of potassium and sodium neutrals that are relatively easily observed in the neutral torus as a consequence of their strong resonant scattering of sunlight. It is evident that much of the ion pickup takes place near Io, because the Alfvén wave produced by the interaction, involving a current of some 10^6 A, causes strong decametric radio emission on interacting with the ionosphere of Jupiter. Strong polar auroral emissions are observed, partly associated with the plasma torus of Io but also at high latitudes, presumably associated with outer magnetospheric phenomena.

3.4 The Magnetosphere of Saturn

The magnetosphere of Saturn is much more like that of the Earth than that of Jupiter in that there is no strong source of plasma in the inner magnetosphere comparable to Io (Gehrels and Matthews, 1986; McNutt, 1991; Bagenall, 1992). The atmosphere of Titan, including its neutral torus, is potentially a strong source, but this satellite spends much of its orbit outside the magnetosphere ($20.3R_S$), or at least on its outer fringes, so that the plasma it contributes, which is mainly N_2^+ or an ion with similar mass, is largely lost into the plasma sheet in the tail. The planetary magnetic field has a dipole component that is almost exactly aligned with the rotational axis and has an equatorial field strength of 0.22 G; the minimum distance to the magnetopause is typically $(15–20)R_S$. The dipole may be displaced from the center of the planet, as the surface field strength appears to vary from 0.18 to 0.84 G. One might expect substorms to be as prevalent as they are in the Earth's magnetosphere, but the plasma contributed by Titan and its torus as well as the rapid rotation of the planet may shield the inner magnetosphere from their effects to some extent.

The inner magnetosphere of Saturn is apparently dominated by plasma sputtered from the water-ice mantles of the larger satellites, Dione and Tethys. As a result, the plasma contains H_2O^+ ions and their dissociation products, some directly sputtered and others produced from the disk-shaped cloud of neutral molecules surrounding these satellites in the equatorial plane of the planet. Interestingly, energetic molecular hydrogen ions have also been observed in Saturn's magnetosphere, suggesting, perhaps, that an ionospheric source might play a role, especially for protons.

One of the most interesting aspects of the energetic particle population in the magnetosphere of Saturn is that it is sufficiently stable for clear absorption signatures coincident with several of the satellites to have been found. These provide, in principle, an indication of the rate of radial transport of the particles concerned. Similarly, the rings provide absorption signatures in the inner magnetosphere, which suggest that the particle population is very stable indeed in this region.

3.5 The Magnetosphere of Uranus

Uranus was expected to have an unusual magnetosphere, because at the present epoch the rotational pole is tipped so that it points almost directly toward the sun. In fact, this is to a large extent compensated by the 59° tilt of the magnetic dipole relative to the axis of rotation. Thus, the magnetosphere does not wobble much more than that of the Earth, although it turns over and presents a different magnetic field direction to the external interplanetary medium with each half-rotation. The dipole equatorial field strength is almost the same as that of Saturn (0.23 G) and is similarly displaced from the center of the planet so that the surface fields vary from 0.08 to 0.96 G (McNutt, 1991; Bagenall, 1992).

The magnetosphere of Uranus is rather quiet, since there are no strong satellite sources of plasma, as at Jupiter and Saturn, and the rotation of the planet tends to keep any solar-wind–induced convection to beyond $5R_U$ as evidenced by a sudden dropout of hot plasma inside this region. The main ions are protons, which could originate both in the solar wind and in the ionosphere but, probably, mostly in the latter. The energetic particle population is not intense and is sufficiently stable to show absorption features associated with the satellites, as at Saturn.

3.6 The Magnetosphere of Neptune

Neptune's magnetosphere proved to be a surprise when first encountered, since its magnetic dipole axis is inclined by 47° from the axis of rotation of the planet, which, in turn, is inclined by 30° relative to the ecliptic (Figure 7). By chance, the polar cusp was

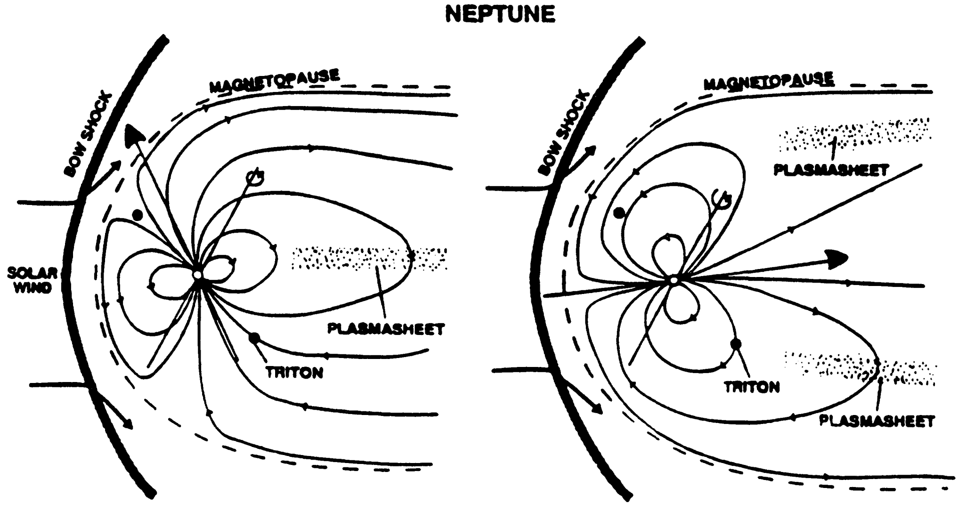

FIG. 7. The magnetosphere of Neptune at two phases of the planet's rotation separated by half a rotation period. (From Bagenall, 1992.)

pointing directly into the solar-wind direction at the time of the approach to the planet by Voyager 2, and the magnetopause was not encountered until well after the initial bow shock crossing. This situation had originally been expected at Uranus but not found. In fact, apart from differences associated with the direction of the axis of rotation, the magnetospheres of the two planets are very similar, the dipole equatorial field strength at Neptune being 0.14 G but the surface field varying from 0.1 to 0.9 G (McNutt, 1991; Bagenall, 1992). As a consequence of the tilts of the magnetic dipole and rotational axes, the magnetotail of Neptune continually changes, having, at times, an Earth-like configuration with a roughly plane plasma sheet separating the two tail lobes and, at other times, the originally expected Uranus configuration with a cylindrical plasma sheet separating the field from the sunward-directed pole (outside) from that of the night-side pole (inside).

The energetic-particle population in the magnetosphere of Neptune is about as intense as that at Uranus but, in comparison with the other planets, is of no great significance. The major satellite Triton, which has a retrograde orbit at $14.6R_{\mathrm{N}}$, well inside the magnetosphere, has an atmosphere. This atmosphere clearly contributes to the plasma background (notably N^+ ions) and also to a neutral hydrogen disk which extends in to about $8R_{\mathrm{N}}$. There must be some potential for substorms, especially in view of the forced reconfiguration of the magnetotail, as described above. However, the plasma and the rotation may well provide some protection for the inner magnetosphere from the associated convection and other disturbances. There is some evidence for auroral activity.

3.7 The Magnetosphere of Pluto–Charon

It seems unlikely that either of these very interesting bodies is large enough or has a suitable internal constitution to have an intrinsic magnetic field (McNutt, 1991). However, there are indications of the presence of a thin atmosphere, which would permit a Mars-like interaction with a very weak solar wind existing at 40–50 a.u. from the Sun and involving an induced magnetosphere with a maximum field strength of a few nT.

GLOSSARY

Alfvén Wave: Transverse magnetohydrodynamic wave.

Aurora: Emissions from the upper atmosphere (>90 km) associated with the precipitation of magnetospheric particles.

Bow Shock: Collisionless shock wave produced by the interaction of the supersonic solar wind with an obstacle such as a magnetosphere.

Electrojet: Intense electric current flowing in the ionosphere at 100–120 km altitude, especially at the geomagnetic equator and in the auroral zone.

Exosphere: Outer atmosphere of a planet where the collision mean free path of its constituents is comparable to the scale height.

Flare: Eruption on the Sun associated with regions of strong and complex magnetic field.

Geomagnetic Storm: A severe disturbance of the magnetic field, especially of the Earth, associated with multiple substorms (see below) and the buildup of a ring current (see below) which persists for several days.

Ionopause: A plasma barrier ahead of a planet capable of withstanding the pressure of the solar wind.

Ionosphere: The region of the upper atmosphere of the Earth (or other planet) in which photoionization by solar UV produces a plasma (typically in the altitude range 80–1000 km).

Magnetopause: The interface between the magnetosphere and the solar wind.

Magnetosphere: The region surrounding the Earth (or other planet) in which the intrinsic magnetic field plays a dominant role in controlling the behavior of the plasma.

Magnetotail: The comet-like tail of the magnetosphere swept downstream by the solar wind to a distance of thousands of planetary radii.

Pickup ions: Ions produced initially at rest in a moving magnetized plasma.

Plasmasphere: The region surrounding the Earth, typically contained by the shell of magnetic field lines defined by ca. 60° geomagnetic latitude, which contains dense plasma originating from the ionosphere.

Plasmapause: The outer boundary of the plasmasphere.

Plasma Torus: A torus-like region surrounding a planet and containing plasma originating from a satellite (e.g., Io at Jupiter and Titan at Saturn).

Polar Cusp: A region on the sunward side of the magnetosphere where magnetic field lines link the auroral zones and the magnetopause.

Polar Wind: A flow of plasma from the ionosphere in polar regions upward into the magnetosphere.

Radiation Belt: [Also called the Van Allen belt(s) in the case of the Earth.] Regions of energetic particles trapped in a planetary magnetosphere.

Reconnection: A term used to describe the changes in linkages of magnetic field lines in magnetized plasmas.

Ring Current: The electric current surrounding the Earth and produced as a result of the pressure of trapped energetic particles in the magnetosphere.

Solar Wind: A supersonic wind flowing radially outward from the Sun into space, which interacts with the magnetospheres of the planets.

Substorm: A short-lived disturbance, usually part of a geomagnetic storm, in which there is strong auroral electrojet activity, auroral particle precipitation, and the injection of fresh plasma into the magnetosphere from the magnetotail.

Whistlers: Audio-frequency radio waves that travel through the magnetosphere, more or less along magnetic field lines, and that have a characteristic frequency dispersion running from high to low following impulsive injection from lightning flashes.

INTRODUCTION

Magnetism developed as a science separate from the study of electricity until the discovery by H. C. Oersted in 1819 that an electric current deflects a compass needle. Prior to this, magnetism had been treated from the point of view of magnetic poles—north and south. Even though it was not possible to isolate these poles, a close approximation to an individual point pole was obtained at the ends of a long thin permanent magnet. Thus it was possible experimentally to determine a law of pole attraction and repulsion. The force between poles varied inversely as the square of the separation and directly as the product of pole strengths, in exact analogy with the force between point electric charges. Both the electrostatic and magnetostatic force laws were established by C. A. Coulomb.

Permanently magnetized materials such as lodestone were known to the ancient Greeks. These materials eventually came to be used in compasses for navigation. In 1600, with the publication of *De Magnete*, W. Gilbert put forth the view that the Earth itself was a giant magnet and that this could account for the behavior of compasses. With the development of the galvanic pile or battery by A. Volta around 1800, it became feasible to experiment with direct-current electricity. This invention made possible Oersted's discovery that currents produce magnetic fields. The laws governing the magnetic interactions between currents were formulated by

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

A. M. Ampère, J. B. Biot, and F. Savart soon after Oersted's discovery.

Ampère quickly realized that all magnetic phenomena, even permanent magnetism, could be accounted for by currents or charges in motion. Thus he postulated the existence of circulating atomic currents as the origin of material magnetism. These currents, called *Ampèrian currents*, do indeed exist according to our present understanding of atomic physics. However, the electron itself possesses an intrinsic magnetic moment that is much harder to understand in terms of charges in motion. Nevertheless, basing magnetostatics on magnetic fields produced by currents does not require the notion of isolated magnetic poles, whose existence has never been demonstrated, and thus leads to a natural and unified description of magnetism.

It should be noted that the use of fictitious magnetic poles can be justified as a mathematical device in solving a broad class of magnetostatic problems. It often leads to simpler methods of solution than would be possible from a strictly Ampèrian current viewpoint. This procedure involves no contradiction with fundamental theory or, more importantly, with experiment. However, the terminology such as the use of the word *poles* can be misleading.

Modern theories of magnetism are based on a quantum-mechanical treatment of the electron's spin and orbital magnetic moments and their interactions. Because of the mathematical difficulties involved in treating this complex many-body system, our understanding of magnetism at this level is still incomplete. However, by making suitable approximations and taking averages, a semiclassical treatment of magnetism, called micromagnetics, has emerged that retains many features of the atomic-level description. The discreteness of quantum mechanics, however, is replaced by a continuum description. Thus a continuous magnetization distribution results. The magnetization vector has a constant magnitude but can vary in direction from point to point. Quantum-mechanical interactions are approximated by interactions sensitive to the direction of the magnetization vector. In addition, the usual classical dipole–dipole interactions are present as well as interactions with external magnetic fields.

While micromagnetics calculations can also present formidable difficulties when applied to complex geometries, successful calculations have been performed for ideal or reasonably simple configurations. For instance, the characteristics of magnetic domains (regions where the magnetization vectors are aligned) and domain walls (transition regions between domains having different orientations) can be understood to a large extent from this theory. Magnetic domains were predicted by P. Weiss in 1907 and were subsequently observed experimentally.

Magnetostatics and micromagnetics play a crucial role in the magnetic recording industry, e.g., in magnetic-tape, hard- or floppy-disk, and bubble-memory technologies (see MAGNETIC STORAGE OF INFORMATION). States of remanent magnetization represent information on these devices that can be stored for long periods of time.

Magnetic fields produced by permanent magnets or electromagnets (see MAGNETS) are used to bend and focus charged particles in particle accelerators and in electron microscopes. Magnetic fields are used to store energy in inductors, to transfer electrical energy in transformers, and to transfer electrical to mechanical energy or vice versa in motors and generators.

In this article, we present a classical-field approach to magnetostatics. Vector and scalar potentials are defined as an aid to the mathematical development of the theory. Material magnetism is treated classically, which means that in materials with a domain structure the magnetization vector represents an average over many domains and therefore can vary in both magnitude and direction from point to point in the medium. The phenomenon of hysteresis in ferromagnetic materials is presented. General expressions are derived for magnetic force and energy. Magnetic flux and flux linkages are introduced together with the concept of inductance. The magnetic circuit approach is presented as a practical method of obtaining an approximate solution to certain types of problems. Throughout, useful examples are given to illustrate the theory.

1. UNITS

The development of a system of units to measure magnetic effects mirrors the history of discoveries in this field. When the two subjects of electricity and magnetism were thought to be unrelated, the force laws between point electric charges q_e and magnetic poles or charges q_m were used to define the unit electric or magnetic charge. Thus the forces in vacuum are

$$\mathbf{F}_e = k_e \frac{q_e q_e'}{R^2} \hat{\mathbf{a}}_R, \tag{1}$$

$$\mathbf{F}_m = k_m \frac{q_m q_m'}{R^2} \hat{\mathbf{a}}_R, \tag{2}$$

where R is the separation distance, $\hat{\mathbf{a}}_R$ is a unit vector pointing along R, and k_e and k_m are constants that set the units. The simplest choice is to take $k_e = k_m = 1$. This defines the charge in terms of mechanical units $(ML^3T^{-2})^{1/2}$. This also, in a natural way, sets the units for the electric and magnetic fields, which are defined at each point in space as the force that would act on a unit test charge placed at that point:

$$\mathbf{E} = \mathbf{F}_e/q_e, \tag{3}$$

$$\mathbf{B} = \mathbf{F}_m/q_m. \tag{4}$$

However, once it was realized that magnetic fields are created by currents, the question of the units of current had to be addressed. In vacuum, a current I flowing in a thin wire of infinitesimal length dl produces a magnetic field given by

$$d\mathbf{B} = k_i(I d\mathbf{l} \times \hat{\mathbf{a}}_R/R^2), \tag{5}$$

where $d\mathbf{l}$ is the directed length of the wire, R is the distance from the wire element to the field point, and $\hat{\mathbf{a}}_R$ is a unit vector directed along R from the source towards the field point (see Fig. 1). k_i is used to adjust the units. This is called the Biot-Savart law. The mathematical notation used in this paper and key theorems and definitions are indicated in the Appendix. The cross product is defined there in Eq. (A3).

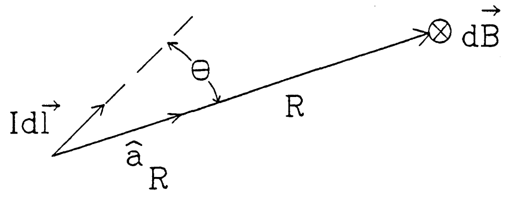

FIG. 1. Biot-Savart law illustrated.

The magnetic field given by Eq. (5), or any magnetic field **B**, acts on another current element $I'dl'$ to produce a force given by

$$d\mathbf{F} = k_f I' d\mathbf{l}' \times \mathbf{B}. \tag{6}$$

When **B** is produced by another current element, the force law between two such elements becomes

$$d\mathbf{F} = k_f k_i \frac{I'I}{R^2} d\mathbf{l}' \times (d\mathbf{l} \times \hat{\mathbf{a}}_R). \tag{7}$$

Such a force between isolated current elements cannot occur in reality but is an abstraction from experiments performed on complete circuits.

By setting $k_f k_i = 1$, Eq. (7) can be used to define a unit of current that in the cgs system is called the abampere. However, since current is the flow of electrical charge, a unit of charge, called the abcoulomb, is naturally defined as the charge accumulated by the flow of one abampere for one second. But Eq. (1) with $k_e = 1$ defines another unit of charge in the cgs system, called the statcoulomb. It was discovered experimentally that the ratio of a given charge measured in statcoulombs to the same charge measured in abcoulombs was numerically and dimensionally equal to the speed of light, $c = 2.9979 \times 10^{10}$ cm/s. The consequence of this on the system of units is that, from Eqs. (1) and (7) and the observation that the force measured in a given set of mechanical units between two given current elements or two given charges must be the same regardless of the units in which the charges or currents are expressed, we require

$$k_e/k_f k_i = c^2. \tag{8}$$

It follows from Eqs. (4) and (5) that for the magnetic field produced by a unit pole to be the same as that produced by a unit current element, we must have $k_i = k_m$.

Various systems of units can be identified with the choice of k's within the above constraints. With $k_f = k_i = k_m = 1$, $k_e = c^2$, currents in abamperes, and charges in abcoulombs, we get the electromagnetic system (cgs-emu). With $k_e = k_f = 1$, $k_i = k_m = 1/c^2$, we get the electrostatic system (cgs-esu). It was noted by C. F. Gauss that one could have a consistent set of units with charge measured in statcoulombs ($k_e = 1$) and current in statamperes while retaining Eq. (2) with $k_m = 1$, provided we set $k_i = 1/c$. In this Gaussian system, $k_i \neq k_m$ since the unit pole and current element produce different fields B. However, $1/c$ provides the required conversion factor. We also have $k_f = 1/c$ in this system.

While the Gaussian system is favored in fundamental physics research, the system of units generally used in practical engineering or laboratory work is the rationalized mks system (or mksa system since the ampere is the standard unit of current). In this system, charge is assigned a new fundamental unit called the coulomb, abbreviated C. A current of 1 C/s is called an ampere, k_e in vacuum is defined in terms of another constant ϵ_0 by $k_e = 1/4\pi\epsilon_0$. k_i in vacuum is defined in terms of a new constant μ_0 by $k_i = \mu_0/4\pi$. In Eq. (6), $k_f = 1$ so that from Eq. (8), $\epsilon_0\mu_0 = 1/c^2$. The units of ϵ_0 or μ_0 can readily be determined in the mksa system from Eqs. (1) and (7). However, these are more simply expressed in terms of derived units,

$$\mu_0 = 4\pi \times 10^{-7}\ \mathrm{H/m},$$
$$\epsilon_0 = 1/\mu_0 c^2 = 8.8542 \times 10^{-12}\ \mathrm{F/m}, \tag{9}$$

where the henry (H) is the unit of inductance (V s/A) and the farad (F) the unit of capacitance (C/V), and 1 V = 1 J/C. We will use mksa units in this paper. This is a subset of the Système International d'Unités or SI system of units. μ_0 is called the permeability of vacuum and ϵ_0 the permittivity of vacuum.

2. MAGNETIC INDUCTION B AND VECTOR POTENTIAL

The magnetic field, like the electric field, was devised to replace action at a distance. Thus one object (an electric charge or a current element) gives rise to a field throughout space that then acts on another object. Since these fields are vectors, the net field arises as the vector sum or integral of the fields produced by all the relevant objects.

2.1 Current Density

In general the current need not be confined to a thin wire, and we define a current density **J** as the current per unit area flowing through an infinitesimal directed surface element $d\mathbf{S}$ oriented in such a way that the unit normal to dS, **n**, is in the direction of **J**. Thus

$$\mathbf{J} = \frac{dI}{dS}\mathbf{n}. \tag{10}$$

In this case $Id\mathbf{l}$ generalizes to $(\mathbf{J}\cdot\mathbf{n})dSd\mathbf{l}$. But since **J**, **n**, and $d\mathbf{l}$ are collinear, this can be written as $\mathbf{J}dV$, where dV is the volume element. Occasionally there is a need for a surface current element. This is defined as the current per unit length flowing perpendicular to an infinitesimal element of length dL along a surface:

$$\mathbf{K} = \frac{dI}{dL}\hat{\mathbf{a}}_K, \tag{11}$$

where $\hat{\mathbf{a}}_K$ is normal to the direction of $d\mathbf{L}$ in the direction of **K**. Thus $Id\mathbf{l}$ becomes $(\mathbf{K}\cdot\hat{\mathbf{a}}_K)dLd\mathbf{l}$. But since **K**, $\hat{\mathbf{a}}_K$, and $d\mathbf{l}$ are collinear, this becomes $\mathbf{K}dS$, where dS is the element of surface area.

Magnetostatics deals with stationary magnetic fields produced by steady currents. It also assumes that any electric charge present is not changing with time. Therefore the net current flowing into any closed surface is zero, since otherwise charge would accumulate. This implies by the divergence theorem, Eq. (A4), that

$$\nabla\cdot\mathbf{J} = 0. \tag{12}$$

2.2 Biot-Savart Law

In terms of current density, Ampere's force law, Eq. (6), can be expressed more generally as

$$d\mathbf{F} = \mathbf{J}\times\mathbf{B}\,dV, \tag{13}$$

where $\mathbf{J}\times\mathbf{B}$ is a force density. The Biot-Savart law, Eq. (5), now becomes, in integral form,

$$\mathbf{B} = \frac{\mu_0}{4\pi}\int\frac{\mathbf{J}\times\hat{\mathbf{a}}_R}{R^2}dV', \tag{14}$$

where $R = |\mathbf{r} - \mathbf{r}'|$, **r** being a vector from the origin to the field point and **r**′ one to the source point. Primes are used to distinguish source variables whenever necessary. The units of B are teslas (T). This field is called the magnetic flux density or the magnetic induction. It is often simply referred to as the B field. It is considered the fundamental magnetic field because it produces the force on a current element.

In Eq. (14), R involves both the source and field coordinates, as does $\hat{\mathbf{a}}_R$ since $\hat{\mathbf{a}}_R = \mathbf{R}/R$. $\mathbf{J}$ and dV' are evaluated at the source point. Let ∇ denote taking the gradient with respect to the field position and ∇' with respect to the source position. Then

$$\nabla'(1/R) = -\nabla(1/R) = \hat{\mathbf{a}}_R/R^2. \tag{15}$$

Using this, we can rewrite Eq. (14):

$$\begin{aligned}\mathbf{B} &= -\frac{\mu_0}{4\pi}\int \mathbf{J} \times \nabla\left(\frac{1}{R}\right)dV' \\ &= \nabla \times \frac{\mu_0}{4\pi}\int \frac{\mathbf{J}}{R}\,dV'.\end{aligned} \tag{16}$$

The second equality follows from Eq. (A15) and the fact that ∇ operates on the field position. Thus $\mathbf{B}$ has been expressed as

$$\mathbf{B} = \nabla \times A, \tag{17}$$

with $\mathbf{A}$, called the vector potential, given by

$$\mathbf{A} = \frac{\mu_0}{4\pi}\int \frac{\mathbf{J}dV'}{R} \quad \text{or} \quad \mathbf{A} = \frac{\mu_0}{4\pi}\int \frac{Id\mathbf{l}'}{R}. \tag{18}$$

The two forms for $\mathbf{A}$ are appropriate to a distributed current source and one localized to a thin wire, respectively.

We should note that since the curl of a gradient is identically zero, Eq. (A10), an arbitrary gradient can be added to $\mathbf{A}$ without changing the value of B. This arbitrariness is exploited in calculations by imposing additional requirements on $\mathbf{A}$, e.g.,

$$\nabla \cdot \mathbf{A} = 0. \tag{19}$$

That this condition can be imposed consistently follows from Helmholtz's theorem, which states that a vector field is determined by specifying its curl and divergence. [The curl of $\mathbf{A}$ is given in Eq. (17).] Equation (19) is called the Coulomb gauge. (Changing $\mathbf{A}$ without changing $\mathbf{B}$ is called a gauge transformation.) Also, since the divergence of a curl vanishes identically, Eq. (A9), we see from Eq. (17) that

$$\nabla \cdot \mathbf{B} = 0. \tag{20}$$

This equation recalls the experimental fact that isolated magnetic poles do not exist.

2.3 Ampère's Circuital Law

We obtain another important relationship by taking the curl of $\mathbf{B}$. Using Eq. (A11) and the Coulomb gauge, we obtain

$$\nabla \times \mathbf{B} = -\nabla^2 \mathbf{A} = -\frac{\mu_0}{4\pi}\int \mathbf{J}\nabla^2\left(\frac{1}{R}\right)dV'. \tag{21}$$

Here ∇^2 has been taken inside the integral, where it can operate only on $1/R$ since this is the only factor depending on the field point. If we use spherical coordinates, we find that $\nabla^2(1/R) = 0$ except at the origin where it is undefined. However, by applying the divergence theorem to a small volume surrounding the origin, we find that $\int \nabla^2(1/R)\,dV = -4\pi$ so that Eq. (21) becomes

$$\nabla \times \mathbf{B} = \mu_0 \mathbf{J}. \tag{22}$$

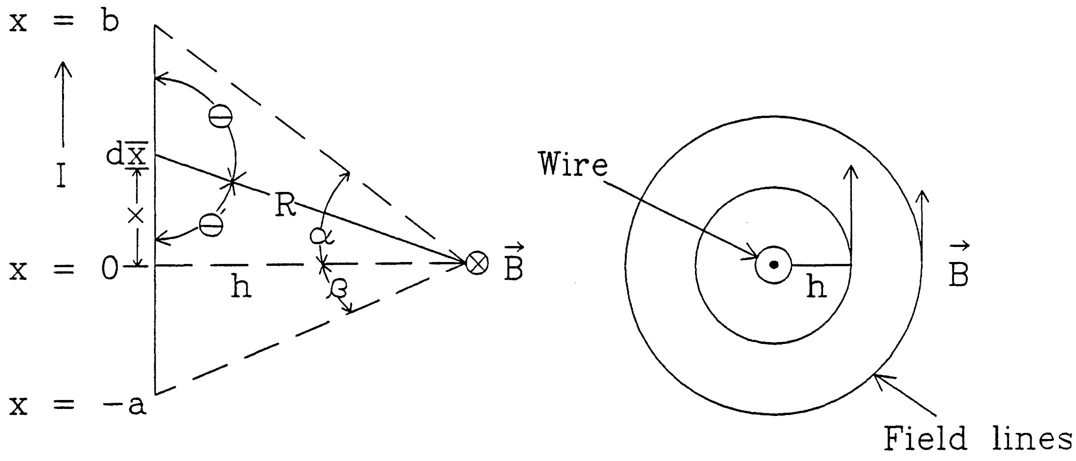
Applying Stokes's theorem to this, we obtain

$$\oint_{\mathscr{C}} \mathbf{B} \cdot d\mathbf{l} = \mu_0 \int_S \mathbf{J} \cdot \mathbf{n}\, dS = \mu_0 I, \tag{23}$$

where I is the total current through the surface S, which is bounded by the closed path $\mathscr{C}$. This is Ampère's circuital law and is very useful when applied to problems that have sufficient symmetry.

2.4 Examples of Field Calculations

2.4.1 Straight Wire Segment We calculate the field of a straight wire segment carrying current I as shown in Fig. 2(a). This cannot exist as a separate entity but could be part of a circuit made up of connected wire segments. We use Eq. (5) to obtain the field $\mathbf{B}$ at some point a perpendicular distance h from the wire or its straight-line extension. The current flows upward in the direction of the positive x axis so that $dl = dx$. We have, without loss of generality, shown the wire



(a) (b)

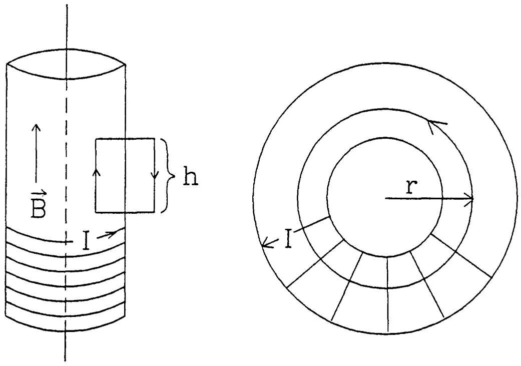
FIG. 2. (a) Geometric parameters used in calculating the field *B* produced by a straight wire segment carrying current *I*. (b) Pattern of field lines surrounding the wire.

segment and field point in the plane of the paper in Fig. 2(a). We see that $d\mathbf{l} \times \hat{\mathbf{a}}_R$ points into the plane of the paper for any position along the wire so that the vector sum reduces to a scalar sum. In fact $|d\mathbf{l} \times \hat{\mathbf{a}}_R| = dx \sin\theta = dx \sin\theta' = hdx/R$ from the figure. Thus

$$\begin{aligned} B &= \frac{\mu_0 Ih}{4\pi}\int_{-a}^{b}\frac{dx}{R^3} \\ &= \frac{\mu_0 Ih}{4\pi}\int_{-a}^{b}\frac{dx}{(x^2+h^2)^{3/2}} \\ &= \frac{\mu_0 Ih}{4\pi}\left[\frac{x}{h^2(x^2+h^2)^{1/2}}\right]_{-a}^{b} \\ &= \frac{\mu_0 I}{4\pi h}\left[\frac{b}{(b^2+h^2)^{1/2}}+\frac{a}{(a^2+h^2)^{1/2}}\right] \\ &= \frac{\mu_0 I}{4\pi h}(\sin\beta+\sin\alpha). \end{aligned} \tag{24}$$

The last form is particularly simple. Because the selected field position could have been anywhere along a circle of radius *h* centered on the wire or its straight-line extension without affecting the calculation, we see that the field directions are tangent to such circles everywhere in space as shown in Fig. 2(b). The sense of the field is easily found by pointing the thumb of the right hand in the direction of current flow. Then the fingers will curl in the field direction. If we let the wire become infinitely long so that $\alpha = \beta = \pi/2$, we obtain $B = \mu_0 I/2\pi h$. There is sufficient symmetry in this case to use Ampère's circuital law directly to find *B*.

2.4.2 Ideal Solenoid and Toroid The magnetic field *B* inside an infinitely long ideal solenoid or an ideal toroid can be found by exploiting the symmetry and using Ampère's circuital law, Eq. (23) (see Fig. 3). The solenoid and toroid are assumed to be wrapped with many closely spaced turns of fine wire. From symmetry considerations, only an axial field can exist inside the solenoid. (There



(a) (b)

FIG. 3. Using Ampère's circuital law to find the field *B* inside (a) an ideal solenoid and (b) a toroid.

is a small azimuthal B component outside the solenoid due to the slight pitch of the coil.) The solid path in the figure has a nonvanishing contribution only along the inside vertical path, and by the circuital law $Bh = \mu_0 nhI$, where n is the number of turns per unit length and I the current in each turn. Therefore the field inside the solenoid is

$$B = \mu_0 nl \tag{25}$$

and is independent of radial distance from the axis.

For the toroid in Fig. 3(b), symmetry requires that B tangential to the circular path of radius r shown be constant along the path. This path loops the entire toroidal current of NI, where N is the total number of turns and I the current in each turn. Therefore, by the circuital law, $2\pi r B_t = \mu_0 NI$, so that

$$B_t = \mu_0 NI/2\pi r. \tag{26}$$

Thus this tangential component is a function of r.

3. MATERIAL MAGNETISM

Magnetic fields that arise from the presence of matter have their origin in localized atomic currents. To study this type of magnetism, we therefore begin with the study of the magnetic fields generated by localized current sources at distances far from the sources. This is done most conveniently by considering the vector potential, Eq. (18), which we write more explicitly in terms of source (primed) and field coordinates as

$$\mathbf{A}(\mathbf{r}) = \frac{\mu_0}{4\pi}\int \frac{\mathbf{J}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}\,dV'. \tag{27}$$

Since $r' \ll r$, we may approximate the denominator:

$$\begin{aligned}|\mathbf{r} - \mathbf{r}'| &\cong \sqrt{r^2 - 2\mathbf{r}\cdot\mathbf{r}'}\\ &= r\sqrt{1 - 2\mathbf{r}\cdot\mathbf{r}'/r^2}\\ &\cong r(1 - \mathbf{r}\cdot\mathbf{r}'/r^2)\end{aligned} \tag{28}$$

so that Eq. (27) becomes approximately

$$A \cong \frac{\mu_0}{4\pi r}\int \mathbf{J}(\mathbf{r}')\left(1 + \frac{\mathbf{r}\cdot\mathbf{r}'}{r^2}\right)dV'. \tag{29}$$

Because the current source is localized, $\int \mathbf{J}dV' = 0$. (If the current were confined to a thin wire, then $\mathbf{J}\,dV = I\,d\mathbf{l}$ and $I \oint d\mathbf{l} = 0$ since the current loop is closed. Because $\nabla\cdot\mathbf{J} = 0$, tubes of current can be defined that approximate thin wire circuits.) Therefore, to lowest order,

$$A \cong \frac{\mu_0}{4\pi r^3}\int \mathbf{J}(\mathbf{r}')(\mathbf{r}\cdot\mathbf{r}')dV'. \tag{30}$$

Using Eq. (A13), we can write

$$\mathbf{J}(\mathbf{r}\cdot\mathbf{r}') = (\mathbf{r}\cdot\mathbf{J})\mathbf{r}' - \mathbf{r}\times(\mathbf{r}'\times\mathbf{J}). \tag{31}$$

Choose a Cartesian coordinate system with $\mathbf{r}$ along the x axis (ith coordinate) and consider the jth component of the left-hand side of Eq. (31):

$$\begin{aligned}rJ_j r_i' &= r[\nabla'\cdot(r_j'\mathbf{J})r_i']\\ &= r[\nabla'\cdot(r_i'r_j'\mathbf{J}) - r_j'\mathbf{J}\cdot\nabla' r_i']\\ &= r[\nabla'\cdot(r_i'r_j'\mathbf{J}) - J_i r_j'].\end{aligned} \tag{32}$$

The first equality in Eq. (32) follows from Eq. (A14), together with $\nabla'\cdot\mathbf{J} = 0$ and $\nabla'(r_j') = \mathbf{j}$, the unit vector along the jth Cartesian coordinate. The second equality follows directly from Eq. (A14) and the third equality from $\nabla'(r_i') = \mathbf{i}$, the unit vector along the ith coordinate direction. Now the volume integral over the divergence produces a surface integral by the divergence theorem, and this vanishes if the surface is taken outside the current distribution. Therefore, omitting the integral signs for convenience,

$$[\mathbf{J}(\mathbf{r}\cdot\mathbf{r}')]_j = rJ_j r_i' = -rJ_i r_j' = -[(\mathbf{r}\cdot\mathbf{J})\mathbf{r}']_j \tag{33}$$

so that the first term on the right-hand side of Eq. (31) is the negative of the left-hand side. Hence

$$\int \mathbf{J}(\mathbf{r}\cdot\mathbf{r}')dV' = -\tfrac{1}{2}\int \mathbf{r}\times(\mathbf{r}'\times\mathbf{J})dV' \tag{34}$$

so that Eq. (30) may be written

$$\mathbf{A} = \frac{\mu_0}{4\pi r^3}\left[\frac{1}{2}\int \mathbf{r}'\times\mathbf{J}\,dV'\right]\times\mathbf{r}. \tag{35}$$

The term in brackets is called the magnetic moment of the localized current distribution $\mathbf{m}$:

$$\mathbf{m} = \tfrac{1}{2}\int \mathbf{r}' \times \mathbf{J}\, dV' \quad \text{or}$$
$$\mathbf{m} = I\,\tfrac{1}{2}\oint \mathbf{r}' \times d\mathbf{l}'. \tag{36}$$

The latter expression applies to a thin wire loop. In the case of a plane loop, the magnetic moment equals the current times the loop area, $\mathbf{m} = IS\mathbf{n}$, where $\mathbf{n}$ is the unit normal to the surface, as visualized in Fig. 4. The field $\mathbf{B}$ can be found by means of Eq. (17), remembering that $\mathbf{m}$ is constant with respect to the curl operation. We find, using vector identities found in the Appendix,

$$\begin{aligned}\mathbf{B} &= \nabla \times \left(\frac{\mu_0}{4\pi}\frac{\mathbf{m} \times \hat{\mathbf{a}}_r}{r^2}\right)\\ &= (\mu_0/4\pi r^3)[3(\mathbf{m}\cdot\hat{\mathbf{a}}_r)\hat{\mathbf{a}}_r - \mathbf{m}].\end{aligned} \tag{37}$$

This is seen to be the field of a dipole, analogous to that of an electric dipole of dipole moment $\mathbf{p}$, except for the constants.

3.1 Magnetization

The above derivation shows that, to first order, the field far from a localized current distribution is that of a magnetic dipole. If the current distribution is associated with an atom or molecule, then the dipole approximation would be good a few atomic diameters away, which is small on a macroscopic scale. On an atomic scale, we are not usually interested in field variations but are more interested in averages. We therefore define an average magnetic moment per unit volume, called the magnetization $\mathbf{M}$, by averaging over the atomic moments $\mathbf{m}_{\text{at}}$:

$$\mathbf{M} = \sum_{\Delta V} \frac{\mathbf{m}_{\text{at}}}{\Delta V}. \tag{38}$$

Here the volume ΔV is large enough to include a significant number of atoms but small on a macroscopic scale, so that we can consider $\mathbf{M}$ to vary smoothly with position, except possibly at boundaries.

The vector potential associated with this magnetization distribution is given by

$$\mathbf{A} = \frac{\mu_0}{4\pi}\int \frac{\mathbf{M}(\mathbf{r}') \times \hat{\mathbf{a}}_R}{R^2}\, dV', \tag{39}$$

where $R = |\mathbf{r} - \mathbf{r}'|$. Using Eqs. (15) and (A15), Eq. (39) becomes

$$\begin{aligned}\mathbf{A} &= \frac{\mu_0}{4\pi}\int \mathbf{M}(\mathbf{r}') \times \nabla'\left(\frac{1}{R}\right) dV'\\ &= \frac{\mu_0}{4\pi}\int \left[\frac{\nabla' \times \mathbf{M}}{R} - \nabla' \times \left(\frac{\mathbf{M}}{R}\right)\right] dV'.\end{aligned} \tag{40}$$

Using Eq. (A7) on the last term, we get

$$\mathbf{A} = \frac{\mu_0}{4\pi}\left(\int \frac{\nabla' \times \mathbf{M}}{R}\, dV' + \int \frac{\mathbf{M} \times \mathbf{n}}{R}\, dS'\right). \tag{41}$$

3.2 Magnetization Currents

Comparing Eq. (41) with the vector potential derived for a current density, we see that a magnetization distribution gives rise to an equivalent volume current density given by

$$\mathbf{J}_m = \nabla \times \mathbf{M} \tag{42}$$

and a surface current density

$$\mathbf{K}_m = \mathbf{M} \times \mathbf{n}. \tag{43}$$

The surface current expressions can be made plausible by means of Fig. 5. We see a cross section of a long cylinder having a uniform magnetization distribution. Away from the surface, the currents from neighboring dipoles are in opposite directions so that their fields cancel. However, at the surface there is an unbalanced current that appears to flow completely around the cylinder. If we approximate the dipoles as wire loops carrying

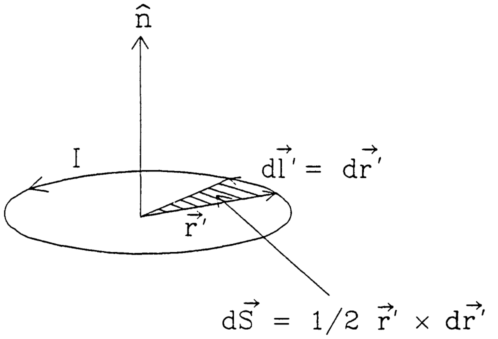


FIG. 4. Illustration of area formula for a plane wire loop.

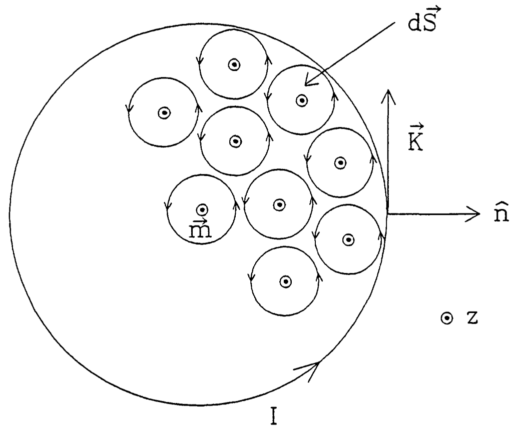

FIG. 5. Illustration of the equivalence of a uniform magnetization distribution with a surface current.

current I and of area dS, their magnetic moment is the current times the loop area. However, their magnetic moment can also be obtained from the magnetization distribution, i.e., $\mathbf{m} = I\, d\mathbf{S} = \mathbf{M}\, dV = \mathbf{M}\, dS\, dz$. Since $d\mathbf{S}$ and $\mathbf{M}$ point in the same direction, the surface current is given in magnitude by $I = M\, dz$ so that the surface current density or current per unit distance in the z direction is just M in magnitude. Its direction is tangential to the surface, in the direction of $\mathbf{K}_m$ in Eq. (43). Thus both the magnitude and direction are given correctly by Eq. (43). A similar plausibility argument can be given to show the reasonableness of Eq. (42).

3.3 Magnetic Field Intensity H

Since a surface current density can be regarded as a limiting case of a volume current density, we can consider the second term in Eq. (41) as a special case of the first term. It can be approximated by means of a rapidly changing magnetization over a short distance or dealt with by means of boundary conditions. Thus the vector potential, when both free currents and magnetizable matter are present, is given by

$$\mathbf{A} = \frac{\mu_0}{4\pi} \int \frac{(\mathbf{J} + \nabla' \times \mathbf{M})}{R}\, dV'. \tag{44}$$

If we repeat the steps leading up to Eq. (22), we obtain, using Eq. (44) for $\mathbf{A}$,

$$\nabla \times \mathbf{B} = \mu_0(\mathbf{J} + \nabla \times \mathbf{M}). \tag{45}$$

$\mathbf{J}$ is the free current density and $\nabla \times \mathbf{M}$ the current density associated with magnetized matter. Rewriting Eq. (45),

$$\nabla \times (\mathbf{B}/\mu_0 - \mathbf{M}) = \mathbf{J}, \tag{46}$$

suggests the definition of a new field, called the magnetic field intensity H or simply the H field,

$$\mathbf{H} = \mathbf{B}/\mu_0 - \mathbf{M}. \tag{47}$$

The units of H and M are amperes/meter or ampere-turns/meter in the mksa system. Thus when magnetized matter is present Eq. (22) is replaced by

$$\nabla \times \mathbf{H} = \mathbf{J} \tag{48}$$

and Ampère's circuital law becomes

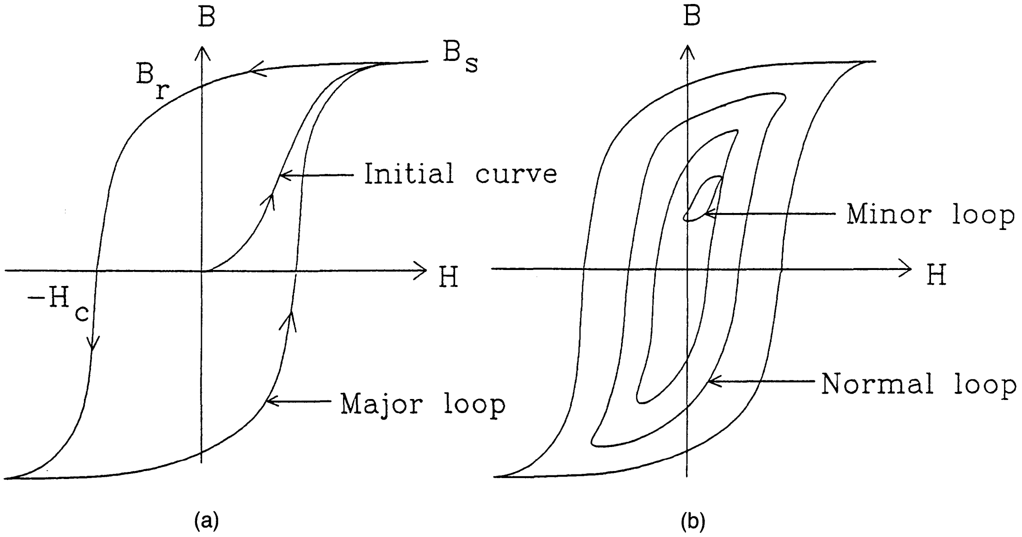
$$\oint \mathbf{H} \cdot d\mathbf{l} = I. \tag{49}$$

When $\mathbf{M} = \mathbf{0}$, $\mathbf{B} = \mu_0\mathbf{H}$ so that the two fields differ by a constant factor.

3.4 Permeability and Hysteresis

For many materials, $\mathbf{M}$ is proportional to $\mathbf{H}$, $\mathbf{M} = \chi\mathbf{H}$, where χ is called the magnetic susceptibility. In this case, $\mathbf{B} = \mu_0(1 + \chi)\mathbf{H} = \mu_0\mu_r\mathbf{H} = \mu\mathbf{H}$, where $\mu_r = 1 + \chi$ is the relative permeability and μ is called the permeability. For most materials χ is close to zero, and so μ_r is close to one. Materials with $\chi < 0$ are called diamagnetic while materials with $\chi > 0$ but not much greater than 1 are called paramagnetic. Materials with very large χ, often for which a linear relation between $\mathbf{M}$ and $\mathbf{H}$ is no longer satisfied, are called ferromagnetic. For these latter materials, M or B may not even be a single-valued function of H but may depend on the magnetic history of the material, a phenomenon called hysteresis.

Figure 6(a) shows such a hysteresis process. The material starts out in a demagnetized state at the origin of the B-H plane. We are assuming that B, H, and M are collinear here so that only signed magnitudes are involved. In this configuration, the magnetic moments are, on average, randomly distributed so that they vectorially sum to zero. As H increases, B follows the initial curve. Eventually all the magnetic moments are



(a) (b)

FIG. 6. (a) Parameters of the major hysteresis loop for a ferromagnetic material. (b) Normal and minor loops.

aligned so that M reaches a maximum value called the saturation magnetization, M_s. The field B associated with this value is called the saturation induction, B_s. Any further increase in B beyond this point is due entirely to an increase in H. As H is lowered, B does not retrace the initial curve but rather follows the upper curve in the figure. When H drops to zero, there is still some induction present, called the remanent induction, B_r. As H is reversed, the magnetization and induction drop further until eventually B reaches zero at a point where $H = -H_c$, where H_c is called the coercivity. If H continues to drop, i.e., continues to increase in a reversed direction, eventually all the dipoles align in the opposite direction at reverse saturation. If H in then increased, the lower curve in Fig. 6(a) is followed. Over many cycles, the outer curve or hysteresis loop will be retraced. While this process occurs for many ferromagnetic materials, in general it is even more complicated because B, H, and M are not necessarily collinear.

Figure 6(b) shows some of the other processes that can occur for collinear hysteresis. If H reverses before saturation is reached, smaller loops, called normal loops, can be traced. Reversing the field in the process of generating a normal loop can lead to the generation of incremental or minor loops, etc. For these nonlinear processes, the ratio of B to H is called the permeability, although other permeabilities, such as the differential permeability, which is the slope of the B-H curve, can be defined.

3.5 Fictitious Magnetic Poles

Many problems in magnetostatics can be simplified mathematically by the use of fictitious magnetic poles, associated with H and not with the more fundamental field B. From the definition equation (47), together with the divergence-free property of B, we see that

$$\nabla \cdot \mathbf{H} = -\nabla \cdot \mathbf{M}. \tag{50}$$

This looks like an electrostatic equation with the electric displacement D corresponding to H and the charge density corresponding to $-\nabla \cdot \mathbf{M}$; i.e.,

$$\rho_m = -\nabla \cdot \mathbf{M} \tag{51}$$

defines an equivalent magnetic charge or pole density. Integrating Eq. (51) over a pillbox-shaped volume partially inside and partially outside a magnetic material, as shown in Fig. 7, and applying the divergence theorem lead to the concept of a surface pole density given by

$$\sigma_m = \mathbf{M} \cdot \mathbf{n}, \tag{52}$$

where $\mathbf{n}$ is the outward normal to the sur-

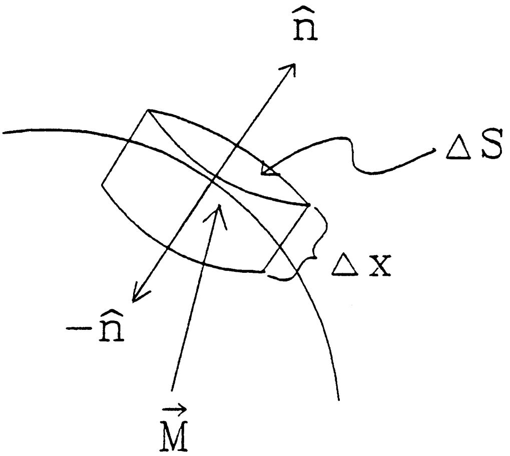


FIG. 7. Surface pole density calculation illustrated.

face. For convenience, as was the case with surface magnetization currents, it is sometimes easier to deal with surface poles as a limiting case of a rapidly varying magnetization over a small distance near the surface of the material or by means of boundary conditions.

From the preceding, it can be seen that these fictitious poles can be thought of as producing the field **H**, just as electric charge produces the field **D**. This point of view is contrasted with the magnetization current point of view in Fig. 8 for an ideal uniformly magnetized cylinder. In Fig. 8(a), the magnetic charge resides on the two ends of the cylinder and the lines of H emanate outwardly from the positive pole and inwardly towards the negative pole. In contrast, B arises from peripheral surface currents, the same as for a tightly wound solenoid, so that the lines of B are continuous, maintaining the same direction through the end surfaces. On the outside of the magnet, B and H are related by the scale factor μ_0. The surface poles tend to demagnetize the magnet. The magnet is operating in the upper left-hand quadrant of the B-H plane of Fig. 6(a).

3.6 Magnetic Scalar Potential

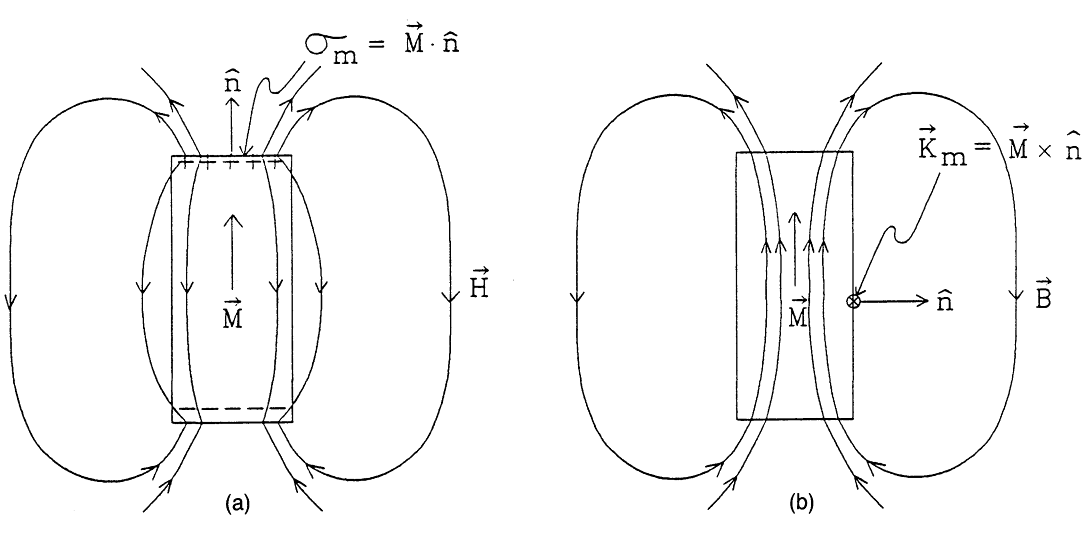
When there are no free currents present or when a region of space excluding such currents and excluding any closed path that could link such currents can be identified, then $\nabla \times \mathbf{H} = 0$ from Eq. (48). This enables us to define a magnetic scalar potential U_m by

$$\mathbf{H} = -\nabla U_m \tag{53}$$

since the curl of a gradient is identically zero. Substituting into Eq. (50), we obtain

$$\nabla^2 U_m = -\rho_m, \tag{54}$$

which is Poisson's equation. If the charge density (volume and surface) is known throughout space, then the solution to Eq. (54)



$\sigma_m = \vec{M} \cdot \hat{n}$
$\hat{n}$
$\vec{M}$
$\vec{H}$
(a)
$\vec{K}_m = \vec{M} \times \hat{n}$
$\vec{M}$
$\hat{n}$
$\vec{B}$
(b)

FIG. 8. Contrasting behaviors of fields B and H for a uniformly magnetized cylinder.

is given by

$$U_m = \frac{1}{4\pi}\left(\int \frac{-\nabla'\cdot\mathbf{M}}{R}\,dV' + \int \frac{\mathbf{M}\cdot\mathbf{n}}{R}\,dS'\right), \tag{55}$$

where R is the distance between field and source points. This solution follows from the property of the operator ∇^2 used in the derivation of Eq. (22). Equation (54) can also be solved as a boundary-value problem. In fact all the apparatus of electrostatic potential theory can be brought to bear in this context. Using Eqs. (A14) and (A15), Eq. (55) can be rewritten as

$$\begin{aligned} U_m &= \frac{1}{4\pi}\int \mathbf{M}\cdot\nabla'\left(\frac{1}{R}\right)dV' \\ &= \frac{1}{4\pi}\int \frac{\mathbf{M}\cdot\hat{\mathbf{a}}_R}{R^2}\,dV'. \end{aligned} \tag{56}$$

We can obtain H in terms of the magnetization from Eqs. (53), together with (55) and (15):

$$\begin{aligned} \mathbf{H} = \frac{1}{4\pi}\Bigg[\int \frac{(-\nabla'\cdot\mathbf{M})\hat{\mathbf{a}}_R}{R^2}\,dV' \\ + \int \frac{(\mathbf{M}\cdot\mathbf{n})\hat{\mathbf{a}}_R}{R^2}\,dS'\Bigg] \end{aligned} \tag{57}$$

since the gradient in Eq. (53) is only with respect to the field point.

4. INTERFACE CONDITIONS ON THE FIELDS AND POTENTIALS

In crossing an interface between two materials having different magnetic properties, e.g., different permeabilities, some conditions are placed on the fields by the laws discussed so far. A condition on **B** can be found by integrating Eq. (20) over a pillbox-shaped volume as shown in Fig. 9(a), applying the divergence theorem, and letting the cylinder sides go to zero. We find

$$\mathbf{B}_1\cdot\mathbf{n} = \mathbf{B}_2\cdot\mathbf{n}, \tag{58}$$

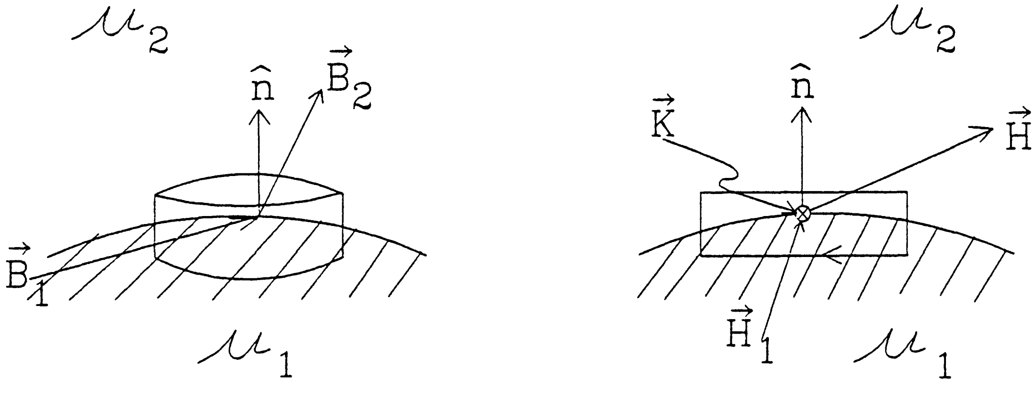
i.e., the normal component of **B** is continuous across an interface. An interface condition on **H** can be found by applying Eq. (49) to the integration path shown in Fig. 9(b). By letting the sides normal to the interface approach zero, we obtain

$$\mathbf{n}\times(\mathbf{H}_2 - \mathbf{H}_1) = \mathbf{K}, \tag{59}$$

where **K** is a possible surface current. In the absence of such a surface current, the tangential component of **H** is continuous across an interface.

The tangential **B** and normal **H** components are not, in general, continuous across an interface. In fact, if materials 1 and 2 have permeabilities μ_1 and μ_2, respectively, then Eq. (58) can be used to establish a condition on the normal **H** components,

$$\mu_1\mathbf{H}_1\cdot\mathbf{n} = \mu_2\mathbf{H}_2\cdot\mathbf{n}, \tag{60}$$



(a) (b)

FIG. 9. Interface conditions on the fields *B* and *H*.

while Eq. (59) implies, for the tangential **B** components,

$$\mathbf{n} \times (\mathbf{B}_2/\mu_2 - \mathbf{B}_1/\mu_1) = \mathbf{K}. \tag{61}$$

Thus these components are not continuous if the permeabilities are dissimilar, even in the absence of free surface currents. A closer examination shows that the origin of these discontinuities is in the material magnetization currents and surface pole densities.

The vector potential **A** is continuous, including across interfaces. Since **B** is obtained from **A** by differentiation, a discontinuity in **A** could lead to an infinite value of **B**. However, the derivatives of **A** need not to be continuous. It can be shown that across an interface separating materials of permeability μ_1 and μ_2,

$$\frac{1}{\mu_2}\frac{\partial \mathbf{A}_2}{\partial n} - \frac{1}{\mu_1}\frac{\partial \mathbf{A}_1}{\partial n} = -\mathbf{K}, \tag{62}$$

where $\partial/\partial n = \mathbf{n}\cdot\nabla$ is the normal derivative.

The magnetic scalar potential is continuous, including across interfaces. This is necessary to keep H finite and to keep the potential single valued. An interface boundary condition can be obtained from Eq. (58):

$$\mu_1 \frac{\partial U_1}{\partial n} = \mu_2 \frac{\partial U_2}{\partial n}. \tag{63}$$

5. MAGNETIC CIRCUITS

A magnetic circuit approach is often useful in obtaining approximate solutions and physical insight into magnetics problems. The possibility of doing this follows from the mathematical similarity between the equations governing electric circuits and their magnetic counterparts. The basic equations governing electric circuits, from which Kirchhoff's laws follow, are

$$\nabla\cdot\mathbf{J} = 0, \quad \oint \mathbf{E}\cdot d\mathbf{l} = \text{emf}. \tag{64}$$

The first equation implies that the algebraic sum of currents into a node is zero and the second says that the voltage drop around a circuit equals the applied electromotive force (emf). The parallel magnetic equations are

$$\nabla\cdot\mathbf{B} = 0, \quad \oint \mathbf{H}\cdot d\mathbf{l} = I. \tag{65}$$

Here **B** corresponds to **J**, **H** to **E**, and I to emf. The analogy is made even closer when we compare Ohm's law

$$\mathbf{J} = \sigma\mathbf{E} \tag{66}$$

to its magnetic parallel

$$\mathbf{B} = \mu\mathbf{H}. \tag{67}$$

The analogy between these last two equations, when applied to materials comprising actual circuits, is not exact. This is because, whereas the electrical conductivity of a conductor is many orders of magnitude higher than that of the surrounding air or insulation, the permeability of ferromagnetic materials is typically only a few orders or magnitude higher. The consequence of this is that the electric current remains confined to the electric circuit whereas the magnetic field has a greater tendency to leak beyond the confines of the circuit.

Corresponding to the electric current, $I = \int\mathbf{J}\cdot d\mathbf{S}$, we have the magnetic flux Φ,

$$\Phi = \int \mathbf{B}\cdot d\mathbf{S}. \tag{68}$$

In the mksa system, the units of flux are T m^2 or webers. If we have a conductor of uniform cross-sectional area S carrying a constant current density $J = I/S$ and having a length l over which the electric field has a constant value of $E = V/l$, where V is the voltage drop, then substituting in Eq. (66), we obtain $V = I(l/\sigma S)$, where the quantity in parentheses is recognized as the electrical resistance. Similarly, for a ferromagnetic bar having the same dimensions and uniformity, the magnetic parallel is

$$\int \mathbf{H}\cdot d\mathbf{l} = \text{mmf} = \Phi(l/\mu S), \tag{69}$$

where the quantity in parentheses is called the reluctance of the bar. The left-hand side is referred to as the magnetomotive force or mmf. In a complete circuit, it is just the total current looped.

5.1 Example

Consider the simple magnet with air gap shown in Fig. 10. Assume a uniform cross-sectional area S and no fringing. Then the flux Φ around the circuit is constant and the mmf

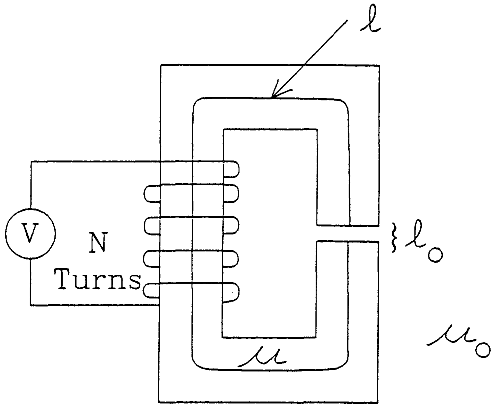


FIG. 10. An example of a magnetic circuit.

is NI since there are N turns, each turn carrying current I. The reluctance of the iron section is $l/\mu S$ and that of the air gap $l_0/\mu_0 S$. Since these reluctances are in series, we have

$$\begin{aligned} NI &= \Phi\left(\frac{l}{\mu S} + \frac{l_0}{\mu_0 S}\right) \\ &= \Phi\frac{l}{\mu S}\left(1 + \mu_r\frac{l_0}{l}\right). \end{aligned} \tag{70}$$

Thus the effective reluctance with air gap can be much larger than the reluctance without an air gap since $\mu_r l_0/l$ is often much greater than 1. This means that, for a given mmf, the flux and hence the flux density are generally much lower with an air gap than without one.

6. MAGNETOSTATIC ENERGY

6.1 Faraday's Law

Although not strictly within the field of magnetostatics, we need to state Faraday's law in order to derive expressions for the magnetostatic energy. This law, discovered in 1831 by M. Faraday, states that the voltage change or emf induced around a closed path is equal to the time rate of change of flux enclosed by the path. The sign of the emf is such that if the path were made of wire, the current would flow in a direction such as to oppose the flux change. Mathematically,

$$V = \oint \mathbf{E}\cdot d\mathbf{l} = \frac{d\Phi}{dt} = -\frac{d}{dt}\int \mathbf{B}\cdot d\mathbf{S}. \tag{71}$$

The positive direction of **B** is given by the direction a right-hand screw would advance if turned in the direction of the path integration. Stokes's theorem can be used to convert the above formula into a differential form of the law,

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}. \tag{72}$$

Thus the electric field is no longer conservative when a changing magnetic field is present.

6.2 Energy in Terms of Current Sources

To obtain the energy content associated with a collection of fixed circuits carrying steady currents with or without the presence of magnetizable matter, we assume that the currents are increased gradually in such a manner that $\nabla\cdot\mathbf{J} = 0$ holds. We also assume that there are no dissipative losses for simplicity. Then, because of the induced emf's in the circuits by Faraday's law, the batteries must supply equal and opposite emf's to keep the currents quasistationary. Thus, at any point in the process of increasing the currents, the incremental energy required to increase the currents further is given by

$$dW = -\sum_i I_i V_i dt = \sum_i I_i d\Phi_i. \tag{73}$$

The sum is over all the current loops.

An alternative expression for the flux can be obtained from Eqs. (17) and (A5):

$$\Phi = \int (\nabla \times \mathbf{A})\cdot d\mathbf{S} = \oint \mathbf{A}\cdot d\mathbf{l}. \tag{74}$$

Thus for fixed current loops, Eq. (73) can be written

$$dW = \sum_i I_i \oint \delta\mathbf{A}\cdot d\mathbf{l}_i = \sum \oint \delta\mathbf{A}\cdot I_i d\mathbf{l}_i. \tag{75}$$

We use δ here to distinguish it from the integration differential. This can be easily generalized to the case where the wire has a finite cross section by subdividing the wire into current tubes. Then each tube carries a current ΔI_i and $\Delta I_i d\mathbf{l}_i = \mathbf{J}_i dV_i$ so that Eq. (75) becomes

$$dW = \sum_i \int \delta\mathbf{A}\cdot\mathbf{J}_i dV_i = \int \delta\mathbf{A}\cdot\mathbf{J}\, dV. \tag{76}$$

The last integral above is over all space since **J** is nonzero only at the wire locations. In case **A** increases linearly with **J**, Eq. (76) can be integrated to yield

$$W = \tfrac{1}{2}\int \mathbf{A}\cdot\mathbf{J}\, dV. \tag{77}$$

6.3 Energy in Terms of Fields

We can transform Eq. (76) by means of Eqs. (48) and (A16) to obtain

$$\begin{aligned} dW &= \int [\mathbf{H}\cdot(\nabla\times\delta\mathbf{A}) - \nabla\cdot(\delta\mathbf{A}\times\mathbf{H})]\, dV \\ &= \int \mathbf{H}\cdot\delta\mathbf{B}\, dV. \end{aligned} \tag{78}$$

The last form follows on transforming the volume integral to a surface integral, using the divergence theorem, and letting the surface approach infinity, where the integral will vanish because the sources are localized. If **B** increases linearly with **H**, we obtain

$$W = \tfrac{1}{2}\int \mathbf{H}\cdot\mathbf{B}\, dV \tag{79}$$

but, in general,

$$W = \int dV \int_0^{\mathbf{B}} \mathbf{H}\cdot d\mathbf{B}, \tag{80}$$

so that $\int \mathbf{H}\cdot d\mathbf{B}$ is a magnetic energy per unit volume.

The expression for W in Eq. (77) shows that the magnetic energy is associated with the sources, while Eq. (80) indicates that it resides in the fields. Both points of view are valid, and one form or the other may be more convenient in specific calculations. If the magnetic fields are taken around a hysteresis loop as shown in Fig. 6(a), then the energy per unit volume is seen to equal the area of the loop. This magnetic energy is dissipated on each traversal of the loop. In the absence of hysteresis and other losses, the magnetic energy associated with a given state of the sources or fields is unique and may be regarded as a stored energy.

7. FLUX LINKAGES AND INDUCTANCE

If N wire loops in series link the same flux Φ, then the emf induced in the series circuit is given by

$$V = -N\frac{d\Phi}{dt} = -\frac{d\lambda}{dt}, \tag{81}$$

where $\lambda = N\Phi$ is the flux linkage. More generally, if N_1 wires link flux Φ_1, N_2 wires link flux Φ_2, etc., and all the wires are in series, then $\lambda = N_1\Phi_1 + N_2\Phi_2 + \ldots$. The flux linkage is the relevant concept when circuit emf's are desired.

For a finite cross-section wire, Eqs. (73) and (76) imply that

$$VI\, dt = -dW = -\int \delta\mathbf{A}\cdot\mathbf{J}\, dV, \tag{82}$$

where the integral is over the wire. Thus

$$\begin{aligned} V &= -\frac{1}{I}\int \frac{d\mathbf{A}}{dt}\cdot\mathbf{J}\, dV \\ &= -\int \frac{d\mathbf{A}}{dt}\cdot\left(\frac{\mathbf{J}}{I}\right) dV \\ &= -\frac{d}{dt}\left(\frac{1}{I}\int \mathbf{A}\cdot\mathbf{J}\, dV\right). \end{aligned} \tag{83}$$

In going to the last equality we have assumed that $\mathbf{J}/I$ is independent of time. Thus comparing Eq. (81) with (83), we obtain a general expression for the flux linkage for a finite cross-section wire:

$$\lambda = \frac{1}{I}\int \mathbf{A}\cdot\mathbf{J}\, dV. \tag{84}$$

Here **A** is the vector potential due to all sources and the integral is over the volume of the wire. For a thin wire circuit, this reduces to $\lambda = \int \mathbf{A}\cdot d\mathbf{l}$. In general, for a collection of windings, Eq. (73) is replaced by

$$dW = \sum_i I_i d\lambda_i, \tag{85}$$

where $d\lambda_i = (1/I)\int \delta\mathbf{A}\cdot\mathbf{J}_i dV_i$.

Often we are interested in the details of how different circuits are coupled to each other, and so we distinguish the flux linkages produced by one circuit from that of another. Then we write $d\lambda_i = \Sigma_j d\lambda_{ij}$, where $d\lambda_{ij}$ is the differential flux produced by circuit j and linking circuit i. Since for rigid circuits, a change in λ_{ij} is, to a good approximation, only due to a change in the current in circuit j, we have

$$d\lambda_i = \sum_j \frac{d\lambda_{ij}}{dI_j} dI_j = \sum_j M_{ij} dI_j, \qquad (86)$$

where we have defined a (coefficient of) mutual inductance M_{ij}. The coefficient M_{ii} is called the self-inductance (coefficient) and is generally denoted by L_i. These inductances have units of webers/ampere or henrys. The sign is determined by the chosen direction of positive current flow in the two circuits. Substituting Eq. (86) into Eq. (81) yields

$$V_i = -\sum_j M_{ij} \frac{dI_j}{dt} = -L_i \frac{dI_i}{dt} - \sum_{j \neq i} M_{ij} \frac{dI_j}{dt}. \qquad (87)$$

This equation gives only the emf in circuit i associated with the magnetic fields and does not include resistances, capacitors, etc.

7.1 Energy in Terms of Inductances

Substituting Eq. (86) into (85), the differential magnetic energy can be expressed as

$$dW = \sum_i \sum_j M_{ij} I_i dI_j. \qquad (88)$$

Before we can integrate this, we need to look more closely at the M_{ij}. From Eqs. (84) and (86),

$$M_{ij} = \frac{1}{I_i} \int \frac{d\mathbf{A}_j}{dI_j} \cdot \mathbf{J}_i dV_i. \qquad (89)$$

If we assume that $\mathbf{J}/I$ depends only on position, then using Eq. (18) for $\mathbf{A}$ gives

$$\mathbf{A} = I\left(\frac{\mu_0}{4\pi I} \int \frac{\mathbf{J}\, dV}{R}\right), \qquad (90)$$

where the quantity in parentheses is independent of current. Therefore $d\mathbf{A}/dI = \mathbf{A}/I$ and Eq. (89) becomes

$$\begin{aligned} M_{ij} &= \frac{1}{I_i I_j} \int \mathbf{A}_j \cdot \mathbf{J}_i dV_i \\ &= \frac{\mu_0}{4\pi I_i I_j} \int \int \frac{\mathbf{J}_i \cdot \mathbf{J}_j}{R_{ij}} dV_i dV_j, \end{aligned} \qquad (91)$$

where R_{ij} is the distance between the positions of the two current densities. It can be seen here that $M_{ij} = M_{ji}$. This is a general result for linear systems. If the space between the circuits were filled with a material of linear permeability μ, Eq. (91) would hold with μ_0 replaced by μ.

Assuming these properties for M_{ij}, Eq. (88) becomes

$$\begin{aligned} dW &= \sum_i L_i I_i dI_i + \sum_{i<j} M_{ij}(I_i dI_j + I_j dI_i) \\ &= \tfrac{1}{2} \sum_i L_i d(I_i)^2 + \sum_{i<j} M_{ij} d(I_i I_j), \end{aligned} \qquad (92)$$

so that integration produces

$$W = \tfrac{1}{2} \sum_i L_i I_i^2 + \sum_{i<j} M_{ij} I_i I_j. \qquad (93)$$

7.2 Example

We calculate the self-inductance of the torus of Fig. 3(b). Assume that it is uniformly wound with N turns of thin wire carrying current I and that it is filled with magnetic material of constant permeability μ. From Eq. (26), with μ replacing μ_0, we find approximately

$$\Phi = B_t S = \mu NIS/2\pi r_c, \qquad (94)$$

where S is the cross-sectional area and r_c is the distance from the axis to the center of the circular cross-sectional area. Hence the self-inductance is

$$L = \frac{d\lambda}{dI} = \frac{\lambda}{I} = \frac{N\Phi}{I} = \frac{\mu N^2 S}{2\pi r_c}, \qquad (95)$$

and we see that L is a geometric quantity apart from the factor μ. The approximations used here amount to assuming that the radius of the small circle is much less than r_c and that there are many fine wire turns, uniformly wound.

8. MAGNETIC FORCES AND TORQUES

8.1 Force and Torque on Current Distributions

The magnetic force on a current distribution is obtained by integrating Eq. (13):

$$\mathbf{F} = \int \mathbf{J} \times \mathbf{B}\, dV \quad \text{or} \quad \mathbf{F} = \int I d\mathbf{l} \times \mathbf{B}, \qquad (96)$$

where the second equation refers to filamentary conductors. Similarly, the magnetic torque about some point O is given by

$$\mathbf{T} = \int \mathbf{r} \times (\mathbf{J} \times \mathbf{B})\, dV \quad \text{or}$$
$$\mathbf{T} = \int \mathbf{r} \times (I\, d\mathbf{l} \times \mathbf{B}), \tag{97}$$

where $\mathbf{r}$ is measured from the point O.

8.1.1 Example The force between two infinitely long, thin, parallel wires a distance h apart and carrying currents I_1 and I_2 is found from Eq. (96) and the previously obtained value of B produced by a single long wire, $B_1 = \mu_0 I_1/2\pi h$, where 1 labels the first wire. From Fig. 2(b), we see that this field is everywhere perpendicular to the second wire and constant along its length so that the force per unit length is given by $F/L = \mu_0 I_1 I_2/2\pi h$. The sense of the cross product is such that if the currents are flowing in the same direction the force is attractive; otherwise it is repulsive.

8.2 Force and Torque on Localized Current Distributions

We assume that the localized current distribution is in an external magnetic field that varies slowly over the distribution. Then the field can be written

$$\mathbf{B}(\mathbf{r}) = \mathbf{B}(0) + (\mathbf{r}\cdot\nabla)\mathbf{B}(0) + \ldots, \tag{98}$$

where the origin is taken inside or near the current distribution, and in the second term on the right hand side the evaluation at $\mathbf{r} = 0$ is performed after the gradient operation. Substituting into Eq. (96), we obtain approximately

$$\mathbf{F} = \left(\int \mathbf{J}\, dV'\right) \times \mathbf{B}(0) + \int \mathbf{J} \times (\mathbf{r}'\cdot\nabla)\mathbf{B}(0)\, dV'. \tag{99}$$

The first term vanishes because the currents are localized and $\nabla\cdot\mathbf{J} = 0$. The gradient operator only operates on $\mathbf{B}$ in the second integral. After a series of manipulations similar to those leading to Eq. (35), the force can be transformed to the form

$$\mathbf{F} = (\mathbf{m}\cdot\nabla)\mathbf{B}, \tag{100}$$

where $\mathbf{m}$ is the magnetic dipole moment given by Eq. (36). Thus a magnetic dipole experiences a force if the field has a gradient.

The torque on a localized current distribution is found by substituting Eq. (98) into Eq. (97). Here the constant term in Eq. (98) contributes, so that to lowest order

$$\mathbf{T} = \int \mathbf{r}' \times [\mathbf{J} \times \mathbf{B}(0)]\, dV'. \tag{101}$$

This likewise can be transformed, by means of identities and similar procedures to those used to derive Eq. (35), to the form

$$\mathbf{T} = \mathbf{m} \times \mathbf{B}. \tag{102}$$

Thus a magnetic moment experiences a torque in a uniform magnetic field. An example is a compass needle in the Earth's magnetic field.

8.3 Maxwell Stress Tensor

In general, when both free currents and magnetization are present, we expect the force to be given by

$$\mathbf{F} = \int (\mathbf{J} + \nabla \times \mathbf{M}) \times \mathbf{B}\, dV = \frac{1}{\mu_0}\int (\nabla \times \mathbf{B}) \times \mathbf{B}\, dV, \tag{103}$$

where the second equality follows from Eqs. (47) and (48). The integral is over the volume of the object on which the force is acting. By means of Eq. (A17) the above integrand can be written

$$(\nabla \times \mathbf{B}) \times \mathbf{B} = (\mathbf{B}\cdot\nabla)\mathbf{B} - \tfrac{1}{2}\nabla B^2. \tag{104}$$

By adding a term $\mathbf{B}(\nabla\cdot\mathbf{B})$, which is zero, to the right-hand side, Eq. (104) can be written as the divergence of a tensor so that Eq. (103) becomes

$$\mathbf{F} = \int \nabla\cdot\mathsf{T}\, dV, \tag{105}$$

where $\mathsf{T} = (1/\mu_0)[\mathbf{BB} - (\tfrac{1}{2})\mathsf{I}B^2]$ is called the Maxwell stress tensor. We are using dyadic notation, where I, the unit dyadic, is given in Cartesian coordinates by $\mathsf{I} = \mathbf{ii} + \mathbf{jj} + \mathbf{kk}$, where $\mathbf{i}$, $\mathbf{j}$, $\mathbf{k}$ are the Cartesian unit vectors. The tensor components are given by $T_{ij} =$

$\mathbf{i}\cdot\mathbf{T}\cdot\mathbf{j}$, so that, in component form

$$T_{ij} = (1/\mu_0)(B_iB_j - \tfrac{1}{2}\,\delta_{ij}B^2), \tag{106}$$

where $\delta_{ij} = 1$ if $i = j$ and 0 otherwise.

Inserting Eq. (104) into (103) and making use of Eqs. (A6) and (A8), we can express **F** as a surface integral:

$$\mathbf{F} = \frac{1}{\mu_0}\oint [\mathbf{B}(\mathbf{B}\cdot\mathbf{n}) - \tfrac{1}{2}B^2\mathbf{n}]dS. \tag{107}$$

To avoid ambiguity, the integral should be taken over a surface slightly outside the object. If we decompose **B** into a normal and tangential component at the surface, $\mathbf{B} = B_n\mathbf{n} + B_t\mathbf{t}$, the last equation becomes

$$\mathbf{F} = \frac{1}{\mu_0}\oint [\tfrac{1}{2}(B_n^2 - B_t^2)\mathbf{n} + B_nB_t\mathbf{t}]dS. \tag{108}$$

8.3.1 Examples From Eq. (108), we see that when B is normal to a surface, so that $B_t = 0$, the surface force density is $\mathbf{F}/S = (B_n^2/2\mu_0)\mathbf{n}$ so that the force is directed along the outward normal to the surface. This means the object is being pulled on, i.e., the force is attractive. An illustration of this is shown in Fig. 11 where an iron slab is near a lifting magnet. The field B is nearly normal to the upper surface of the bar under the magnet poles and nearly vanishes along the other surfaces. Since the force does not depend on the sign of B_n, both poles of the magnet exert the same force on the magnet. The force is upward or attractive since this is the direction of the outward normal to the top surface surrounding the slab.

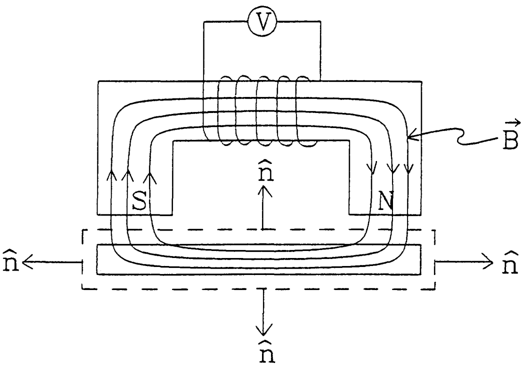

FIG. 11. An electromagnet exerting a force on a ferromagnetic slab.

When the magnetic field is tangential to a surface so that $B_n = 0$, then the surface force density is $\mathbf{F}/S = (-B_t^2/2\mu_0)\mathbf{n}$ so that it is directed along the inward normal to the surface, regardless of the sign of B_t. A long solenoid illustrates this situation since B is tangential along the inner surface but zero outside the solenoid. If we draw an imaginary surface around the solenoid wires, the outward normal to the inner part of the surface points toward the axis. Therefore the surface force pushes outward on the inner surface of the wires.

8.4 Force and Torque by Energy Methods

Since we are interested in static or nearly static magnetic forces, we assume that displacements occur so slowly that no kinetic energy is produced. We also ignore losses and capacitive energy. Then the principle of conservation of energy says that for a collection of circuits, with or without the presence of magnetizable material, the energy supplied by the sources equals the increase in magnetic energy plus the mechanical work done by the forces. The energy supplied by the sources is given by Eq. (85), and so the energy principle states

$$\sum_i I_i d\lambda_i = dW_m + F_x dx. \tag{109}$$

We have isolated a single force acting in a specified direction x. To find torques, simply substitute $T_\theta d\theta$ for the force term. Since we are ignoring hysteresis, the magnetic energy W_m is a state function of the independent variables of the system. If we choose the independent variables to be the λ_i and x, so that $W_m = W_m(\{\lambda_i\},x)$, where $\{\lambda_i\}$ means the set $\lambda_1,\lambda_2,\ldots$, then

$$dW_m = \sum_i \left(\frac{\partial W_m}{\partial \lambda_i}\right)_{x,\{\lambda_{j\neq i}\}} d\lambda_i + \left(\frac{\partial W_m}{\partial x}\right)_{\{\lambda_i\}} dx, \tag{110}$$

where the subscript notation indicates the variables held constant in the partial differentiation. Substituting into Eq. (109), we obtain

$$\sum_i \left[I_i - \left(\frac{\partial W_m}{\partial \lambda_i}\right)_{x,\{\lambda_{j\neq i}\}} \right] d\lambda_i - \left[\left(\frac{\partial W_m}{\partial x}\right)_{\{\lambda_i\}} + F_x \right] dx = 0. \tag{111}$$

Since the λ_i and x are independent, all the coefficients of the $d\lambda_i$ and dx above must vanish; in particular,

$$F_x = -\left(\frac{\partial W_m}{\partial x}\right)_{\{\lambda_i\}}. \tag{112}$$

Thus, at constant flux linkages, the force is the negative gradient of the magnetic energy.

If the I_i and x are taken as independent variables so that $W_m = W_m(\{I_i\},x)$, then define a magnetic coenergy, $W'_m(\{I_i\},x)$, by

$$W'_m = \sum_i I_i \lambda_i - W_m. \tag{113}$$

Then

$$dW'_m = \sum_i I_i d\lambda_i + \sum_i \lambda_i dI_i - dW_m \tag{114}$$

with

$$dW'_m = \sum_i \left(\frac{\partial W'_m}{\partial I_i}\right)_{x,\{I_{j\neq i}\}} dI_i + \left(\frac{\partial W'_m}{\partial x}\right)_{\{I_j\}} dx. \tag{115}$$

Substituting Eqs. (114) and (115) into (109), we obtain

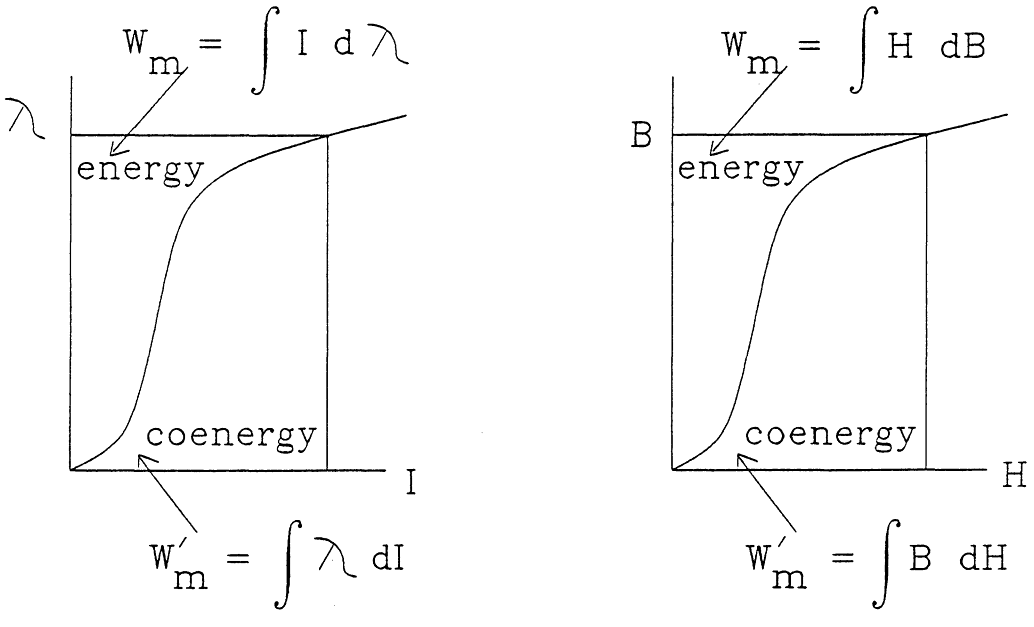
$$\sum_i \left[\lambda_i - \left(\frac{\partial W'_m}{\partial I_i}\right)_{x,\{I_{j\neq i}\}} \right] dI_i + \left[F_x - \left(\frac{\partial W'_m}{\partial x}\right)_{\{I_i\}} \right] dx = 0. \tag{116}$$

By the independence of the I_i and x, we have

$$F_x = \left(\frac{\partial W'_m}{\partial x}\right)_{\{I_i\}}. \tag{117}$$

Thus the force at constant current is given by the positive gradient of the magnetic coenergy.

The force calculated by means of the magnetic energy or coenergy is the same force. Mathematical convenience dictates which of these methods is used to obtain the force. For linear systems, both methods are equivalent



(a)

(b)

FIG. 12. Graphical illustration of energy and coenergy in terms of (a) λ–I and (b) b–H variables.

since, in this case, the energy and coenergy are equal. For a single circuit, the energy and coenergy are shown graphically in Fig. 12. The magnetic energy can be obtained from the current–flux relationship as shown in Fig. 12(a) or via the fields as shown in Fig. 12(b). When these relationships are linear, the equivalence of the energy and coenergy is apparent.

8.4.1 Example As an illustration of these ideas, consider a system of coupled linear inductors with magnetic energy given by Eq. (93). If the forces between inductors i and j is desired and x is taken to be their relative separation, then only M_{ij} depends on x, so that

$$F_x = \left(\frac{\partial W'_m}{\partial x}\right)_{\{I_i\}} = I_i I_j \frac{\partial M_{ij}}{\partial x} \tag{118}$$

since the magnetic energy and coenergy are equal.

APPENDIX: MATHEMATICAL NOTATION AND USEFUL THEOREMS

Vector or scalar fields are assumed to have the required continuity or differentiability to make the mathematical manipulations performed on them valid. In the following **A**, **B**, **C** are general vector fields; Φ is a general scalar field; V is a volume and dV a volume differential; S is a surface and dS a surface differential; **n** is a surface unit outward normal vector; $d\mathbf{S} = \mathbf{n}\, dS$ is a vectorial surface differential; $\boldsymbol{l}$ is a path length and $d\mathbf{l}$ is a vectorial differential path length; $\oint$ denotes an integral over a closed path or closed surface; $\hat{\mathbf{a}}$ is a general unit vector; **i**, **j**, and **k** are unit vectors pointing in the x, y, and z directions, respectively, in a Cartesian coordinate system; ∇ is the gradient operator, which in Cartesian coordinates is given by

$$\nabla = \mathbf{i}\frac{\partial}{\partial x} + \mathbf{j}\frac{\partial}{\partial y} + \mathbf{k}\frac{\partial}{\partial z}. \tag{A1}$$

Dot product:

$$\mathbf{A}\cdot\mathbf{B} = |\mathbf{A}|\,|\mathbf{B}|\cos\theta \tag{A2}$$

where θ is the angle between the two vectors.

Cross product:

$$\mathbf{A}\times\mathbf{B} = |\mathbf{A}|\,|\mathbf{B}|\sin\theta\mathbf{n}, \tag{A3}$$

where θ is the angle measured from **A** to **B** and **n** is a unit vector perpendicular to **A** and **B** and directed in the sense that a right-hand screw would advance in being turned from **A** to **B**.

Divergence theorem:

$$\int_V \nabla\cdot\mathbf{A}\, dV = \oint_S \mathbf{A}\cdot\mathbf{n}dS, \tag{A4}$$

where S is the closed surface enclosing volume V and **n** is its outward normal.

Stokes's theorem:

$$\int_S (\nabla\times\mathbf{A})\cdot\mathbf{n}\, dS = \oint_{\mathscr{C}} \mathbf{A}\cdot d\mathbf{l}, \tag{A5}$$

where $\mathscr{C}$ is the closed path enclosing surface S. If a right-hand screw is turned in the direction of $d\mathbf{l}$, it will advance in the direction of **n**.

Other theorems:

$$\int \nabla\Phi\, dV = \oint \Phi\mathbf{n}\, dS, \tag{A6}$$

$$\int \nabla\times\mathbf{A}\, dV = \oint \mathbf{n}\times\mathbf{A}\, dS, \tag{A7}$$

$$\int [(\mathbf{A}\cdot\nabla)\mathbf{B} + \mathbf{B}(\nabla\cdot\mathbf{A})]dV = \oint (\mathbf{A}\cdot\mathbf{n})\mathbf{B}\, dS, \tag{A8}$$

$$\nabla\cdot(\nabla\times\mathbf{A}) = 0, \tag{A9}$$

$$\nabla\times\nabla\Phi = \mathbf{0}, \tag{A10}$$

$$\nabla\times(\nabla\times\mathbf{A}) = \nabla(\nabla\cdot\mathbf{A}) - \nabla^2\mathbf{A}, \tag{A11}$$

$$\mathbf{A}\cdot(\mathbf{B}\times\mathbf{C}) = \mathbf{C}\cdot(\mathbf{A}\times\mathbf{B}) = \mathbf{B}\cdot(\mathbf{C}\times\mathbf{A}), \tag{A12}$$

$$\mathbf{A}\times(\mathbf{B}\times\mathbf{C}) = (\mathbf{A}\cdot\mathbf{C})\mathbf{B} - (\mathbf{A}\cdot\mathbf{B})\mathbf{C}, \tag{A13}$$

$$\nabla\cdot(\Phi\mathbf{A}) = \mathbf{A}\cdot\nabla\Phi + \Phi\nabla\cdot\mathbf{A}, \tag{A14}$$

$$\nabla\times(\Phi\mathbf{A}) = \nabla\Phi\times\mathbf{A} + \Phi\nabla\times\mathbf{A}, \tag{A15}$$

$$\nabla\cdot(\mathbf{A}\times\mathbf{B}) = \mathbf{B}\cdot(\nabla\times\mathbf{A}) - \mathbf{A}\cdot(\nabla\times\mathbf{B}), \tag{A16}$$

$$\nabla(\mathbf{A}\cdot\mathbf{B}) = (\mathbf{A}\cdot\nabla)\mathbf{B} + (\mathbf{B}\cdot\nabla)\mathbf{A} + \mathbf{A} \times (\nabla\times\mathbf{B}) + \mathbf{B}\times(\nabla\times\mathbf{A}), \qquad \text{(A17)}$$

$$\nabla\times(\mathbf{A}\times\mathbf{B}) = \mathbf{A}(\nabla\cdot\mathbf{B}) - \mathbf{B}(\nabla\cdot\mathbf{A}) + (\mathbf{B}\cdot\nabla)\mathbf{A} - (\mathbf{A}\cdot\nabla)\mathbf{B}. \qquad \text{(A18)}$$

INTRODUCTION

When some materials are placed in a varying magnetic field (which alters the material's magnetic state), a change in the physical dimensions of these materials occurs. This effect is called *magnetostriction*, and it is important for device applications because it represents an avenue for converting magnetic energy into physical motion for actuator applications. In addition, the magnetostrictive effect is reversible; changes in a material's applied stress generate magnetic energy, i.e., the material can be used as a sensor. The physical mechanism that couples the material's magnetic state to its physical dimension is the change in orientation of spatially asymmetric magnetic ions. Figure 1 shows a mechanical analog of this. In (a), there is no magnetic field and the asymmetric ions are turned to their "short" direction by the weight of the mass. In (b), a magnetic field

(a) (b)

FIG. 1. A schematic showing how the rotation of asymmetric atomic ions changes the length of a material. H is the applied field. (a) No magnetic field, (b) magnetic field.

is applied and pulls the ions toward their long direction.

Historically, magnetostriction was discovered by Joule in 1847 when he measured the change in length of an iron rod when it was magnetized. During World War II, nickel was used in the magnetostrictive sonar devices on warships. In the 1960s, measurements on Tb and Dy revealed magnetostrictive strains of nearly 1%. Unfortunately, these strains occur only at low temperatures. Attempts to obtain large magnetostrictions at room temperature culminated in the synthesis of $TbFe_2$ (Terfenol) compounds in the early 1970s. Dy was later added to the recipe to improve performance at low applied fields, and the result is now commercially available as Terfenol-D ($Tb_{0.27}Dy_{0.73}Fe_{1.95}$).

Magnetostrictive materials have applications as both sensors and actuators. The most important traits differ, however, depending upon the application. The crucial property for sensors is sensitivity, i.e., how much of the input energy can be converted into output energy. Transverse-field–annealed iron-based amorphous ribbons offer the highest sensitivity for sensor applications. For actuators, the magnitude of the strain and the available force are the most important properties.

This article first describes various magnetostrictive effects in Sec. 1, then looks at the commonly used materials and their properties in Sec. 2, and finally discusses current and planned magnetostrictive devices in Sec. 3. Electromagnetic units and symbols always offer an opportunity for confusion. In this article, we follow IEEE Standard 319-1990 (IEEE, 1990), which is based on the SI system of units.

1. EFFECTS

There is an entire menagerie of magnetostrictive effects. Almost all of them can be used in either sensor or actuator devices. The most commonly used effect is linear magnetostriction.

1.1 Linear Magnetostriction

A magnetic material is composed of domains, small regions in which all of the atomic moments are aligned. In an unmagnetized state, the domains point in directions that minimize the total energy. If a large enough magnetic field is applied, the minimum-energy configuration is one in which all of the magnetic moments line up in the same direction as the applied field; under these conditions, the material is said to be *saturated.* In order to get some idea of the size of the magnetostriction effect, let us consider one important type of magnetostriction. The sample is placed in a saturating magnetic field whose direction is rotating. As the direction of the field changes, the atomic moments rotate to keep themselves aligned with the applied field. The rotation of the moments changes the sample dimensions according to the formula $\Delta l/l = \frac{3}{2}\lambda_s(\cos^2\theta - \frac{1}{3})$, where $\Delta l/l$ is the fractional change in length, λ_s is the saturation magnetostriction coefficient, and θ is the angle between the field and the measurement direction. Values for some materials of interest are shown in Table 1. Positive values of λ_s indicate that the material lengthens when the applied magnetic field is increased; negative values indicate that the material shortens. The change in sample dimensions in the direction of the applied magnetic field is called Joule magnetostriction. The inverse effect, a change in the magnetic state of a material when applied stress is changed, is called the Villari effect.

In actual use, a geometry like that shown in Fig. 2 is normally used. A rod of the material is wrapped with a coil. As the coil is energized, the material changes its dimen-

Table 1. Saturation magnetostrictions.

sions. Figure 3 shows the magnetostriction of a Terfenol-D rod vs applied field at three different compressive stresses. The magnetization M is intimately linked with the magnetostriction, since both are caused by the rotation of the magnetic moments. Figure 4 shows the magnetization corresponding to the magnetostriction in Fig. 3. Note that the strain does not depend on the direction of the applied field.

1.2 ΔE Effect

In addition to the conventional stress-strain elasticity arising from atomic forces, magnetostrictive materials can also change their length when stress is applied by rotating their magnetic moments. This is known as the ΔE effect, where $\Delta E = (E_s - E_0)/E_0$, where E_0 is the Young's modulus at high field and E_s is the minimum value of the modulus. The compression of the material due to moment rotation is in addition to the nonmagnetic elastic compression, so that the material becomes softer when the moments are free to move. Figure 5 shows the ΔE effect in $Tb_{0.67}Dy_{0.33}$. The modulus decreases by about a factor of 7 as the magnetic field is varied. At high applied magnetic fields, the moments are virtually locked in place and the

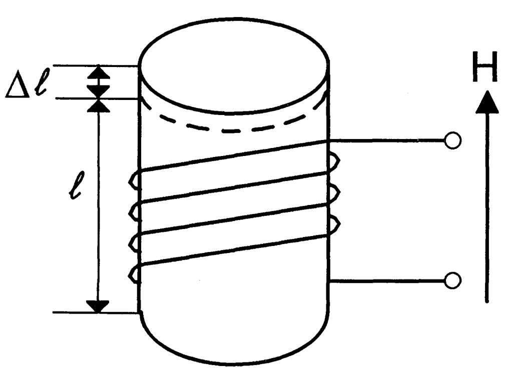

FIG. 2. Joule magnetostriction. An applied axial field H causes the rod to change its length by Δl; the magnetostriction is given by $\Delta l/l$.

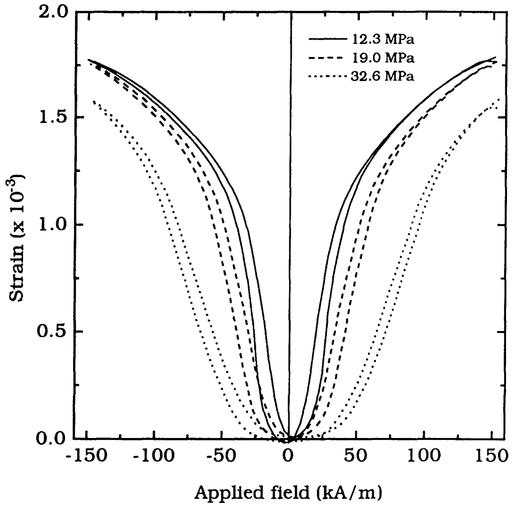

FIG. 3. Strain of a Terfenol-D rod as a function of applied field at various applied stresses.

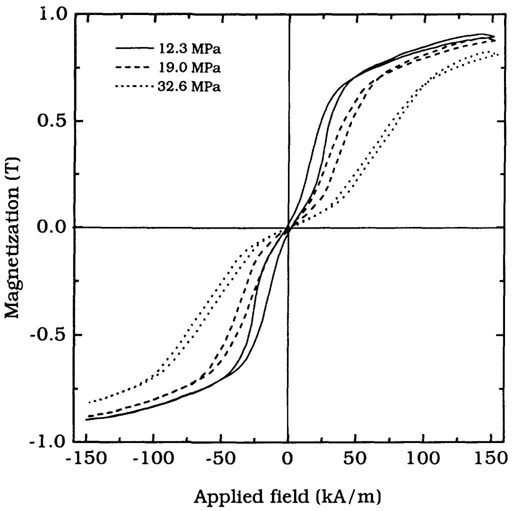

FIG. 4. Magnetization of a Terfenol-D rod as a function of applied field at various stresses. In this plot, *M* has been multiplied by μ_0 and plotted in units of teslas. Technically, this is called the intrinsic magnetic flux density *J*.

modulus becomes larger. The ΔE effect is about 0.06 in Ni, 2 in Terfenol-D, and 10 in transverse-field–annealed amorphous Fe_{81}-$B_{13.5}Si_{3.5}C_2$ ribbons.

1.3 Magnetovolume Effect

The magnetovolume effect is a change in volume caused by a change in the applied magnetic field which in turn alters the magnetization. The largest magnetovolume effects occur near the Curie temperature where $\Delta M/\Delta T$ is large. In cubic and isotropic materials, the change in volume caused by rotation of the magnetization is zero. The magnetovolume effect is also called the Barrett effect, and the inverse, a change in magnetic state caused by a change in the volume, is called the Nagaoka–Hondo effect. In the $Ni_{0.36}Fe_{0.64}$ alloy Invar, the magnetovolume effect compensates the usual thermal expansion, giving a material with a nearly zero thermal expansion coefficient at room temperature (Bozorth, 1951).

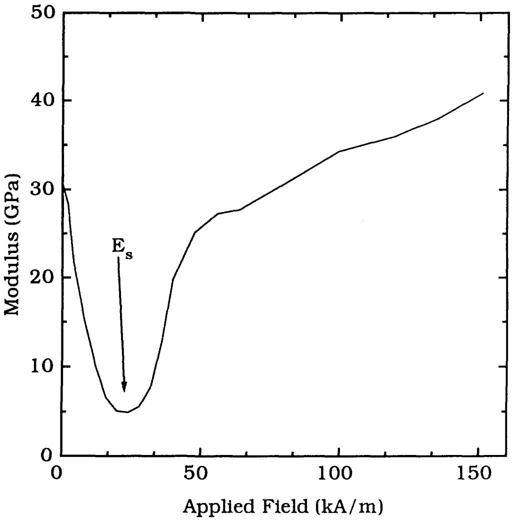

FIG. 5. ΔE effect in a $Tb_{0.67}Dy_{0.33}$ rod at 77 K.

1.4 Wertheim Effect

In a ferromagnetic rod placed in an axial magnetic field, the moments are predominantly lined up axially. When the rod is twisted, some of the moments become helically oriented, and a transient voltage is generated across the ends of the rod. This is called the Wertheim effect (see Fig. 6). In the inverse Wertheim effect, a voltage applied to the rod ends causes a twist in the rod.

1.5 Wiedemann Effect

A current carrying ferromagnetic wire has the preponderance of its moments lined up in the circumferential direction, parallel to the magnetic field. When an axial magnetic field is applied, some of the moments align themselves in a helical fashion, twisting the wire. This is called the Wiedemann effect (see Fig. 7). The inverse Wiedemann effect is the

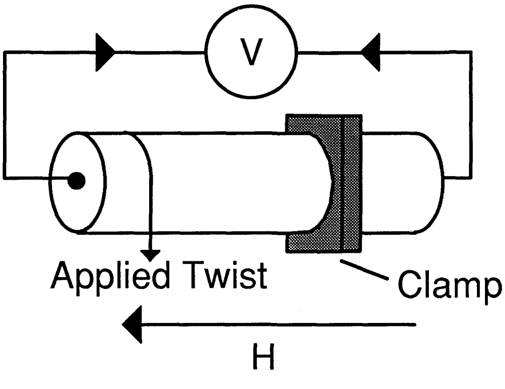

FIG. 6. Wertheim effect.

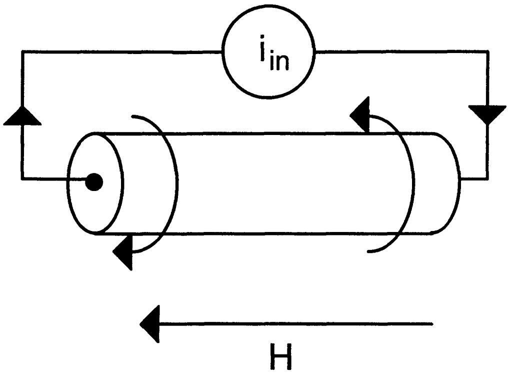

FIG. 7. Wiedemann effect.

change in axial magnetization of a current carrying wire when it is twisted.

1.6 Garshelis Effect

The magnetization of a spring formed of ferromagnetic wire changes with the length of the spring; this is called the Garshelis effect. Depending on whether the magnetization is due to currents in the wire or is a remanent magnetization, the Garshelis effect can be an extrapolation of the Wertheim or inverse Wiedemann effect.

1.7 Magnetoacoustic Effect

The change in dimensions of a magnetostrictive material can generate acoustic energy. An example of this effect is hum that electrical transformers give off or a "click" that is sometimes heard when a field is applied to a magnetostrictive material. For this reason, transformer core materials are usually designed with the least possible magnetostriction.

2. MATERIALS

2.1 Linear Magnetostriction Theory

2.1.1 Magnetostriction at Magnetic Saturation In general, the effect of a saturating magnetic field on a magnetostrictive material is given by a fourth-rank tensor which couples strain to field. In the most general case, it takes 15 constants to describe the magnetostriction in a material. However, for the important cases of cubic and hexagonal symmetry, only two and four constants, respectively, are needed. The following equation shows the saturation magnetostriction for cubic crystals (neglecting the volume change):

$$\Delta l/l = \tfrac{3}{2}\lambda_{100}(\alpha_x^2\beta_x^2 + \alpha_y^2\beta_y^2 + \alpha_z^2\beta_z^2 - \tfrac{1}{3}) + 3\lambda_{111}(\alpha_x\alpha_y\beta_x\beta_y + \alpha_y\alpha_z\beta_y\beta_z + \alpha_z\alpha_x\beta_z\beta_x), \tag{1}$$

where λ_{100} and λ_{111} are the saturation magnetostrictions measured along the (100) and (111) directions, respectively, and the α's and β's are the direction cosines of the applied field and the measurement direction with respect to the crystal axes (Clark, 1980).

2.1.2 Linearized Magnetostriction below Saturation Many devices operate at fields much less than saturation where the magnetostrictive response is quasilinear, even though in general, the magnetic properties depend on the applied field H. Also, in practice, the applied field and the strain are often in the same direction. In this linear approximation, the applied magnetic field H and the strain S are related by the *effective piezomagnetic constant d*. The relationship is given by

$$d = \frac{\partial S}{\partial H}. \tag{2}$$

This relationship describes the simplest idea of a change in magnetic field causing a change in a material's length. In a similar fashion, the relationship between a change in the magnetic flux density B and a change in H is given by

$$\mu = \frac{\partial B}{\partial H}, \tag{3}$$

where μ is the usual permeability. However, the changes in S and B also depend on the changes in applied stress. The complete linearized difference equations of state for S and B are given by

$$\begin{aligned} \Delta S &= s^H \Delta T + d\Delta H, \\ \Delta B &= d\Delta T + \mu^T \Delta H, \end{aligned} \tag{4}$$

where T is the applied stress, s^H is elastic compliance at constant H, d is the effective piezomagnetic constant, and μ^T is the permeability at constant stress. For this one-dimensional, linear case, it is useful to define a figure of merit from the fundamental properties described above. This figure of merit is called the coupling factor and is denoted by k, with

$$k^2 = d^2/s^H \mu^T. \tag{5}$$

The coupling factor is a measure of the conversion efficiency of magnetic energy into mechanical energy, and vice versa.

2.2 Magnetic Anisotropy

In some magnetostrictive crystalline materials, it is energetically favorable for the magnetization vector to lie along certain crystallographic directions. This is called the *magnetic anisotropy energy* and has units of J/m^3. If a smoothly varying magnetic field is applied to a material with a sufficiently high anisotropy, the resultant variation in magnetostriction is not smooth: "jumping" occurs. An example of such a material is shown in Figs. 8(a) and 8(b). This figure shows a $\mathrm{Tb}_x\mathrm{Dy}_{1-x}$ alloy that has substantial magnetic anisotropy. Note the jumping and nonjumping regions of the curve. The magnetization is also shown, since it displays the "jumps" more clearly. This jumping occurs when the moment direction abruptly enters or leaves a low-energy direction. Jumping is frequently an undesirable trait for device applications, and elements with opposite anisotropies are often alloyed together in an attempt to reduce or eliminate the magnetic anisotropy energy. Figures 8(c) and 8(d) show a different $\mathrm{Tb}_x\mathrm{Dy}_{1-x}$ alloy with nearly zero anisotropy; the magnetostriction is much smoother.

2.3 Important Material Properties

In this section, we discuss some of the material properties that are desirable from a device standpoint.

The effective piezomagnetic constant d represents the rate of change in length with applied field. The "d constant" should be large.

Magnetization M is the internal magnetic moment per unit volume of the sample along a given direction. Useful magnetostriction occurs either by rotation of the internal moment or by motion of the domain walls. The saturation magnetization M_s is the maximum value of M. A large M gives a large "handle" to rotate the moments using an applied magnetic field; in addition, the magnetic energy available for conversion to mechanical energy is given by $\mathbf{M}_s \cdot \mathbf{H}$.

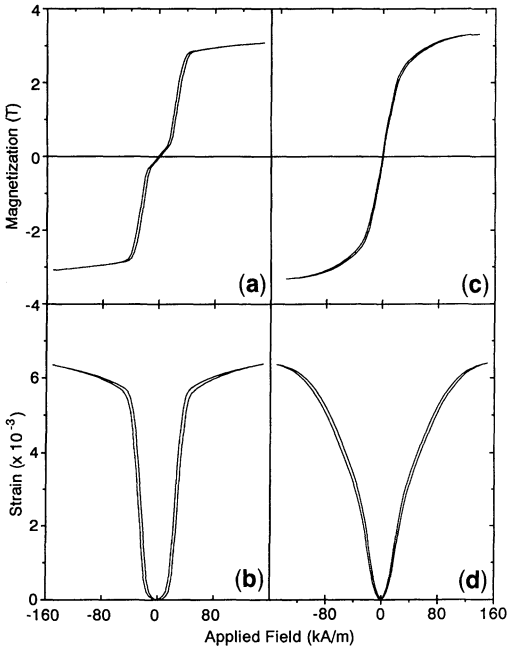

FIG. 8. (a),(b) Magnetization and strain of a $\mathrm{Tb}_{0.67}\mathrm{Dy}_{0.33}$ rod with large anisotropy. (c),(d) The same measurements on $\mathrm{Tb}_{0.6}\mathrm{Dy}_{0.4}$, which has almost zero anisotropy. Note the sharp jumps in (a) and (b). See Fig. 4 for a note on the units.

Permeability μ is the rate of change in B with applied field. It should be large when the object is free to change its dimensions.

Magnetic anisotropy K is a measure of the energy required to move the moment away from its preferred crystallographic direction. For most applications, K would ideally be zero. The magnetic anisotropy provides a restoring force when no external stress is applied.

Elastic compliance s describes the stiffness of the material and has units of Pa^{-1}. The compliance is the inverse of the modulus. A material with a high compliance is very "soft." In order to generate large amounts of work, a large force is desired. Therefore, the material should have low compliance; i.e., it should be "stiff" in order to support the large forces.

In saturation magnetostriction λ_s, the saturation strain, is the strain measured at full extension. This number should be as large as possible in actuators; it is not as critical in sensor applications.

The coupling factor k is a measure of the conversion efficiency between mechanical and magnetic energies. If a very sensitive device is desired, it is critical that this number be large, i.e., close to 1.

2.4 Useful Materials

2.4.1 Crystalline Materials Nickel, with a magnetostriction of -35×10^{-6}, was the first material used for magnetostrictive devices. It was used for sonar transmitters in World War II. At the same time, the Japanese, who did not have access to large supplies of nickel, developed the $Al_{0.13}Fe_{0.87}$ alloy Alfer. Alfer has a positive magnetostriction of about 40×10^{-6}.

Terfenol-D ($Tb_{0.27}Dy_{0.73}Fe_{1.95}$) is the principal room-temperature magnetostrictive material now in use. Its large magnetostriction (about 0.15% for polycrystalline material) and commercial availability make it an attractive material. The combination of Tb and Dy leads to near-zero anisotropy at room temperature. It is available in rods of up to nearly 4-cm (1.5-in.) diameter and 20-cm (8-in.) length. It is normally operated with compressive stresses of between 10 and 40 MPa.

Tb, Dy, and their alloys have the largest known magnetostriction; however, this is achieved only at cryogenic temperatures. The advent of high-temperature superconductors has rekindled interest in TbDy, since the combination of superconducting coils and materials with extraordinary magnetostrictions is attractive. The alloy $Tb_{0.6}Dy_{0.4}$ has near-zero anisotropy at liquid nitrogen temperature (77 K) where these superconductors operate. The magnetostriction is huge, about 0.6 percent, and operation is possible with stresses as high as 20 MPa (Clark *et al.*, 1992). Use of this material is in the prototype stage.

Structural steels have a small but usable magnetostriction for some applications—for example, torque sensors. In addition, various iron alloys, especially alloys containing nickel, have been developed. The nickel content can be varied to obtain the best possible tradeoff between magnetostriction and other necessary properties. The magnetostrictive properties of these alloys varies widely with composition and crystal orientation. For example, with a composition of 40% Ni, the [100] direction has a negative magnetostriction of about 7×10^{-6} and the [110] and [111] directions have positive magnetostrictions around 23×10^{-6}. The material is nearly isotropic at 60% Ni with a positive magnetostriction of 20×10^{-6}, while at 85% Ni, the magnetostriction is almost zero (Bozorth, 1951).

2.4.2 Amorphous Materials Amorphous magnetic materials are made by rapidly quenching the melt. These materials can be made in the form of ribbons (commercial ribbons are typically about 13 cm wide and 13–50 μm thick) and wires (diameter about 125 μm). The ribbons are made by spraying the liquid material onto a cooled metal wheel; cooling rates in the region of millions of degrees/second prevent the formation of crystals. Wires are made by injecting the molten metal into a much cooler liquid. In the case of the wires, cooling rates are somewhat less than those for ribbons. Typical magnetostrictive materials consist of iron and boron, with other materials such as silicon and carbon added as needed. The ribbon materials are designed to be used in transformer cores; however, after proper annealing in a magnetic field (Modzelewski *et al.*, 1981), they become excellent sensor materials, with extremely high coupling coefficients, i.e., almost complete conversion between mechanical and magnetic energy. In contrast to their high coupling coefficients, amorphous materials have low magnetostrictions (0.004%) and saturate at low magnetic fields. Similar properties can be obtained in the wire materials by the same annealing process.

3. DEVICES

3.1 Sensor Applications

In this section, we use the term sensor in a broad sense, which includes any application that measures a physical phenomenon. When sensitivity is of prime importance, sensor materials need to have a very high coupling coefficient. In the case of transverse-field–annealed amorphous ribbons, k can be as high as 0.95. Magnetostrictions (40×10^{-6}) and saturation magnetic fields (80 A/m) are low. This means that, although the materials are very sensitive, they can easily be saturated if even moderate strains or fairly low stray magnetic fields are present. Furthermore, they are mechanically fragile. In applications requiring less sensitivity, ordinary steels or alloys specially formulated for high magnetostriction provide enough sensitivity and are strong enough to carry mechanical loads. For example, the magnetostriction in a steel shaft can be used to measure the applied torque.

Many sensor designs use a measurement of the active material's permeability to derive the output signal. This measurement is accomplished by using a drive coil to generate a magnetic field. The resulting magnetic flux (which includes the contribution from the material's magnetization) is measured with a pickup coil. A common refinement of this technique is to use multiple coils in a bridge arrangement. The two coils can either measure materials that are stressed in opposite directions (Fig. 9) or measure stressed and unstressed sensors (Fig. 10). This helps reduce problems such as thermal drift.

Magnetostrictive sensors have a wide range of applications. All that is needed is that the desired phenomenon can generate a force that results in a change in length. For example, a pressure gauge can be made by attaching a magnetostrictive material to a metal diaphragm. As the pressure changes, the diaphragm bends and strains the sensor. One important advantage of sensors based on magnetostrictive "strain gauges" is that the measurement can be made on a noncontact basis; it is not necessary to attach leads to moving objects in order to measure the strain. Magnetostrictive sensors can also be used to measure magnetic field. As the magnetic field changes, the material changes length. This length change can be measured by a variety of means, such as strain gauges.

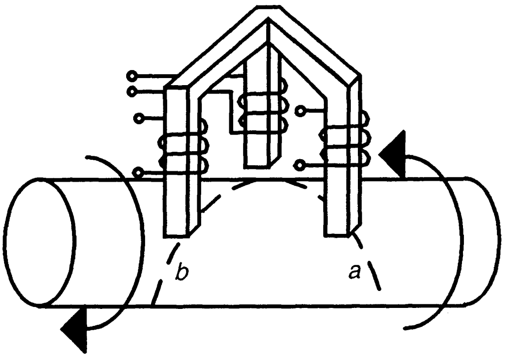

FIG. 9. Differential torque measurements on a shaft.

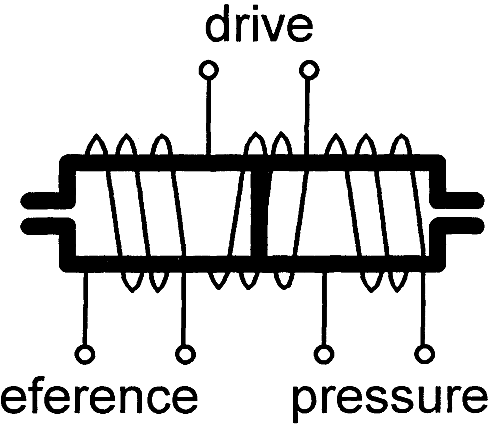

FIG. 10. Differential measurements on a pressure sensor.

3.1.1 Inventory Control Magnetostrictive ribbons are used for inventory control (antitheft) systems. A short section of ribbon is attached to the item that is to be protected, and a monitoring station is placed at the store exit. The monitoring station generates an ac magnetic field. When the ribbon encounters the magnetic field, its length begins to oscillate. If the applied frequency matches the mechanical resonant frequency of the ribbon, energy is absorbed. This energy loss is detected and an alarm sounds when a tagged item is carried out of the store. Other designs use ribbon shapes that generate harmonics or subharmonics of the applied frequency. The presence of the additional frequency is used to trigger an alarm. The ribbon can be deactivated by permanently magnetizing a piece of steel or other permanently magnetizable material that is colocated with the ribbon. This magnetically saturates the ribbon which then no longer responds to the ac field.

3.1.2 Torque Sensors Consider a shaft that has a torque applied (see Fig. 9). The material along line *a* is compressed and that along line *b* expanded. If the shaft is magnetostrictive or has a magnetostrictive material attached to it, the magnetic properties along *a* and *b* will change. These properties are usually measured in a differential fashion, as shown in the figure. An alternative method is to measure the magnetization change directly with the use of Hall sensors.

3.1.3 Pressure Sensors Magnetostrictive pressure sensors measure the change in magnetic properties of a magnetostrictive material when it is deformed by applied pressure. To compensate for environmental changes, such as temperature, a differential measurement technique is generally used. A schematic of such a sensor is shown in Fig. 10. The pressure sensor consists of two chambers: one is exposed to the pressure to be measured and the other is exposed to a reference pressure or the atmosphere. Magnetostrictive material either forms the chamber or is attached to it. A drive coil excites both chambers of the sensor, and the signal from the two pickup coils measures the permeability of the sensor material. An alternative approach is to measure the deflection of a metal diaphragm in a similar fashion.

3.1.4 Anisotropy Sensors Strain anisotropies in a magnetostrictive material are converted into magnetic anisotropies; therefore, a measurement of magnetic anisotropies reveals the anisotropy in the strain. For example, when metal is rolled to reduce its thickness, the metal expands in the other two dimensions. Improper roller settings can cause the metal to expand more in one direction than another, which leads to either wavy edges or buckling in the center. If the metal is magnetostrictive, an anisotropy sensor can be used to make a noncontact measurement of the strain in each direction and adjust the roller settings. Figure 11 shows a typical bridge arrangement used to measure magnetic anisotropy (Burke, 1986).

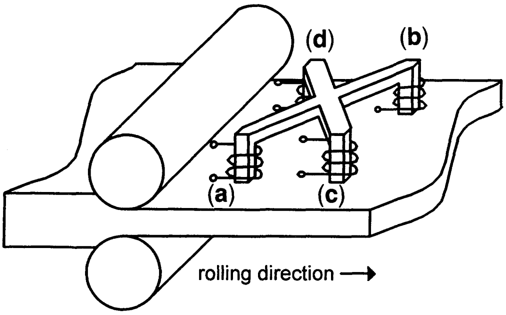

FIG. 11. A bridge arrangement for measuring strain anisotropy. The drive field is applied to legs (c) and (d), and the difference is measured across (a) and (b).

3.1.5 Villari Bridges Villari bridges are force transducers sold by ABB under the name Pressductor®. They consist of two coils of wire oriented to produce zero mutual inductance. The coils are wound through a block of laminated steel (Fig. 12) and force is applied to the top and bottom. The force causes a decrease in the permeability of the steel in the direction of the applied force, which breaks the symmetry of the device and allows an energy transfer to the pickup coils. These devices have been used in a variety of applications, such as rolling-mill pressure sensing. One interesting use is in metal rolling. A sensing roller with a series of force sensors along its length measures the pressure applied by the rolled metal as it passes over. If rolling conditions are not correct, ripples appear in the sheet metal and the pressure at different points across the roller varies. Corrections can then be applied to the rolling machinery.

3.1.6 Magnetostrictive/Piezoelectric Combinations A combination of piezoelectric and magnetostrictive materials can be used to measure magnetic field. The two materials

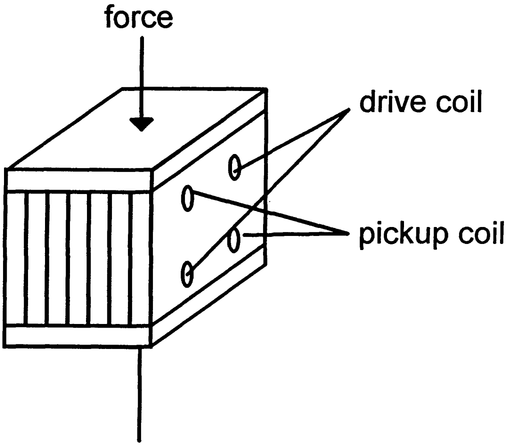

FIG. 12. Villari bridge force sensor. A drive coil is wound through two of the holes, and the pickup coil is wound through the other two. The pickup is rotated 90° with respect to the drive coil.

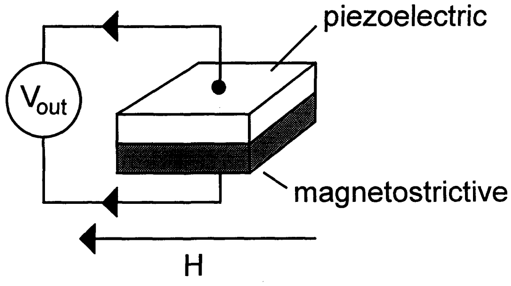

FIG. 13. Magnetostrictive/piezoelectric combination.

are bonded together (Fig. 13), and when a magnetic field is applied to the magnetostrictive material, it changes its length. This strains the piezoelectric material which then generates a voltage proportional to the magnetic field.

3.1.7 Position Sensing Position sensing can be accomplished with a rather clever device that uses a magnetostrictive material as an acoustic waveguide. The waveguide is placed inside a hollow tube (for environmental protection), and a doughnut-shaped sensor containing permanent magnets rides on the outside of the tube (Fig. 14). For liquid level sensing, the sensor floats on the liquid to be measured; for general position sensing, the sensor and the tube are connected to the moving parts. The magnet interacts with the magnetostrictive waveguide and changes its physical properties where the sensor is. In one version, an acoustic pulse is sent down the waveguide. When the pulse hits the region of the waveguide changed by the magnet, which in this case produces a different modulus (ΔE effect), the discontinuity partially reflects the pulse back to the sensor head. The far end of the waveguide is embedded in a damper material to prevent unwanted reflections. An alternative method sends a current pulse down the waveguide where the cylindrical field from the current pulse interacts with the axial field from the sensor magnets to form a local helical magnetic field. The Wiedemann effect generates a helical twist in the wire, which travels back to the sensor head. In both designs, a measurement of the transit time of the pulse gives the position of the sensor. At least one design also uses magnetostrictive tapes to measure the occurrence of the arriving pulse.

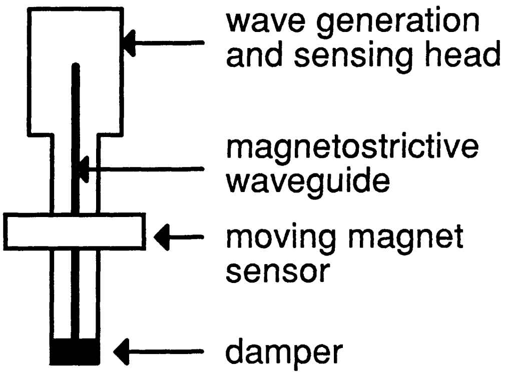

FIG. 14. Position sensor.

Adjustable limit switches using a compliant magnetostrictive sensor element are available. The element is excited at the power line frequency, and the output of the sensor depends on the strain produced by the plunger position. A threshold sensor sets the on-off position; travel up to 1.25 mm is available.

3.1.8 High-Sensitivity Strain Gauges In many of the sensors discussed in this article, the magnetostrictive material is acting as a strain gauge, measuring the strain induced by the physical parameter of interest. The transverse-annealed magnetostrictive ribbons and wires make very sensitive strain gauges (Wun-Fogle *et al.*, 1987). If a gauge factor F is defined as the fractional change in the measured parameter (permeability or resistance) divided by the change in strain, we find that conventional wire and foil resistive strain gauges have F equal to about 2, semiconductor gauges have F equal to about 250, and ribbons have F equal to about 200 000 (with μ as the parameter). The rotating magnetic state also affects current flow in the materials; annealed ribbons with resistance as the measured parameter have an F equal to about 60 (Restorff *et al.*, 1991). One problem encountered with this extraordinarily high-sensitivity strain gauge is that normal thermal expansion can saturate the sensor. This problem is solved by mounting the material with an extremely viscous fluid; however, this in turn limits operations to ac measurements.

3.1.9 Accelerometers Prototype accelerometers based on a cantilevered beam that bends under acceleration using a magnetostrictive pickup have been constructed. Magnetostrictive material is attached to the top and bottom of the beam (when the beam bends, one is under compression and the other, tension), and a differential measurement is made of the induced stress.

3.1.10 Engine-Knock Sensors A sensor for detecting engine knock has been devised (Anderson *et al.*, 1984). It consists of a resonant "C"-shaped structure with a magnetostrictive element across the open ends of the C. A permanent magnet bias is applied, and a pickup coil senses the vibration.

3.1.11 Nondestructive Evaluation There are several techniques involving magnetostriction that are useful for nondestructive testing of materials. The first of these techniques involves the measurement of sound velocity either in or, using surface waves, on a material (Kwun, 1985). The sound velocity is affected by both strain and applied magnetic field (ΔE effect). A magnetic bias is applied to the material, and an ultrasonic generator and detector measures the sound velocity. From the velocity-vs-bias information, the strain can be deduced. Another technique measures the *amplitude* of ultrasonic waves generated in a material as a function of applied bias field (Alers and Thompson, 1977). The amplitude and bias information also reveals strains in the material. A third technique using sound is the utilization of magnetic Barkhausen noise. When an ac magnetic field is applied to a material, the internal magnetization does not change smoothly on a microscopic scale. Each domain abruptly changes direction when it becomes energetically favorable. Since the material is magnetostrictive, the dimensions also change abruptly, which generates a small sound. The sum of the many weak sounds is called Barkhausen noise. The amount of Barkhausen noise emitted depends upon the strain, so that noise measurements reveal information about the material strain. In the third technique, the permeability depends upon the strain, and so direct measurements of this property also give strain information.

3.1.12 Magnetometers When exposed to a magnetic field, a magnetostrictive material by definition changes its length. This converts the problem of measuring magnetic field into one of measuring length. Many methods for measuring length have been used to make a magnetometer: laser interferometric, capacitance, conventional strain gauge, and piezoelectric. In addition, the magnetic properties can be measured directly.

3.1.13 Potential Applications Much of the future use of magnetostrictive materials depends upon the application of new materials to conventional measurement schemes. These new materials, such as transverse-field–annealed amorphous ribbons or wires, and new alloys with giant magnetostrictions, will extend the sensitivity of current sensors. For example, Giallorenzi (1981) calculates that optical-fiber interferometers coated with a magnetostrictive material will exploit the most sensitive aspect of the interferometer and should achieve magnetic field measurement capabilities of 10^{-9}–10^{-10} A/m.

3.2 Actuator Applications

The purpose of an actuator is to convert an electrical signal into mechanical motion. Many types of actuators are needed, from micropositioning actuators that require precise movements and little force to high-power actuators that can deliver up to 45 000 N (10 000 lb) or more of force. Magnetostrictive actuators have advantages over other types of actuators in applications that need low-frequency operation and/or low voltages, since they can easily be driven by conventional low-impedance amplifiers at low frequency. The low impedance of a magnetostrictive actuator means that driving voltages can be low. This can simplify designs, for example, in medical applications.

It is possible to make a very simple actuator by taking a nickel or Terfenol rod and wrapping a coil around it. Such an actuator will work, but it will be far from optimum. A *prestress* is needed on the rod to make sure that the moments are aligned properly. A rod without prestress has the moments aligned randomly and will only achieve about half of its maximum magnetostriction. This is because some of the moments are already aligned with the rod axis and will not be affected by an applied field. Another technique that is often used is *permanent magnet biasing*. Because the magnetostriction is independent of the sign of the magnetic field, a magnetostrictive actuator driven by an ac signal moves at twice the drive frequency and the motion is only in one direction. Both of these problems can be corrected and a quasi-linear operating region achieved by placing a static magnetic field on the material to bias the material half-way up the magnetostriction curve (see Fig. 15). This can be accomplished either by adding a dc current to the drive coil or by placing permanent magnets into the magnetic path. Permanent-magnet biasing has the advantage of considerable power savings. Finally, careful design of the magnetic circuit is required, especially in high-power devices, in order to achieve high efficiency.

There are two basic high-power actuator designs in use today. The first, shown in Fig. 16(a), is a simple "one-legged" axially symmetric design. The second [Fig. 16(b)] is a "two-legged" design, usually used for high-power devices.

3.2.1 Sonar Transmitters The first widespread use of sonar transmitters was during World War II and used nickel magnetostrictive elements. Sonar transmitters are perhaps an ideal application for magnetostrictive transducers, since low frequencies and high forces are needed. One commercial family of sonar transmitters has a usable frequency range of 50 Hz–5 kHz and an output of 206 dB (relative to 1 μPa at 1 m) at the transmitter's resonant frequencies. Uses include submarine detection, mine sweeping, seismic studies, and communication links.

3.2.2 Active Vibration Control Magnetostrictive actuators have been used as the active elements in active vibration control applications. The high-force, low-frequency response of the actuators makes them attractive in some applications.

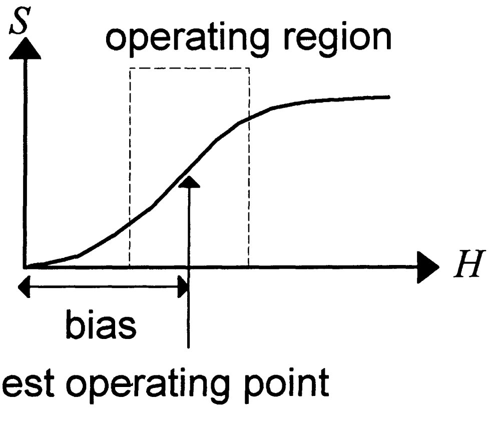

FIG. 15. Permanent-magnet bias used to pick a linear operating region.

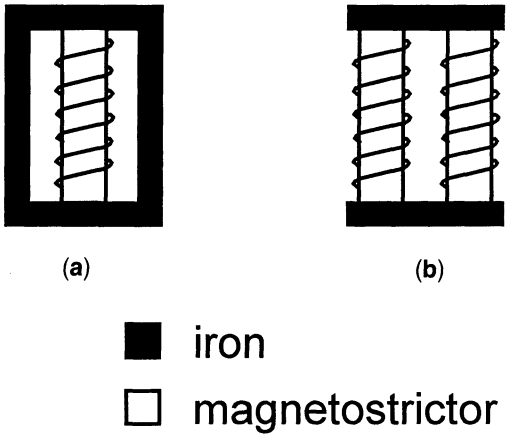

FIG. 16. Typical high-power actuator configurations; (a) single-legged design and (b) double-legged design.

3.2.3 Deformable Mirrors A deformable mirror is one whose shape is changed by a group of actuators. There are several reasons for doing this. Large mirrors (such as those used in astronomy) must be very thick in order to maintain their shape against gravitational and mounting forces. A deformable mirror can be made much thinner and use the actuators in concert with a real-time control system to maintain the correct figure. Another use is to warp the mirror actively to correct for atmospheric turbulence. The same high-force, low-frequency response that makes magnetostrictive actuators useful for vibration control makes them attractive for use in deformable mirrors. One problem that must be considered in this application is that of removing the heat generated by the driving coils, since the actuators would be placed fairly close together.

3.2.4 Magnetostrictive/Piezoelectric Combinations Sonar transducers using magnetostrictive and piezoelectric elements have been built (Butler *et al.*, 1990) (see Fig. 17). Since magnetostrictive elements present an inductive load to the driving amplifier and piezoelectric elements present a capacitive load to the driver, at resonance, the driver sees a purely resistive load. This greatly simplifies amplifier design. The motion of the two

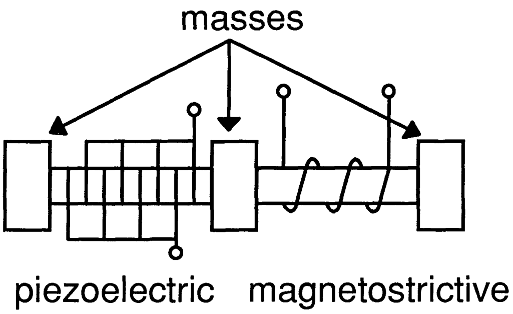

FIG. 17. Piezoelectric/magnetostrictive sonar transmitter.

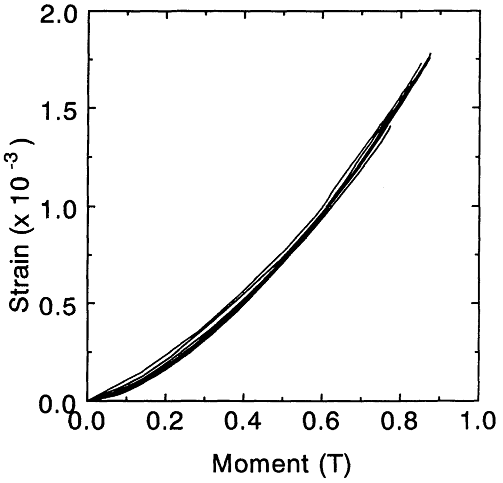

FIG. 18. Moment vs strain for a Terfenol-D rod at various prestresses.

elements is 90° out of phase, and by proper operation, the transmitter in Fig. 17 produces output with a front-to-back ratio of 10 dB.

3.2.5 Geological Tomography Terfenol-D sound sources are used in geological tomography and other oil-well logging applications. An actuator is lowered into the well with one end clamped to the well casing and the other attached to a mass. The resulting shaking induces seismic waves; sensors in the same or other wells are used to study the surrounding geology.

3.2.6 Potential Applications

3.2.6.1 Driven-Tooth Bone-Conduction Hearing Aid Bone-conduction hearing aids can be used by some people with hearing ailments, because the sound travels around the damaged part of the ear. Since the teeth are solidly connected to the jaw bone, exciting the teeth at an audio frequency provides another method of injecting audio signals directly into the inner ear. Magnetostrictive drivers for exciting teeth using a tiny rod as the active element have been built. Magnetostrictive devices are ideal for an "in-mouth" location, because their low impedance allows voltage throughout the hearing aid to be kept low.

3.2.6.2 Smart (Self-Sensing) Actuators The intrinsic magnetization M and the strain in a magnetostrictive material are closely related and almost completely independent of the hysteresis and applied stress. Figure 18 shows a curve of magnetization vs strain for a Terfenol-D rod for several different applied stresses from 5.5 to 40 MPa. This simple relationship allows a measurement of M to be converted into a length; i.e., the rod is "self-sensing." Self-sensing actuators allow a reduced parts count in the device.

3.2.6.3 Magnetostrictive Motors There are two main areas where magnetostrictive motors look promising: linear motion and rotary motion. Since the length change of a 6-cm Terfenol-D rod is on the order of 0.1 mm, direct coupling between the object and magnetostrictive rod is not useful. Instead, the motors are "inch worm" designs, whereby many individual rod movements can be added together to obtain the desired motion. Some designs use multiple sets of magnetostrictive elements, with some of the elements clamping and unclamping the load shaft and other elements moving the shaft. If the clamping and pushing motions are sequenced properly, useful motion can be achieved. A magnetostrictive rotary motor has achieved a torque of 12 N m with 800-μrad steps (Vranish *et al.*, 1991).

An unusual type of linear motor, which utilizes the fact that Joule magnetostriction in Terfenol-D is a constant-volume process, is the Kiesewetter motor. The constant-volume constraint means that the diameter of a magnetostrictive rod decreases slightly when the rod lengthens. In the Kiesewetter motor, a Terfenol rod is placed inside a tube. The diameter of the rod is chosen so that it just fits inside the tube when the rod is extended by an applied magnetic field. When the field is removed, the rod's diameter expands and clamps the rod in place. The rod is moved back and forth by moving a magnetic field along the length of the rod. Where the field is applied, the rod shrinks and lengthens. Figure 19 shows the first step of the process. A version of the motor which has been reported (Roth, 1992) has a useful travel of 200 mm and a speed of 20 mm/s. It also has the advantage of holding its position when no field is applied. The reference also contains a more complete description of the motor's operation.

3.3 Other Applications

The applications in this section do not fit neatly into either the sensor or actuator category and cover a variety of topics, such as variable delay lines and passive damping.

3.3.1 Variable Delay Line The modulus of a magnetostrictive material, and hence the speed of sound, vary with applied magnetic field. If a piece of magnetostrictive material has a transmitter on one end and a receiver on the other end, the transit time can be varied by varying a magnetic field (Hongu, 1979). Simple coils can be used for both the transmitter and the receiver (Fig. 20). A permanent-magnet bias is required to prevent frequency doubling by the magnetostrictive material.

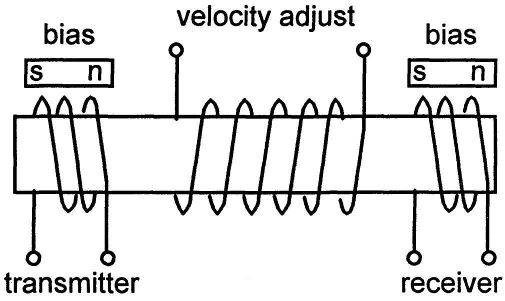

FIG. 20. Variable delay line. The magnetic field varies the modulus and hence the sound speed in the rod.

3.3.2 Passive Damping When a vibratory stress is applied to a magnetostrictive material, the magnetic state of the material constantly varies. An energy loss occurs because of the magnetic hysteresis caused by irreversible domain wall motion. Several alloys have been designed to maximize the hysteresis loss and are used to provide passive damping. One of these alloys is Nivco-10 ($Co_{0.72}Ni_{0.22}Ti_{0.02}Al_{0.005}$). The damping properties of this material are independent of frequency over most of the normal range of engineering concern and increase linearly with applied stress up to 120 MPa, where the ratio of the damping energy to total strain energy is about 0.5 (Goodman, 1988). Because the damping is a magnetic effect, it disappears above the Curie temperature or when the alloy is placed in a saturating magnetic field.

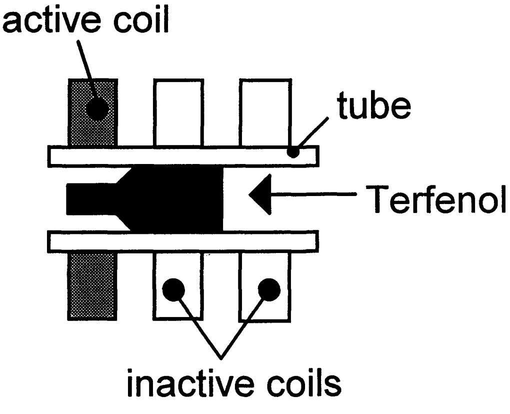

FIG. 19. Kiesewetter motor in the first stage of operation.

3.3.3 Current Threshold Sensors Garshelis (1979) describes a current threshold sensor (Fig. 21) for ac current. The device uses helical anisotropy in a magnetostrictive cylinder as the sensing principle. Below the current threshold, the magnetic moment makes only small variations. When the current exceeds the threshold, the magnetostrictive energy exceeds the anisotropy energy and a large shift in the magnetization occurs. The amount of helical anisotropy, and thus the current threshold, can be varied by altering the twist on the cylinder.

3.3.4 Record/Playback Heads A record/playback head which uses an acoustic wave in a substrate to alter the magnetic properties in an overlying magnetostrictive film has been designed for use with magnetic tape (Ballinger *et al.*, 1986). The head is aligned parallel to the width of the tape. An acoustic wave launched in the substrate generates a magnetically active region in the

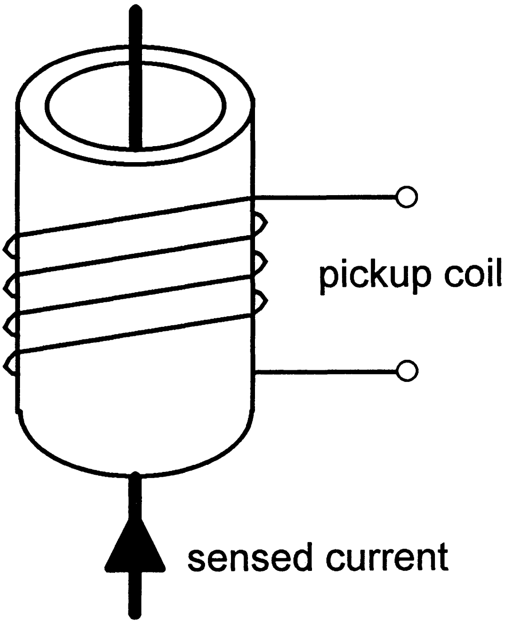

FIG. 21. Current threshold sensor. At currents above the threshold, the magnetization reverses abruptly, generating a large signal in the pickup coil.

magnetostrictive film. A pulse in an adjacent conductor generates a magnetic signal on the tape. This allows a single head to produce many channels across the width of the tape.

3.3.5 Vibratory Stress Relief It is not clear whether or not to call vibratory stress relief an "application" of magnetostrictive materials. Machine tools, such as drills, tool bits, etc., that are constructed of magnetostrictive materials (this includes carbides and steels, among others) are placed in a strong ac field generated at power line frequencies. This induces magnetostrictive vibrations in the material, which in turn relieve internal strains. Tool life extensions of 20–200% are claimed (*Tooling & Accessories*, 1987).

GLOSSARY

Actuator: a device that converts electrical (magnetic) energy to mechanical energy.

Curie Temperature: The temperature above which the thermal energy overwhelms the magnetic energy and the material loses all its ferromagnetic properties.

Domain: a small region in a material where all the atomic moments point in the same direction. A normal material is made up of many small domains. If the material is unmagnetized the domains point in random directions; if magnetized, they point in the same direction.

Magnetization: the sum of all of the atomic moments per unit volume pointing in the measurement direction.

Sensor: a device which converts mechanical energy to electrical (magnetic) energy.

INTRODUCTION

Magnetic minerals (lodestone) were discovered in ancient Greece in the region of Magnesia; by tradition, this is ascribed to Thales of Miletus (Asimov, 1982). Magnets have been surrounded by mystery ever since, because they represent an action at distance that can be directly felt. The use of the compass is documented in China as early as 121 A.D. (on land only). In the West, Peregrinus (born 1240) is credited with giving it the form with the pivot and the rose (compass card) that made it a practical instrument for navigation. This had far-reaching consequences, as it opened the oceans for exploration. Around 1600, Gilbert demonstrated with experiments on a model that the Earth is a spherical magnet. Shortly after the discovery by Oersted in 1819 that an electric current generates a magnetic field, Ampère invented the solenoid electromagnet and guessed correctly that all magnetism is due to circulating electric currents. Sturgeon combined the solenoid with a soft iron core to create the first laboratory electromagnet, whose field was much stronger than that of all permanent magnets known at the time. This gave rise to the development that culminated in the huge electromagnet of the French Académie des Sciences at Bellevue near Paris (in a way, the first "national magnet laboratory") with a total weight exceeding 100 tons. More importantly, iron-core electromagnets have spawned the huge electrical industry by providing the basis for the development of efficient motors and generators.

The foremost pioneer of magnet design in recent times was Bitter (Erber and Fowler, 1969). He designed magnets with high homogeneity as well as a most efficient iron-core magnet; in 1936, he designed and built high-power water-cooled magnets as they are still used today in the big national magnet laboratories. A review of the historical development and of the design principles of these magnets is given by de Klerk (1965).

After the discovery of superconductivity by Kamerlingh Onnes in 1911, it took more than

digital Encyclopedia of Applied Physics

four decades until Matthias discovered type II superconductivity (which is not destroyed by a moderate magnetic field) in niobium-tin that made it possible to build usable superconducting magnets. These magnets can now compete with all but the most powerful water-cooled magnets, and they have been used in conjunction with such magnets to generate the highest continuous magnetic fields in so-called "hybrid" magnets. Still higher fields up into the megagauss range have been generated by pulsed magnets, pioneered by Kapitza (ter Haar, 1964) in the late 1920s. Fields in excess of 100 T can only be generated for very short time intervals (0.1–10 μs) at the expense of a violent destruction of the coil.

Permanent magnets are most suitable for practical applications. Their widespread use was long hampered by their bulk and relatively low field. This has been drastically changed by recent developments in materials technology, which provided a variety of permanent magnets with exceptional properties. Among others, these have made possible the miniaturization of high-performance electric motors, which are now widely used in many technical appliances.

Many aspects of magnet design are discussed in the series of International Conferences on Magnet Technology that was inspired by the extensive use of sophisticated magnets in particle accelerators (e.g., Dawson, 1992). The range of fields obtained with different types of magnet is shown in Fig. 1.

1. ELECTROMAGNETS

1.1 Magnets with Iron Cores

By analogy to an electric circuit where the "electromotive force" $\oint \mathbf{E}\cdot d\mathbf{l}$ drives electrical current through resistors, an iron-core electromagnet can be described as a magnetic circuit where the "magnetomotive force" $\oint \mathbf{H}\cdot d\mathbf{l}$ drives magnetic flux $\Phi = \int \mathbf{B}\cdot d\mathbf{S}$ through materials with different permeabilities μ:

$$I = \oint \mathbf{H}\cdot d\mathbf{l} = \Phi \sum\left(\frac{l}{\mu\mu_0 S}\right) = R\Phi. \tag{1}$$

Here, I (NI in case of a solenoid with N turns) is the total current passing through a surface bounded by the integration path, $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) = \mu\mu_0\mathbf{H}$ is the magnetic induction, $\mathbf{M}$ is the magnetization, and l is the length of each segment with relative permeability μ and cross section S; R is called the (total) magnetic reluctance. Another important concept is the demagnetizing field and associated demagnetizing factor. This is best illustrated with the example of a toroidal ring of magnetic material with permeability μ, total circumference c, and an air gap d, encircled by a total current of NI ampere-turns. The magnetic field in the gap is then given by

$$H = \frac{NI}{(\mu - 1)d + c}; \tag{2}$$

i.e., the integration path in Ampère's law is increased by the amount $(\mu - 1)d$, which results in a substantial decrease of the field. This can formally be represented by a "demagnetizing field" $H_d = (d/c)M$, which is opposed to the applied field; d/c is called the demagnetizing factor and can be calculated for symmetrical shapes of the magnetic ma-

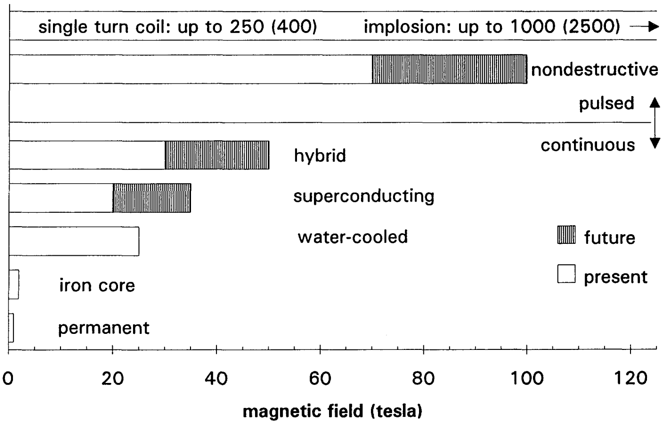

FIG. 1. State of the art and perspectives of generating strong magnetic fields. Estimates for the future are, of course, speculative (and optimistic).

terial such as a sphere where it is equal to $\frac{1}{3}$. Of course this simple type of calculation can only give rough (but useful) estimates, because the $M(H)$ relation is highly nonlinear in a ferromagnet.

From Eqs. (1) and (2), the design of iron-core electromagnets appears fairly straightforward; however, unexpected effects occur due to the strong nonlinearity in the $B(H)$ relation. Magnet performance is drastically reduced when the magnetization is driven into saturation in some part of the magnetic circuit (de Klerk, 1965).

Apart from their general use in motors and generators, iron-core magnets are still widely used in technical applications, e.g., for lifting weights and in actuators and relays, although the latter are now mostly replaced by semiconductor switching devices. In scientific research, iron-core magnets are gradually being phased out in favor of superconducting magnets. A large-scale application is in high-energy particle accelerators, where flexibility in shaping the magnetic field for focusing and beam transport is required. Now there is a trend toward superconducting magnets for these applications as well.

1.2 Solenoid Magnets

1.2.1 Water-Cooled High-Power Magnets

The need for high magnetic fields for research purposes has led to the establishment of several dedicated high–magnetic-field facilities worldwide. In these institutions, continuous (i.e., dc) fields in the range 10–25 T are routinely generated. The basic tool is the water-cooled electromagnet and large dc power supplies of several MW rating which can be either rotary machines, as at Clarendon Laboratory, Oxford University, Oxford, United Kingdom, Francis Bitter National Magnet Laboratory, Cambridge, Massachusetts, U.S.A., and International Laboratory of High Magnetic Fields and Low Temperatures, Wroclaw, Poland, or transformer–rectifier sets used elsewhere. Details of most of the world's facilities can be found in Herlach and Franse (1989), with an update in Miura (1994).

As iron-cored magnets become intolerably large for fields of only a few tesla, it becomes more efficient to dispense with the iron altogether and use air-cored copper-wound solenoids. This is, however, at the expense of power P. The field in an air-cored solenoid is given by

$$B_{\max} = \mu_0 G(\alpha,\beta)(P\lambda/\rho a_1)^{1/2}. \tag{3}$$

Here, $G(\alpha,\beta)$ is the Fabry function, which depends on the current density distribution $j(r,z)$ in the solenoid, where r is the radius and z is the axial displacement from the centroid of the solenoid. The parameters are $\alpha = a_2/a_1$ (outer/inner radius), $\beta = b/a_1$ (b = half length), and λ = packing factor (conductor volume/total volume). Different distributions $j(r, z)$ are described along with their relevant functions $G(\alpha,\beta)$ and values in Montgomery (1969) for each type. One of the most efficient, practical designs is that pioneered by Bitter (Erber and Fowler, 1969) in the early 1930s. The magnet (Fig. 2) consists of a stack of annular copper plates, each of which has a radial split, resulting in a $j \propto 1/r$ distribution. Series electrical connections between plates are made by pressure contact between two sectors adjacent to the split. The remaining area is insulated by insertion of a suitable material, such as polyimide film. Bitter magnets are the most commonly used in the major magnet installations. A more recent development is the polyhelix design. First proposed by Wood and developed by Carden, by Hudson and Jones, and by Schneider-Muntau, this construction comprises a set of single-layer helical windings nested coaxially and joined electrically in series/parallel groups [see references in Herlach and Franse, (1989) and in the Magnet Technology conferences]. This allows the current density to be tailored in any of the layers by adjusting the conductor cross section. Above about 20 T, the problem of electromagnetic forces is such that copper alone is not strong enough. One way to overcome this is to adjust cross section such that the hoop stress given by

$$\sigma = B(r)\,jr \tag{4}$$

nowhere exceeds the proof stress of copper.

Because of the massive power dissipation in these solenoids (of order 10 MW or more), they have to be actively cooled. A cooling fluid has to be pumped through the windings, and therefore, cooling channels have to be incorporated in the structure of the magnet. This has an impact on the space factor λ. Ideally,

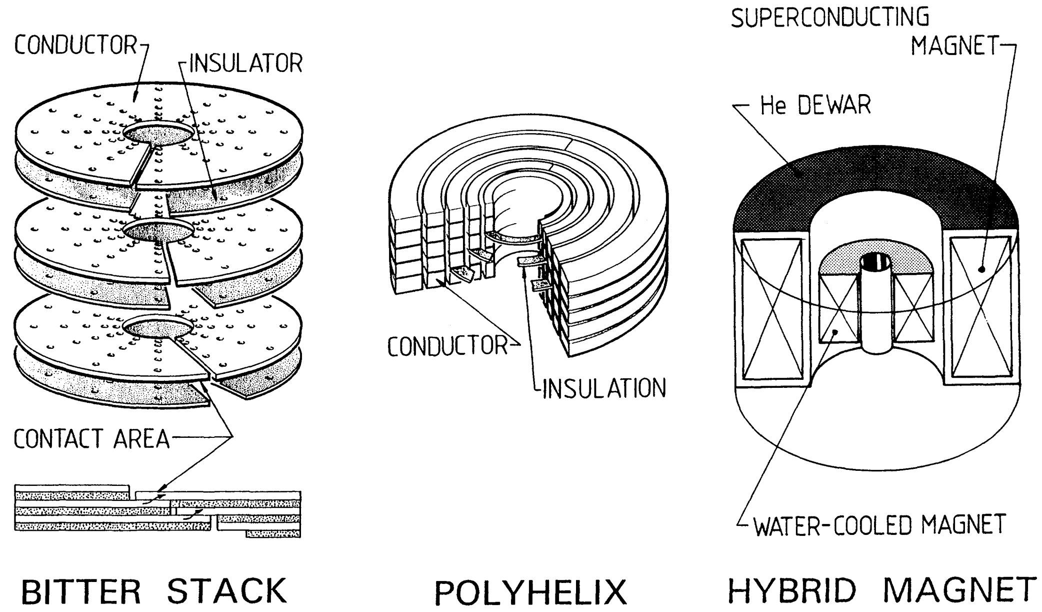

FIG. 2. Schematic drawings of the different types of water-cooled high-power magnets. For the Bitter magnet, only the plates with holes for the coolant are shown. Alternating copper and insulation, these are clamped together axially in a stack to form a solid spiral.

the cooling channels need to sustain high-velocity turbulent flow, and in practice, this is achieved by distributing many narrow channels throughout the winding. This is relatively easy to achieve in polyhelix magnets by separating layers with spacers through which the coolant can flow axially. In the case of Bitter magnets, cooling is achieved by punching a precise array of holes in each plate and insulator and aligning them very carefully in the stack to give continuous axial cooling channels, although there is a variant in which channels are etched in the faces of the plates to allow radial cooling. Water is by far the best coolant, but as the presence of electrical insulation on the cooled surface of the windings would severely impair heat transfer, the water must have very low conductivity and hence be deionized. Deionized water is adequate for the low-voltage (500 V or less), high-current (of order 10 kA) systems installed in most magnet laboratories. Flow rates need to be very high, perhaps several hundred $m^3\ h^{-1}$, so that large pressure drops result, and therefore substantial pumps are required. A typical cooling system then consists of a closed circuit of reservoir, pumps, pipework, magnet, water cooler, and deionizer. Coolers for the water differ from system to system but may, for example, comprise a heat exchanger with a secondary water circuit which dumps the heat into a nearby river as at the French-German "Hochfeld-Magnetlabor" at Grenoble (run by CNRS and the Max Planck Institute), and the Francis Bitter Laboratory, or use a forced-draft air cooler as at Oxford. Some systems incorporate a refrigeration unit as at Katholieke Universiteit, Nijmegen, The Netherlands, and at the new U.S. National High Magnetic Field Laboratory (Tallahassee, Florida). The thermal capacity of the reservoir can be used to some extent, but this places an upper limit on the time for sustained running at high power, especially in hot weather. All systems require an on-site deionizer to keep the water conductivity sufficiently low.

1.2.2 Superconducting Magnets Superconducting magnets are now very common, especially in research laboratories, and are an everyday tool for many experiments. Although there is a significant industrial effort worldwide in the manufacture of superconductors and superconducting magnets, industrial applications of these magnets, with the possible exception of nuclear magnetic resonance (NMR) spectroscopy, are developing rather slowly. This is largely because although modern magnets and their associated cryogenics are relatively reliable, they do require some specialist knowledge and resources, e.g., liquid helium, to operate at a high utilization rate and economically. In the world of medicine, however, magnetic resonance imaging (MRI) is becoming a routine tool for noninvasive diagnosis, sustained by a sizable industry. Great advances have been made here using superconducting magnets as an economic and practical means to generate fields over the large volumes necessary to accommodate the human body.

Conductors that are stable against magnetothermal disturbances have been available commercially for winding superconducting magnets operating in liquid helium for several decades. They consist of fine (≈ 10 μm) filaments of type II superconductor embedded in a copper, or copper-bearing, matrix. In practice, only two materials, NbTi and Nb_3Sn, are routinely available. The former is a ductile alloy that is easily coprocessed with copper and is therefore relatively inexpensive. Its limitation is that its upper critical field B_{c2} is of order 10 T, and thus it is only suitable for lower field applications. Nb_3Sn is a more complex, brittle intermetallic compound and is normally formed into wire by codrawing Nb filaments and a Sn-bearing copper matrix, for example, the "bronze route." The Nb_3Sn is formed by promoting solid diffusion of the Sn into the Nb by heat treating the composite to a temperature of order 700°C for a period of time. Often this heat treatment is applied after the solenoid has been wound, i.e., the "wind and react" method. This is because excess mechanical strain severely degrades the superconducting properties of the material and strains introduced in the winding process can be high. The advantage of Nb_3Sn is its high B_{c2}, and it can be used in magnets operating a little in excess of 20 T below the lambda point of liquid helium (2.2 K). An essential feature of practical superconductors is good flux-pinning properties. Flux-pinning centers prevent the dissipative movement of flux due to the Lorentz force resulting from the interaction of magnetic field and the transport current. In NbTi, these centers are mainly precipitates that form during a final anneal at the sites of defects introduced by the cold work of wire drawing, and in Nb_3Sn, these are the grain boundaries.

The field produced at the centroid of a superconducting solenoid is given by

$$B_0 = \mu_0 F(\alpha, \beta)\, j \lambda a_1, \tag{5}$$

where j is the current density. $F(\alpha,\beta)$ is a geometry function that depends on the shape of the coil. Before selecting his parameters, such as current and shape of the coil, the designer must have knowledge of the performance of the conductor he proposes to use. This is normally in the form of a curve that shows the critical current (the current at which the superconductor becomes normal) against magnetic field as measured on an approximately 1-m length of superconductor and is known as the "short sample curve." Thus, having determined the load line (tesla/A), the maximum possible current and field (i.e., where the load line intersects the critical current) can be seen. In fact, it is not the centroid field that is important here but the value of the peak field which, for a simple solenoid, is at the inner radius on the midplane. For some geometries, typically short fat coils, the ratio of peak field to centroid field can be high (up to 2), and so this must be taken into account. As the field falls off approximately linearly with radius, it is possible to grade the conductor, i.e., increase current density by decreasing conductor size. This can be done by nesting several concentric windings of different size wires that change at the appropriate $B(r)$ value. Also, conductor material can be changed at the appropriate point, and so a typical high-field magnet will have Nb_3Sn inner sections and NbTi windings on the outside.

Potentially a superconducting magnet can suffer from several magneto/mechanical-thermal instabilities. One such is flux jumping. This is eliminated by the fine subdivision of filaments in the copper matrix described above. In the liquid-helium temperature regime, specific heat capacities of materials are very low, so that even the slightest mechanical movement (e.g., of a single loose turn) can result in a temperature rise that exceeds the critical temperature of the superconductor; hence, a "quench" (the whole magnet going normal) can be initiated. Mechanical movement is inhibited by impregnating the winding with a medium, such as epoxy resin or wax. Impregnation itself can be the cause of the problem of training, whereby the strains created by differential contraction when the magnet is first cooled down to 4.2 K get released with the concomitant generation of heat, causing a quench at progressively higher fields until the design field is reached. When a superconducting magnet quenches, the magnetic energy is converted into heat in the windings, and considerable quantities of liquid helium are rapidly boiled off from the cryostat that contains the magnet. Energies stored are typically a few kJ for small magnets but can be many MJ for large windings such as those used, e.g., for high-energy particle detectors and hybrid magnets. Studies are under way for storing electrical energy in large toroidal windings as a buffer reservoir for utilities.

During a quench, high voltages can be developed within the windings. Protection circuitry, consisting of diodes and resistors, is arranged in parallel to the subdivided sections of the magnet so that the energy is dissipated outside the magnet and voltages are limited. One feature of superconducting magnets is that they can be operated in persistent mode using a superconducting switch. This consists of a length of superconducting wire with a high-resistivity matrix, such as CuNi, connected across the terminals. This link can be driven normal with a heater while the magnet is being energized, and at the desired field, the heater is turned off. The power supply can then be dispensed with, as the current is flowing in the windings and the link persistently. This is particularly useful in NMR magnets where very high temporal stability is required.

There are possibilities that superconducting magnets may soon be built for fields well in excess of 20 T. The Chevrel-phase materials, such as $PbMo_6S_8$, have very high B_{c2}'s (up to 60 T) so that, in principle, they could be used for very high-field magnets. So far, attempts to produce practical conductors with sufficient current densities have failed, but work is still going on at several research centers. Probably more promising are the so-called high-temperature superconductors (HTS). Discovered by Bednorz and Müller in 1986, these are superconducting oxides with high critical temperatures (T_c), such as YBaCuO ($T_c \approx 90$ K), BiSrCaCuO ($T_c \approx 105$ K), and TlBaCaCuO ($T_c \approx 125$ K). All of these are superconducting in liquid N_2 (77 K). However, at liquid helium temperatures, these materials have B_{c2}'s of order 100 T and so they could feature in very high-field magnets. It will be some time before long lengths of practical high–current-density conductors will be available, but many programs of work are in train worldwide and results so far are encouraging. At higher temperatures, there is some doubt whether these materials can exhibit the necessary flux-pinning strengths for high-field applications, but for low-field work, such as power transmission and perhaps some NMR magnet systems, superconductivity in liquid N_2 is a very real prospect.

For an extensive treatment of superconducting magnets, see Wilson (1983); for high-temperature superconductors, see Bednorz and Müller (1990).

1.2.3 Hybrid Magnets The highest continuous fields available in the world today are generated using hybrid magnets. Hybrid refers to a system in which a superconducting magnet surrounds a high-power, water-cooled solenoid. The principle is simple and was first proposed by Wood and Montgomery who remarked that, as the field strength of superconducting magnets was intrinsically limited, they could be used in the outer, low-field region of an arrangement whereby the field of a conventional resistive magnet was supplemented by the superconducting section. In practice, the engineering problems are profound. First, the superconducting section has to have a room-temperature bore of up to 500 mm; therefore, necessarily, the superconducting magnet must be very big and its cryostat relatively complicated. The associated cryogenics are very large scale, and often a dedicated helium liquefier is needed. The inner, resistive section has to be compact in order to minimize the bore of the superconducting section, yet at the same time, it must be robustly engineered, as the forces on the windings are severe. Another problem is that the magnetic centers of the two magnets must be accurately aligned or a large (mostly axial) force would displace the inner magnet; in the case of asymmetric failure, this force has to be catered for. The polyhelix design is well suited to hybrid magnets as, in the case of asymmetric failure, the out-of-balance force is restricted to one layer of windings, but Bitter magnets are used or combinations of both.

Inevitably, hybrids are expensive installations and are operated in only a few centers. The first operating hybrid was at Oxford and gave 20 T. At the Francis Bitter National Magnet Laboratory, Grenoble Hochfeld-Magnetlabor, Magnetenlaboratorium at Katholieke Universiteit Nijmegen, and Tohoku University, Japan, there are hybrids generating at least 30 T. At the National Research Institute for Metals, Tsukuba, Japan, a 40-T system is under construction, and at the U.S. National High Magnetic Field Laboratory, a 45-T magnet is planned.

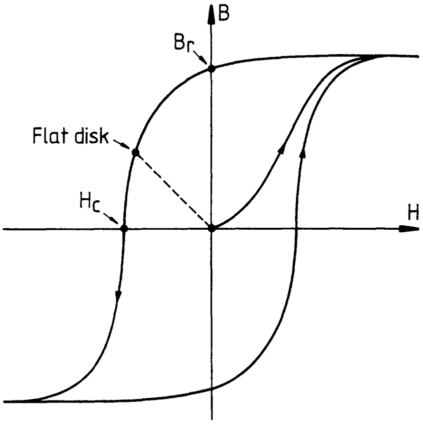

FIG. 3. Schematic of a magnetic hysteresis loop. The surface inside the loop is the energy transformed into heat in one cycle. Also shown are the "virgin" curve of the first magnetization and the line $M = -H$ related to the demagnetizing field in a thin sheet. For a ferromagnet, the values of B and $\mu_0 M$ are nearly identical.

2. PERMANENT MAGNETS

A permanent magnet (Parker, 1990) is an artifact made from a material that can be permanently magnetized when exposed to a magnetic field. The useful field from a permanent magnet can only be accessed outside the material, and therefore, a typical applications magnet comprises a shape such as a ring with an air gap. The field in the air gap can be approximated by

$$\mu_0 H_a^2 = H_c B_r V_m / V_a, \tag{6}$$

where H_c is the coercive field needed to reduce the magnetization of the material to zero, B_r is the remanent magnetic induction (see Fig. 3), V_m is the volume of the magnetic material, and V_a is the volume of the air gap. This argument applies strictly for a rectangular hysteresis loop, but for a real loop with rounded corners, it is the maximum value of the product $H \times B$ that enters on the right-hand side of Eq. (6). This is known as the energy product and is a figure of merit for permanent-magnet materials (Table 1). Between 1880 and 1990, the energy product has increased exponentially from 2 to 400 kJ/m^3 as new materials were developed. In the last 10 years, progress has been such that permanent magnets are now a \$10^9/a industry.

There are basically five families of materials; they are, in order of increasing merit, steels, Alnico, ferrites, samarium-cobalt alloys, and the rare earth-iron-boron compounds. A promising new class of materials now under development comes from the intermetallic nitrides (Wallace and Huang, 1992).

The energy product is a general measure for the magnetic field that can be sustained outside the magnet. For a specific magnet geometry, the outside field is related to the demagnetizing factor. This is the same as discussed with the example of an electromagnet in the shape of a ring with an air gap [Eq. (2)]. Instead of an outer winding carrying current, the permanent magnetization is now sustaining the magnetic field. The demagnetizing factor can be calculated exactly

Table 1. Range of basic data for different classes of permanent magnets.

Material	B_r (T)	H_c (A/m)	$BH_{\max}$ (kJ/m^3)
Steel (3% Cr)	0.98	4	1.8
Steel (35% Co)	0.9	20	7.5
Alnico	0.71	44	14
	1.24	50	44
	1.06	120	73
ferrites	0.23	145	8.4
	0.34	275	22
	0.41	225	32
RE-Co alloys[a]	0.75	560	110
	0.95	720	175
RE-TM-B alloys[a]	1.02	730	190
	1.15	875	240
	1.2	835	280

---

[a] RE represents a rare earth, and TM a transition metal. In most commercial materials, mixtures of different elements are used.

only for a few simple geometries; this is 0 for a long thin needle, $\frac{1}{3}$ for a sphere, and 1 for a thin flat plate. The last case is illustrated in Fig. 3, where a line with slope 1 corresponding to the relation $M = -H$ for a flat disk is drawn to intersect with the hysteresis loop. For a long needle, the corresponding line is the M axis, and for a sphere, it is the line $M = -3H$.

A great step forward in permanent magnet technology was the development of materials that retain their permanence over a long time scale and in the presence of mechanical shock and variations of external fields. This is of great importance for practical applications. The permanence of a magnet is characterized by the coercive field. This depends on several factors and mechanisms. To minimize the total energy, a magnetic material subdivides into domains with random orientations of the magnetization (called Weiss domains). The size of the domains, in the range 10^{-6}–10^{-2} cm^3, is determined by the ratio between the energy in the magnetic field and the energy in the domain walls. If the material is subjected to an external magnetic field, the domain walls are moved to increase the size of those domains with the magnetization oriented parallel to the applied field. The energy needed to move the domain walls results in magnetic hysteresis (Fig. 3). Usually, the magnetization changes in discrete steps, called Barkhausen jumps. A large coercive field is obtained by introducing obstacles (e.g., lattice faults) that impede the movement of the domain walls. Another factor that enhances the coercive field is anisotropy, which results in a favorable direction of the magnetization. This is mainly due to the crystal structure (including the crystalline electric field, spin-orbit interactions, etc.), but it can be enhanced by the shape of the magnet. Anisotropy is most pronounced for ceramic magnetic materials that consist of an agglomeration of many small particles. The ideal situation is given by needle-shaped particles in which the easy direction of the magnetization is parallel to the needles and with the needles oriented in the direction of the global magnetization. Another effect that can result in a strong coercive field is the single-domain particle. Below a certain size of a magnetic particle ($\approx$10 nm for Fe up to 1 μm for some other materials), it is energetically favorable to be homogeneously magnetized in a single domain. An interesting example of this is given by so-called "magnetotactic" bacteria, which synthesize a string of magnetic particles sized just below this critical limit. The particles thus get spontaneously magnetized and serve as simple direct means of guidance for the bacterium by orienting it along the lines of the earth's magnetic field. A propulsion mechanism (flagellum) at one end of the bacterium then propels it along the field lines (Maret and Dransfeld, 1985).

The practical realization of magnetic materials with the desired properties is still largely an empirical process for which the theoretical arguments can only provide a rough guidance. Research and technology are in rapid development, and the latest results are extensively covered by the annual conferences on Magnetism and Magnetic Materials (e.g., Yelon *et al.*, 1993) and INTERMAG (e.g., Lord, 1992).

2.1 Applications

The dramatic improvement of permanent-magnet materials has resulted in a surge of practical applications. Following Parker (1990), these can be classified in four major areas depending on the physical principles involved.

2.1.1 Direct Use of the Magnetic Force

The simplest of these and probably the earliest application is the compass. Attraction/repulsion of the poles of a magnetized needle interacting with the Earth's magnetic field creates a torque that aligns the needle north-south, and this is the basis of the fundamental navigation aid. Other applications related to the compass are polarity indicators and devices that detect ferromagnetic objects.

There are a variety of applications that exploit mechanical force, ranging from simple novelties to major industrial uses such as magnetic clutches. Unlike the electromagnet, a permanent magnet cannot be simply turned on and off. Modification of the magnetic field is achieved by the movement of ferromagnetic plates with appropriate slits that either short-circuit the magnetic flux or guide it to the intended destination. A well-known example is the magnetic clamp used to fix objects to a steel table, which can be released by the easy turn of a lever.

Mechanical force applications depend on whether a simple holding operation is required, i.e., the magnetic device is in contact with a ferromagnetic material on which it is exerting a force, or whether the force is exerted over a distance. In the latter case, the design of the magnet depends on whether the pull is to be maximum at a large distance, and the design is adjusted accordingly. In some applications, a compromise between the two is required. A notable example is in the case of magnetic drum separators where sufficient force is required to be imparted to a ferromagnetic particle so that it is translated over a distance but at the same time a strong holding force is required to make the particle stick to the drum. A related application is the magnetic conveyor belt. Frictionless bearings for small loads can be realized with permanent magnets as well.

2.1.2 Applications Based on Faraday's Law Permanent magnets are widely used to convert electrical into mechanical energy or vice versa. One of the earliest applications was the dc dynamo, which can be used as a generator or a motor. Alternators, in which permanent magnets on the rotor induce a sinewave voltage on the stator windings, are an important applications area. Generally, permanent magnets are used for small motors and generators, while the large machines incorporate electromagnets. However, with the development of permanent-magnet materials such as $SmCo_5$ and NdFeB, use of permanent magnets for the excitation of large alternators is attractive in some applications where high power density is important; permanent magnets can be superior to wound excitation in these cases. The dynamic microphone employs permanent magnets in the field of which a coil moves as a result of the pressure of sound.

Eddy-current devices are a special case of Faraday's-law applications. In these, induced voltages in a conducting element sustain eddy currents that interact with the field of permanent magnets and thus give rise to a mechanical force. This principle is used in torque transmission equipment and damping devices. A common application is the tachometer, where a permanent magnet rotates in front of a conducting disc. The interaction with eddy currents induced in the plate results in a drag that is proportional to the velocity; this can be measured by the torque exerted on the disc.

2.1.3 Lorentz Forces on Electrical Currents This category is based on the principle that is the most basic in converting electrical energy to mechanical energy. It relies on the interaction of current and magnetic flux and is essentially applied in electric motors, although one of the earliest applications of the effect is in loudspeakers. Basically there are four families of electric motors: dc, ac, hybrid, and linear, although subdivisions of these have led to at least 50 different types. In principle, all of these can employ permanent magnets in either the stator or the rotor. The present-day choice of permanent magnetic materials with greatly enhanced properties allows improved motor design in all areas, especially miniaturization. Examples are the very tiny motors used in cameras and clocks.

For linear devices, a modern volume application is in linear force devices in computer peripherals, e.g., printers and disc drives. The high volumetric efficiency of permanent magnets has made a major contribution to the reduction of size, response time, and thermal losses. The increase of digital electronics has led to considerable use of the stepper motor, which is a discrete positioning device (see MACHINES, ELECTRICAL). It uses the field of a permanent-magnet rotor that interacts with the stator poles, of which there can be a great number, and therefore very precise control can be achieved.

The familiar moving-coil or moving-magnet measuring instruments (see ELECTRICAL MEASUREMENTS) require permanent magnets with excellent long-term stability. Another use of permanent magnets in electronics is in reed relays.

2.1.4 Lorentz Forces on Free Electrons A free electron interacting with a perpendicular magnetic field will execute a circular path (cyclotron orbit) of radius

$$r = mv/eB, \tag{7}$$

where m is the mass of the electron, v is its velocity, and e is the electronic charge. This principle, which applies, of course, to other particles, is exploited in many devices and instruments such as magnetrons, traveling-wave tubes, and mass spectrometers. There are also applications of permanent magnets in particle accelerators. A good example is the "wiggler" magnet in the free-electron laser, which consists of a large number of permanent magnets arranged to generate a magnetic field that undulates periodically in space. It appears feasible to use permanent magnets even for MRI.

3. PULSED MAGNETS

3.1 Submegagauss Fields (Nondestructive)

For generating the highest possible fields, the limitations imposed by electrical power and associated cooling are overcome by using pulsed magnets. The pulse duration is proportional to the energy dissipated in the pulse; this energy is limited by the heat capacity of the coil. For copper precooled by liquid nitrogen, this is of the order 100 kJ/kg. A typical value is 50 T in a 20-mm bore for 10 ms at 200 kJ. Most pulsed-field coils are powered by a capacitor discharge (typical voltage 5–20 kV); the resulting wave form is a damped sine wave. To extend the pulse duration, a short circuit can be applied across the coil at peak field (usually by means of diodes). This is called a "crowbar"; it results in an exponential decay with the time constant of the coil. For large magnets with a controllable wave form, power from a flywheel-driven generator or from the mains is used. The peak field is determined by the mechanical strength of the coil. At 50 T, the Maxwell stress $BH/2$ is 1 GPa, which corresponds to the yield strength of a fairly strong steel. Special alloys and fiber composites have an ultimate tensile strength up to 4 GPa. For a given coil construction and materials, the limiting peak field depends on the ratio α between the outer and inner diameter; an approximate scaling law is given by

$$B = g\sqrt{2\mu_0\sigma_h}, \qquad (8)$$

where σ_h is the hoop stress. For constant current density, the geometrical factor g is

$$g = \sqrt{2}(1 - 1/\alpha), \quad \alpha \geq 2, \qquad (9)$$

and for a current distribution optimized for constant stress throughout the coil, it is

$$g = \sqrt{\ln\alpha}. \qquad (10)$$

The optimized current density peaks at the inner and outer radii and therefore results in stronger heating, which reduces the pulse duration. A good alternative is a spatial distribution of reinforcements that results in constant stress throughout the coil. As high mechanical strength and good electrical conductivity are mutually exclusive, it is necessary to develop structurally optimized coils using a combination of different materials. Recent advances in materials technology have resulted in different materials with very high mechanical strength and reasonably good conductivity (Foner, 1986), notably copper wires with microfilaments of niobium or silver. The highest field obtained so far without coil destruction is about 70 T in a 12-mm bore; it is expected to approach the 100-T limit within the next decade or two. Latest results may be found in the proceedings of the conference "Frontiers in High Magnetic Fields" (Miura, 1994); an earlier survey of pulsed field facilities is contained in Herlach and Franse (1989).

3.2 Multimegagauss Fields (Destructive)

Above 100 T, coils are inevitably blown up by the magnetic forces. The magnetic field drives a shock wave into the material; the pulse duration is given by the time interval until the expanding coil is distended so much that the field/current ratio is severely reduced. The strength of a megagauss field and the associated natural pulse duration can be directly related to the particle speed of the magnetically driven shock wave in the conductor material. For copper, this is 4.3 km/s at 1000 T and 1.7 km/s at 500 T. Different methods have been developed to supply adequate power and energy and to cope with the coil destruction. This is comprehensively covered by the series of conferences dedicated to megagauss fields; the most recent of these was held at Albuquerque in 1992 (Cowan and Spielman, 1993); for a review, see Herlach (1985).

3.2.1 Capacitor-Driven Single-Turn Coils The most simple and straightforward method is the fast capacitor discharge into a small single-turn coil. Typically, 150 T can be obtained in a volume of 1 cm^3 for a pulse duration of 2 μs with a 100-kJ capacitor discharge, and 250 T in 0.25 cm^3. The internal inductance of the capacitor bank must be of the order 10 nH, and the current is of the order 2 MA. Although the coil destruction is quite violent, the sample space inside the coil is protected by the magnetic field to the extent that even cryogenic equipment or photographic emulsions placed inside the coil will usually survive the field pulse. Typical field and current wave forms are shown in Fig. 4, and a flash x-ray photograph of an exploding coil is illustrated in Fig. 5. It is remarkable that, at peak field, the coil structure is already breaking up violently, but this is not reflected in the field and current wave forms, which are surprisingly smooth and well suited for experimentation. This leads to the assumption that the current is taken over by the plasma formed by the electrical explosion of the copper, which is visible as a bright fireball that emerges before peak field is reached. This type of magnet is well suited for solid state experiments at cryogenic temperatures.

3.2.2 Magnetic Flux Compression

Higher fields require a strong concentration of energy; at 500 T, the energy density is 100 kJ/cm^3, corresponding to a pressure of 1 Mb = 100 GPa. This can be achieved by magnetic flux compression in a high-speed implosion; the speed must be slightly larger than the particle speed in the shock wave to allow for the diffusion of the magnetic field into the conducting wall that is compressing the field. To compress magnetic flux, an initial flux is injected into a metal cylinder (by diffusion or through a slit) which is then compressed in a time interval much shorter than the L/R time constant which governs the flux diffusion out of the cylinder. Originally, high explosives were used to drive the cylinders; very regular and reproducible implosions can be achieved with precision explosives. Fields in the range 200–2000 T were obtained at several laboratories (Los Alamos, New Mexico, U.S.A.; Kurchatov, Moscow, Russia; EURATOM, Frascati, Italy; CEA, Paris, France; and Foulness, U.K.). An alternative and promising method is the electromagnetically driven implosion. While the implosion speed obtained with chemical explosives is limited by the finite speed of sound in the detonation products, there is no such fundamental limitation in an electromagnetic implosion. So far, fields well in excess of 500 T have been obtained at the Institute for Solid State Physics, University of Tokyo, using a 4-MJ capacitor bank. The pulse duration of the peak field in all implosion systems is a fraction of a microsecond. A typical current and field wave form is shown in Fig. 6.

Another method, developed at Frascati and now used for experiments at Los Alamos, is the compression of magnetic flux from a fairly simple bellows-shaped structure into a massive single-turn coil. The peak field is limited

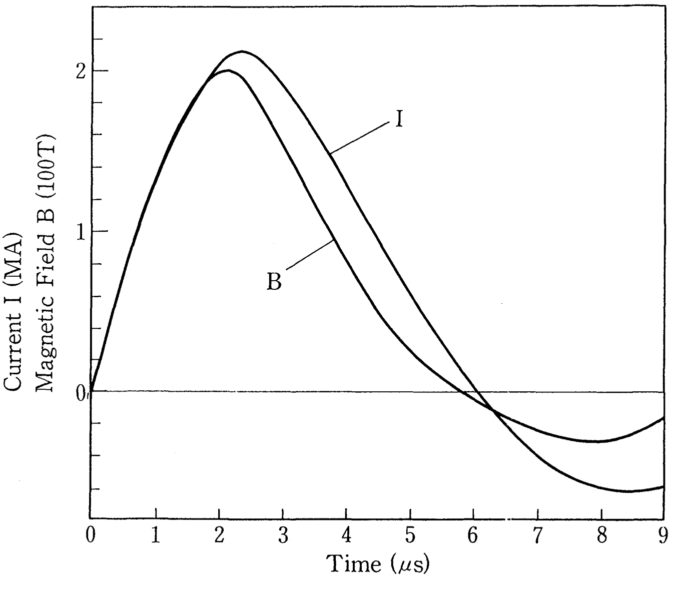

FIG. 4. Current and field wave forms from an exploding single-turn coil. The field maximum and decrease occur before those of the current, indicating the onset of expansion and destruction. The wave form is remarkably smooth and even shows the negative swing of a slightly undercritically damped *C-L-R* discharge, in spite of the violent destruction illustrated in Fig. 5. (Courtesy of N. Miura, ISSP, Tokyo.)

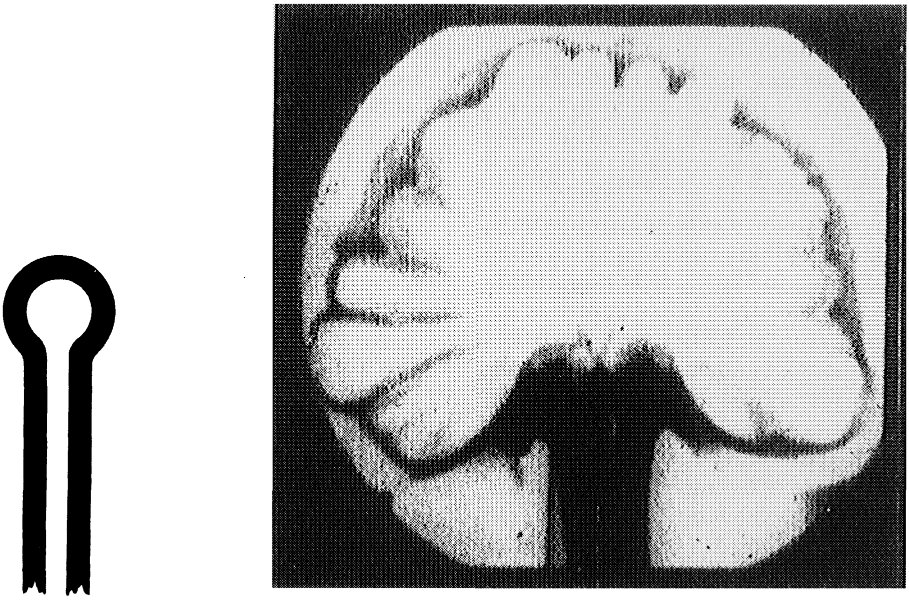

FIG. 5. Flash x-ray photograph of an exploding single-turn coil, taken at the end of a 180-T field pulse. The profile of the coil before the pulse is shown to the left. The coil, with inner diameter 8 mm, was made from a copper plate with 3-mm thickness. (Courtesy of N. Miura, ISSP, Tokyo.)

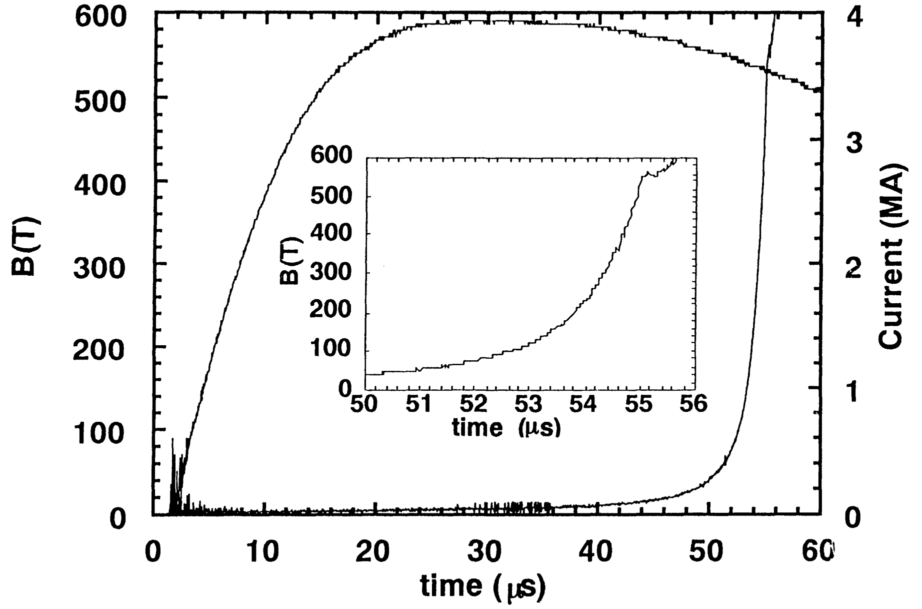

FIG. 6. Current and field wave forms from an electromagnetic implosion. The field wave form is typical for an implosion experiment, with a long flat initial part followed by a rapid increase and probe destruction shortly after the peak. This last part of the pulse is enlarged in the inset; the steps are due to the resolution of the digital recorder. (Courtesy of N. Miura, ISSP, Tokyo.)

around 200 T, but the pulse duration is longer than with the other methods, up to 10 μs.

4. MAGNETS FOR SPECIAL APPLICATIONS

4.1 Magnetic Separation

The separation of ferromagnetic from nonferromagnetic materials is straightforward and does not impose special requirements on the magnets other than that they must withstand a rough environment. There is a large variety of configurations depending on the material to be processed. More sophisticated methods are among the recurrent topics at the magnet technology conferences (e.g., Dawson, 1992).

For the separation of weakly magnetic (e.g., paramagnetic) materials, several methods have been developed. The most widely used of these is high-gradient separation, where a matrix of thin ferromagnetic wires is placed into a magnetic field of the order 1 T that magnetizes the wires perpendicular to their axis. This produces very strong field gradients in the vicinity of the wires, which attract small particles containing weak magnetic dipoles. These particles, usually suspended in a liquid for transport, stick to the wires and must be flushed out after accumulation; this can be a reciprocating or continuous process (e.g., with the matrix on a disk or a moving belt). Iron-core electromagnets are adequate and perform well in this industrial environment; large superconducting magnets have been used with variable success in large installations. These are good candidates for "open-gradient" separators where dry mixtures are processed by gravity feed into an open region where a magnetic field gradient exists.

Other methods are magnetic-field induced flocculation and enhanced sedimentation, and magnetically controlled sedimentation of particles suspended in a ferrofluid.

4.2 Magnetic Levitation and Propulsion

One application of magnets is in the area of mass transport and uses both magnetic levitation and propulsion (see TRANSPORT BY MAGNETIC LEVITATION). The advantage of levitating vehicles is that frictional losses associated with wheeled transport and considerable noise pollution are eliminated. At Birmingham airport in the United Kingdom, a fully commercial operational "people mover" system is installed. This uses conventional electromagnets to levitate the cars by attraction to a ferromagnetic rail. Japanese National Railways have developed a model Maglev train which has been operating on a 7-km test track at Myazaki prefecture for some 10 years, and a much longer track for commercial operation is under consideration for the line between Tokyo and Osaka. This system uses onboard superconducting magnets running in persistent mode. These magnets induce eddy currents in copper loops in the track beneath when the train is propelled by a linear motor (wheels are needed for very low speeds and when at rest). The magnetic field produced by the eddy currents opposes that of the superconducting magnets, and at a certain speed, the force generated exceeds the train's weight and it levitates. Speeds in excess of 500 km/h have been achieved.

With high-temperature superconductors being developed, there is renewed interest in an alternative approach, suggested by Bevir, in which the intrinsic diamagnetism and induced currents in bulk superconducting material can be made to react against a ferromagnetic track (Homer *et al.*, 1977). Also, the long-term possibility of superconducting magnets operating in liquid nitrogen may improve the efficiency of levitated transport using such magnets by reducing refrigeration requirements.

Again, in Japan, a novel form of marine transport has been developed that also uses superconducting magnets. The magnets are long dipoles through the air gap of which sea water is allowed to flow fore-to-aft. Because of the salinity of the sea water, electric currents can be passed orthogonal to the magnetic field and the direction of flow; the magnetohydrodynamic effect results in a force on the water, which is thus expelled from the stern of the ship with consequent forward momentum imparted to the vessel. A successful test ship has been launched.

GLOSSARY

Coercive Field: The magnetic field needed to reduce the magnetization of the fully magnetized material to zero.

Critical Current: The current in a superconductor at a given magnetic field and temperature above which it begins to revert to the normal state. For practical purposes, the definition is arbitrary and usually stated as that current which generates a given electric field along the conductor, typically 10 μVm^{-1}.

Critical Temperature: The temperature above which a superconductor becomes normal.

Cryostat: Alternatively, a Dewar vessel or "Dewar." A vessel (often constructed of stainless steel), usually insulated by vacuum enclosed by a double wall, for holding cryogenic fluids, e.g., liquid helium. Shielding against room-temperature radiation is usually incorporated.

Curie Temperature: The temperature above which a ferromagnet or ferrimagnet becomes paramagnetic.

Ferrimagnet: Similar to a ferromagnet but with magnetic dipoles of different strength oriented in opposite directions, thus also exhibiting spontaneous magnetization.

Ferrite: A material containing iron oxides that is ferrimagnetic, of practical importance because of its low electrical conductivity. There is a variety of ceramic compositions including soft and hard magnetic materials.

Ferromagnet: A material that exhibits spontaneous magnetization (with all dipoles in a domain parallel) below a certain temperature, called the Curie temperature.

Flux Jumping: The phenomenon whereby magnetic flux in a superconductor changes suddenly resulting in a temperature rise.

Flux Pinning: The mechanism whereby flux vortices threading a type II superconductor in the mixed state are prevented from movement under the Lorentz force.

Hard Magnetic Material: A ferromagnet or ferrimagnet with a high coercive field.

Lambda Point: The temperature (2.186 K) at which liquid helium becomes superfluid and has a thermal conductivity some 10^6 times that above the lambda point.

Lorentz Force: The force exerted by an electric field **E** and and a magnetic field **B** on a particle with charge q and velocity $\mathbf{v}$; this is $q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$. For a current I flowing through an infinitesimal length of conductor $d\mathbf{l}$, it is $I\, d\mathbf{l} \times \mathbf{B}$.

Magnetic Dipole Moment: Electric current circulating in a loop represents a dipole moment equal to current times surface of the loop. The magnetic field of a dipole falls off with the third power of the distance.

Magnetic Field, *H*: The measure of the magnetic excitation due to electric currents flowing in conductors; the unit is A/m.

Magnetic Flux, *Φ*: The surface integral of the magnetic induction. The voltage induced in a closed loop encircling the flux is equal to the time derivative of the flux (Faraday's law). The unit is weber = V s.

Magnetic Induction, *B*: The magnetic force field, which is also the source of induced electric fields (Faraday's law); the unit is T (tesla) = V s/m^2 (magnetic flux density).

Magnetic Permeability in Vacuum, μ_0: The ratio B/H in vacuum, which is equal to $4\pi \times 10^{-7}$ V s/A m by definition of the unit ampere.

Magnetic Permeability, Relative, μ: The ratio $B/\mu_0 H$ in a material. For a ferromagnet, this is a function of the magnetic field and history; it is usually taken as the tangent to the $B(H)$ curve.

Magnetic Resonance Imaging (MRI): A specialized form of NMR mostly used in the medical diagnosis of living tissue, in particular, the human body.

Magnetization, *M*: The measure of the magnetic excitation due to magnetic dipoles in a material; the unit is A/m = dipole moment per volume.

Maxwell Stress: The stress (force/surface) $BH/2$ associated with the magnetic field. This is positive (pushing) perpendicular to the field lines and negative (pulling) along the field lines. The Maxwell stress is equal to the energy density of the magnetic field.

Nuclear Magnetic Resonance (NMR): An effect whereby radio frequency radiation interacts with quantized nuclear magnetic moments in a magnetic field. For most applications, the field must be highly homogenous. The effect can be used for the study of chemical compounds.

Paramagnet: A material containing permanent magnetic dipoles that are not strongly interacting with each other. The relative permeability is slightly larger than 1, by an amount of order 10^{-4}. An exception is a ferromagnet above the Curie temperature, which is also considered paramagnetic.

Remanent Induction: The magnetic induction of a fully magnetized material after the magnetizing field is reduced to zero. This is proportional to the spontaneous magnetization.

Soft Magnetic Material: A ferromagnet or ferrimagnet with a small coercive field.

Upper Critical Magnetic Field, B_{c2}: The magnetic field that delineates the upper limit of the mixed state of a type II superconductor at a given temperature and current density.

INTRODUCTION

Calibration and maintenance of laboratory instrumentation are important functional aspects of any manufacturing or research organization. Since the quality of any product, whether it is intellectual material or some manufactured good, relies on the level of conformance to specifications, one's ability to meet desired goals depends on the means for doing so. Measuring and test equipment is used throughout the manufacturing and development process, and hence its performance, or its ability to quantify the performance of a process, depends on a prescribed and regimented measurement assurance program. Calibration and maintenance organizations or individual researchers can provide the measurement assurance necessary to maintain, continually, high standards of productivity and customer satisfaction.

1. CALIBRATION

Calibration can be defined as "the set of operations which establish, under specified conditions, the relationship between values indicated by a measuring instrument or measuring system, or values represented by a material measure, and the corresponding known values of a measurand" (ISO/IEC, 1990). The philosophy of *exactly* what constitutes a calibration has been widely discussed. However, the common thread that pervades most discussions is that a comparison to a standard or reference instrument or some intrinsic physical constant must be made to certify the system or device under test (DUT). The reference instrument or intrinsic value establishes the measurand; understanding the relationship between the DUT indication and the known measurand constitutes the calibration. Of course, the characterization of a device or system involves a

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

myriad of operations including measurements, calculations, judgments, and finally presentation of the information in a meaningful way to the end user.

Overview: In order for any calibration process to be successful, many factors need to be considered. For large manufacturing or research organizations, it is very important to have an operationally structured calibration program—one that is organized to handle the flow of instruments, maintenance of calibration standards, concise and up-to-date documentation, and tracking of standards and DUTs to ensure that recall intervals and inventories are current and adequate. The calibration laboratory environment is a critical component in realizing measurement precision. Ergonomics facilitates efficient and safe measurement practice, while the simple lack of an organized and clean setup may prevent measurement accuracy. The proper standards are necessary to accommodate required accuracy ratios and standards hierarchy. Finally, measurement technique and knowledge or understanding of measurement circumstance can lend significant added value to the calibration.

For the individual researcher, who is concerned with validating a measurement process or quantifying measurement uncertainties, calibration is a critical component. Questions such as How do I calibrate and maintain the instrumentation being used on my project? or What standards do I need in order for my data to have traceability to standards of measurement? or How do I determine the error budget of my calibration process, and how does it relate to the uncertainty requirements of my experiments? need to be answered. The answers to these and many other technical concerns lie in the understanding of the measurement process, calibration methodology, and potential error sources and how to limit or control these error sources.

2. ELEMENTS OF CALIBRATION

In order to characterize measuring and test instrumentation properly, the calibration standard(s) and the measurement techniques employed must mimic the real operating environment. For example, calibrating a resistor in a well-maintained laboratory environment does not necessarily indicate resistor performance in a manufacturing application where the device may be exposed to high moisture levels, contaminating fluids like oils, or thermal variations vastly different from the laboratory environment. Therefore, the proper choice of calibration standards, measurement techniques, and environmental controls will optimize one's understanding of instrumental performance and how it might affect a measurement or research process.

2.1 Calibration Standards

The nature of calibration and the necessity for measurement traceability have led to the establishment of extensive hierarchies of standards laboratories and standards instrumentation. National standards laboratories are at the apex of these hierarchies, providing ultimate reference for every standards laboratory. At the field instrumentation level, the requirements imposed on calibration instruments in a manufacturing or maintenance environment are much less demanding than those imposed on a reference-level instrument or system customarily found in a metrology laboratory. Working standards are at the lowest stratum of the calibration instrumentation hierarchy. These instruments are utilized in daily, routine calibration to check and characterize measuring instrumentation used in research, development, manufacturing, maintenance, or general operation of facilities and equipment. These devices are generally multifunctional source or sense instruments which operate equally effectively as transportable or benchtop standards, or individual artifacts like resistors, thermometers, pressure gauges, or gauge blocks. At the next level are transfer standards; these are laboratory instruments that are used to calibrate working standards. Transfer standards are periodically calibrated by laboratory or reference standards and are unique in that they provide the short-term measurement precision to convey the accuracy of the reference-level standard to the working standard with negligible additional uncertainty. Typically, the reference standards are not available for routine calibration work. Rather, to protect such top-level standards from deterioration or misuse, the transfer-standard class instrument is implemented. The reference standards are the primary instruments or artifacts of most standards laboratories. These devices are carefully maintained and controlled to assure that performance levels remain sufficient to provide accuracy ratios for lower-level standards. Reference standards are highly specialized devices, which are expensive to recertify if proper care is not provided. All standards laboratories depend heavily on these standards to sustain traceability to international standards of measurement. Reference standards provide a direct link to fundamental standards or internationally recognized standards through interlaboratory comparison.

Fundamental standards are those quantities of the *Système International* (SI) whose fundamental physical nature has distinguished them as well-defined, naturally occurring processes. The triple point of water [measured in terms of the SI unit for temperature known as the kelvin (K); one kelvin is defined as the 1/273.16 of the thermodynamic temperature of the triple point of water] and the cesium-beam time standard (measured in the base SI unit of seconds, where 1 s is defined as the duration of 9 192 631 770 periods of radiation emitted by the transition between two hyperfine levels of the ground state of the cesium-133 atom) are two fundamental standards to which many measurements are traced. The platinum-iridium mass artifact (which defines the SI base unit of the kilogram) is a *de facto* standard to which mass measurements as well as many physical and electrical measurements trace their accuracy. There are, of course, other base physical units on which primary reference calibration systems rely. The set of base units includes mass, time, temperature, electric current [ampere (A)], amount of substance [mole (mol)], and luminous intensity [candela (cd)]. The length unit [meter (m)] is now a derived unit relating the distance that light travels in vacuum in a given number of cesium oscillations. Other derived units are force, voltage, resistance, and pressure, whose accuracy and ultimate traceability are derived from the fundamental standards, the kilogram artifact, and base units.

2.2 Precision Measurement

Calibration implies precision and accurate measurement. By virtue of the fact that comparison of a test instrument with a standard necessitates transference of measurement accuracy, minimizing uncertainty and maximizing accuracy require attention to both system configuration and system performance.

System configuration involves the use of standards and measurement system architecture as they relate to maximizing calibration performance. Depending on the accuracy and precision needed to fulfill measurement goals, one may choose to employ standards further up the hierarchy. In doing so, measurement techniques may need to be altered, greater care must be exercised, and time and cost may be somewhat compromised. Therefore, clearly defined goals and objectives for a test or calibration are important for optimizing system performance (e.g., reference standards are not necessary for a 1% accuracy level calibration).

System performance impacts the overall quality of the measurement product as much as system configuration, but performance characteristics are in some sense intensive quantities of the overall system, whereas configuration and choice of the appropriate standards are extensive quantities. Accuracy and uncertainty of a measurement system can be influenced by many things: environmental factors, calibration errors, data acquisition errors, and data reduction errors. Clearly, environmental factors can be controlled by proper construction of the facility and careful operational methodology. Calibration and data contributions can be minimized by employing statistical process control algorithms.

If the output data are to yield a meaningful description of the measurement process, the data must form what is called a random sequence. In other words, the process must be in a state of statistical control. First, note that it is meaningless to speak of the accuracy of an instrument as an isolated device. One must always consider the instrument plus its environment and method of use (i.e., the instrument and its inputs). This aggregate system constitutes the measurement process. Every instrument has practically an infinite number of inputs—that is, causes that can conceivably affect the output, however small. Such effects as atmospheric pressure, temperature, and humidity are among the obvious factors, but there are a number of others if one is willing to concede that some only have a very small influence. In defining the calibration procedure for a specific instrument, one specifies that particular inputs be held constant within certain limits. These inputs, it is hoped, are those that contribute the largest components to the overall error. The other influences are left completely uncontrolled, and through the use of process control charts, it can be shown that each contributes only a very small amount of error and that their aggregate influence on the instrument output will be of a random nature. If this is indeed the case, then the measurement process is said to be in statistical control. Lack of control is often obvious if one takes repeated measurements and plots the results. Any statistically significant trends in the data will indicate that an uncontrolled input to the measurement process has contributed more than a negligible amount to the overall error.

2.3 Measurement Environment

The measurement or calibration environment can be vastly different depending on the level of accuracy required and the circumstances under which the calibration takes place. In any case, environmental conditions can introduce gross errors into the measurement process if not controlled or at least understood. Sensitive electrical measurements are influenced by thermal gradients (air currents in the room or gradients that manifest themselves as emfs or contact potentials because of the thermocouple effect between dissimilar metal contacts) and changes in relative humidity. Pressure measurements can also be affected by thermal gradients since standard pressure devices often derive pressures from force-per-unit-area–type configurations. Hence, environmental controls should be implemented to sustain temperature and relative humidity (and sometimes particulate contamination) levels commensurate with the calibration objectives. For laboratory-type instrumentation, this generally equates to a nominal temperature of 22.4 to 23.6 °C, with variations no greater than 0.6 °C in a 1-h period, and relative humidity controlled between 35 and 55%. For occasions where these levels of control are not possible or practical, environmental conditions should be noted, and instrumental uncertainty calculations should include any significant contributions from these effects.

2.4 Calibration Errors

All measurements have errors. The errors arise from indicated differences between the measuring device being calibrated and the true value being supplied by the calibration standard. The total error of any measurement has two components: a fixed bias error β and a random precision error ϵ_k, such that

$$\delta_k = \beta + \epsilon_k.$$

Since all measurement systems are subject to both bias and precision errors, it follows that an accurate measurement is one that has both small bias and small precision errors. These bias and precision errors are commonly referred to as calibration errors, but other error sources such as data acquisition errors and data reduction errors loom as potential pitfalls to achieving calibration objectives.

Bias (fixed) errors are systematic errors that remain constant for the duration of the test. In repeated measurements employing the same measurement technique and at ambient conditions, each measurement has the same bias error. The bias, however, is usually an accumulation from several individual bias errors. Bias errors include those that are known and can be calibrated out, those that are negligible and are ignored, and those that are unknown and are estimated. The estimated component must be taken into account when performing the uncertainty analysis. In most cases, the bias error is equally likely to be positive or negative. Hence, it is not known if the bias error is plus or minus, and so the bias limit must reflect this as $\pm B$. The bias limit B is estimated as the upper limit of the bias error β. The bias error is difficult to estimate, and so special tests must often be devised to provide bias information. The following tests are useful for obtaining bias information:

1. interlaboratory or interfacility comparisons, which make it possible to obtain the distribution of bias errors between laboratories;
2. comparison of standards with test instruments in the actual test environment;

3. comparison of independent measurements that depend on different principles or have been independently calibrated;
4. when a bias is known to result from a particular cause, calibrations in which the cause is allowed to vary throughout its full range to determine the range of the bias.

In the event that there is no known cause or source of data for bias, an estimate must be made based on judgment or experience. Instrument manufacturers or other references may provide some information.

Precision (random) errors are observed in repeated measurements, which do not and are not expected to agree exactly because of numerous error sources. The standard deviation is a measure of the precision error. For a normal (bell-shaped) distribution, the interval $\mu \pm 2\sigma$ will include approximately 95% of the total scatter in the measurements where μ is the true average of the population and σ is the true standard deviation. A large standard deviation means large scatter in the measurements. The statistic S is calculated to estimate the standard deviation. S is known as the precision index and is defined as

$$S = \sum_{k=1}^{N} (X_k - \bar{X})/(N - 1),$$

where N is the number of measurements made and $\bar{X}$ is the average value of the measurements X_k, given by

$$\bar{X} = \frac{1}{N}\sum_{k=1}^{N} X_k.$$

The effect of precision error is reduced by averaging several measurements and using the average instead of any individual measurement. Thus,

$$S_k = S/\sqrt{N}.$$

2.5 Calibration Results

The results of the calibration or test become an important historical reference document. Calibration reports are useful for predicting instrument maintenance requirements, tracking error budgets, adjusting calibration intervals, and satisfying auditory requirements, and generally as a reference for system accuracy and uncertainty. However, for the calibration results to be truly useful, several important pieces of information must be included such as

1. the date of calibration;
2. reference to the calibration procedure employed;
3. the environmental conditions present at the time of calibration;
4. the calibration standards employed;
5. indication of whether adjustments were required to bring the instrument into specifications;
6. calibration data in the "as found" condition and in the "as left" condition if the instrument was adjusted;
7. indication of the calibration errors; and
8. information about the individual or organization who performed the calibration.

Each of these items is critical to maintaining an instrument's performance history and legitimizing traceability to higher-level standards.

3. CALIBRATION STANDARDS

Calibration standards exist in a wide variety of measurement disciplines. They are employed to provide an accurate and precise measurand relative to which a calibration is made. The accuracy and precision that can be realized depend on the measurement discipline of concern and also at what level in the calibration hierarchy the measurement is being done. At the national level, calibration standards have been segregated in terms of physical discipline as shown in Table 1. These measurement disciplines have well-characterized, stable, and statistically controlled calibration systems for which traceability to the national level is available. However, in a research environment it is often necessary to develop specialized measurement systems, comprised of one or more working standards, to relate less common physical processes or unique physical observables to known measurement parameters.

3.1 Dimensional Measurements

Until recently, all dimensional measurements were tied to the krypton-86 funda-

Table 1. Listing of calibration disciplines.

mental meter standard. Now the meter is traced to the cesium fundamental time standard. There are innumerable secondary and tertiary standards in this area of calibration. Perhaps the most common and well-known length standard is the gauge block. Gauge blocks are generally useful for performing calibration of measuring and indexing equipment with accuracy requirements in the 1 m to 1 mm range. Since the dynamic range of gauge block standards is fairly limited, many interferometry techniques have become more practicable in recent years, offering calibration services from greater than 100 m to less than 1 μm with accuracies in excess of 1 part in 10^7 at the helium-neon wavelength. Many artifact standards exist in the size and length realm, from polystyrene spherical particulates of a few micrometers to straight edges and cylinders up to 2 m in length. Surveying and gauging tapes, leveling rods, sieves, and thread, gear, diameter, angle, and line standards are just a few of the many dimensional artifact standards that support precision tolerance manufacturing.

At the transfer or working level, the computer numerically controlled coordinate measuring machine (CMM) has become the workhorse for part and process validation and certification. These machines rely heavily on reference artifacts for their calibration and are used to certify low-level artifacts that would be employed in a manufacturing process. The most accurate CMMs today, once certified by an artifact and sufficiently error mapped, can provide calibration measurement services over a large operating volume (1 m^3) with accuracies of less than a micrometer. The CMM is a very versatile machine. Gears, threads, straight edges, plug or gauge diameter, ball bearings, and step standards are just a sampling of the geometric dimensional artifact standards that can be calibrated with this technique.

In the ultraprecision regime, many of the calibrations performed are really at the developmental stage of maturity. Less conventional interferometry techniques like Fabry-Pérot interferometry or x-ray interferometry can be used to calibrate with extreme precision. These techniques are usually traceable directly to the cesium time standard or rely on fundamental constants of nature (silicon lattice constant) in order to achieve the accuracy levels needed to calibrate more conventional heterodyne or phase-shifting interferometers, capacitance gauges, and linear variable differential transformers.

The aspect of dimensional calibration that deals with characteristics and properties of surfaces is called surface texture metrology. There are three general categories of surface texture calibrations: those that employ specimens with regular geometric profiles (periodic sinusoids or gratings, etc.), roughness specimens (random texture), and step-height specimens. Information pertaining to surface rms or average roughness, average wavelength, autocorrelation function, or power spectral density function is usually sought. Stylus-type profilometers, laser profilometers, or interferometers are commonly used to certify texture artifacts as secondary or interlaboratory standards.

Volume standards and graduated scales can be calibrated by gravimetric techniques through which direct comparison to mass standards takes place. Secondary or transfer standards are typically well-characterized volumes. Once a volume is determined via the gravimetric techniques with fluids of known densities, the predetermined volume can then be used to certify materials of unknown density via the gravimetric technique.

3.2 Mechanical Measurements

Mechanical calibration systems all derive their accuracy from the fundamental standards of mass and time. Whether flow rate, flow speed, force, or acceleration is of interest, each depends directly on or is related to mass or, in the case of a speed or rate, depends on time.

Two general approaches are used to measure flow. One involves the use of some simple volume flow meter, some means for measuring density, and a computer to calculate mass flow rate. The other, more basic, approach is to find flow metering concepts that are inherently sensitive to mass flow rate (see MEASUREMENT AND INSTRUMENTATION OF FLOW). There are several sensors or transmitters available with signal output that depends on an attenuation of signal strength as a function of fluid density. These sensors can be instrumented on volume flow devices to measure density concurrently and thus provide mass flow information. However, these secondary-level techniques depend on gravimetric methods for higher-level calibration, where a given amount of fluid is allowed to accumulate in a holding tank and the change in tank mass is monitored per unit time. Hence, this technique relies on accurate mass reference standards as well as a precision time base to achieve sufficient accuracy to satisfy current secondary and working standards accuracy ratio requirements.

Studies of fluid-flow phenomena attempt to determine the magnitude and direction of the fluid velocity vector at a point within the medium. In practice, measuring instrumentation can only sample the average conditions over a small area or volume. The pitot-static tube is used as a reference standard in wind tunnel facilities to determine flow velocity, except when flow velocities are not sufficient to produce large enough differential pressures in the tube. At lower flows, laser velocimetry is employed. Air density in the wind tunnel must also be determined from pressure, temperature, and humidity data to assure that measurement errors are minimized. Hot-wire and hot-film anemometers are common working standards as well as spinning-rotor and Venturi-tube gauges. Laminar flow elements and nozzle/orifice type gauges are also in widespread use.

Mass is considered a base unit, and the artifact standard cylinder of platinum-iridium, called the International Kilogram, is kept in a vault in Sèvres, France. Other masses, such as national standards, are compared with this standard via the equal-arm balance technique. At the 1-kg level, measurement precision of a few parts in 10^9 is possible (see MASS AND DENSITY, MEASUREMENT OF). Secondary mass standards generally take the form of single weights or weight sets, which are then used to calibrate working standard weight sets. These weights are then used to certify secondary or working standard scales or digital electronic balances. Standard weight sets are widely used in other branches of calibration and metrology. Dead-weight pressure testers and some force and acceleration measuring equipment rely on mass calibration, as they are derived quantities.

Acceleration is not a base unit but rather is derived from length and time. Length is now derived from the fundamental time standard; hence, acceleration is traceable only to the cesium clock. Acceleration of gravity g is a convenient reference standard, which can be determined with an accuracy of about 1 part in 10^6 by measuring the period and effective length of a simple pendulum. It can also be determined by measuring the rate of change of the speed of a freely falling body. However, in practical terms acceleration or vibration is measured by electrically monitoring the displacement or frequency and amplitude of a displacement of a known mass. Calibration of such a device involves characterizing the internal spring forces or determining the sensitivity and frequency response of the displacement sensor. The instrumental transfer function, which for a mechanically coupled sensor amounts to determining the ratio of the electrical output to the mechanical input, describes the device performance in terms of the frequency and magnitude of the vibration exciter.

Force is defined by Newton's second law, $F = MA$; thus, a standard for force depends on standards for mass and acceleration. When the gravitational constant g has been determined for a particular locality (pendulum technique), the gravitational force (weight) on accurately known standard masses may be computed to establish a force standard. This is the basis for the so-called "dead-weight" calibration of force-measuring systems. Dead-weight calibration can be employed to certify secondary standard load cells or proving rings. Several other techniques are recognized as having sufficient accuracy for field calibration: analytical balance against the gravitational force on a known mass, acceleration measurement of a known mass to which the unknown force is applied, balancing against magnetic forces created by current flowing through a coiled wire, or conversion of the force to a fluid pressure via a piston gauge or similar transducer. Finally, once force measurement capability is established, torque standards can be realized by sufficiently defining the length of a moment arm to which a known force is applied.

Measurement of air-borne and water-borne sound is generally performed using microphones or hydrophones, which are basically pressure-measuring devices (see MEASUREMENTS, ACOUSTICAL). Sonic measurement involves sensing the magnitude of the fluctuating component of pressure in some fluid medium. The rms value of the fluctuating component of pressure is employed because most sounds are random signals rather than periodic functions. Sound-level meters, microphones, or pistonphones are calibrated by comparison with standard microphones or by assessing the open-circuit voltage response to pressures applied uniformly over the diaphragm of the sensor.

3.3 Thermodynamic Measurements

The principal thermodynamic quantities of interest to a calibration laboratory are pressure, temperature, humidity, and heat flux. These quantities are ultimately traceable to the triple point of water and the mass standard, but an array of reference standards is utilized in routine calibration.

Pressure is not a base unit but rather is derived from force and area, which in turn are derived from mass and time. The basic calibration standards for pressure ranging from medium vacuum up to several hundred thousand pounds per square inch are the mercury manometer and the dead-weight piston gauge. For pressures ranging further down in vacuum, the McLeod gauge is considered the standard. Hot-cathode or radioactive-ionization gauges as well as molecular drag gauges are useful for exploring the high-vacuum regime, but each requires a spot check against the McLeod gauge and characterization of instrumental linearity to provide useful high-vacuum measurements. Since pressure can easily be transduced to force by allowing it to act on a well-characterized area, the basic method for measuring force applies to pressure except for the high-vacuum regime.

Temperature can be considered to be a measure of the *level of thermal energy* of a system given by the average of the random kinetic energy of all constituents of the system. The zeroth law of thermodynamics also represents a useful concept. Thus, if temperature is thought of as the level of thermal energy, it can be considered the driving force for heat flow just as voltage is for electrical current flow. Fixed points of temperature are used to establish a reproducible means of generating a range of temperatures (see TEMPERATURE MEASUREMENT AND CONTROL). Calibration is subsequently performed by comparing unknown temperatures to standard temperatures through the use of a thermometer. The most common thermometer employed as a calibration standard is the platinum resistance thermometer (PRT). Generally, the PRT is allowed to come into equilibrium with some number of temperature-fixed points, and its accuracy and linearity are noted. The calibration process amounts to measuring the resistance of the PRT once it has come into equilibrium with the thermal reservoir. Resistance measurements can be made directly using an ac bridge network or by exciting the PRT with a low-level dc current (1 mA or less) and detecting the voltage drop across the resistance element. The latter technique involves measuring the voltage drop with a precision digital multimeter and employing Ohm's law to determine the resistance values. Once a set of resistance values is measured, temperatures on the ITS-90 temperature scale are expressed in terms of the ratio $W(T_{90}) = R(T_{90})/R(273.16\ \mathrm{K})$ where $R(T_{90})$ is the resistance at temperature according to the defining fixed points of the ITS-90 temperature scale, and $R(273.16\ \mathrm{K})$ is the resistance at the triple point of water (Mangum and Furakawa, 1990). The PRT is perhaps the most useful secondary standard because of its inherent stability and precision; it is, however, fragile and cumbersome to work with, and so for applications requiring a robust temperature indicator, thermistors are commonly employed. PRTs provide temperature reference from 13.8 K [hydrogen triple point; from 0.65 to 5.0 K, helium vapor-pressure thermometry is employed, and from 3.0 to 24.5561 K (triple point of neon), helium constant-volume gas thermometry is used] up to 1234.9 K (the silver freezing point). The working standard temperature devices commonly employed for routine calibration are the thermocouple or thermistor. These devices are much more hardy, and while sacrificing accuracy and stability, they provide sufficient reference for maintenance and process instrumentation. At high temperatures, optical methods are used to assess temperature. Above the silver freezing point, the International Temperature Scale is defined in terms of Planck's radiation law. Temperature is defined by the relation

$$\frac{L_\lambda(T_{90})}{L_\lambda(T_{90}(X))} = \frac{e^{[c_2/\lambda T_{90}(X)]} - 1}{e^{[c_2/\lambda T_{90}]} - 1}$$

where $L_\lambda(T_{90})$ and $L_\lambda(T_{90}(X))$ are the spectral concentrations of the radiance of a blackbody at wavelength λ (in vacuum) at T_{90} and at $T_{90}(X)$, respectively. $T_{90}(X)$ refers to the temperature at a fixed point such as the silver, gold, or copper freezing point, and $c_2 = 0.014388$ mK. The values of temperature are obtained by observing the ratios of spectral concentrations, or the radiance, of a blackbody. Usually, optical pyrometers or photoelectric pyrometers are used to determine the ratio of the radiance of a source of unknown temperature to that of a reference source. The reference source in this case might be a calibrated filament lamp.

Knowledge of the amount of moisture in the environment is important for many manufacturing operations. Hence, calibration of hygrometers, dew-point sensors, and other humidity-sensing instrumentation has become ubiquitous. The national standard in this discipline is the gravimetric hygrometer, which has traceability to the fundamental standard of mass. However, more commonly used measuring and test equipment relies on determination of the dew-point temperature from observations of first condensation on a mirrored surface. Other devices are in use that employ psychrometric charts and dual temperature measurement of one dry- and one wet-bulb thermometer. In any case, a calibration typically requires characterization of instrumental response to moisture-laden environments from 0 to 100% relative humidity and in some cases down to a few parts per million moisture.

3.4 Optical Radiation Measurements

Calibration and testing of optical radiation instrumentation pertains to measurement of light—more specifically the measurement of energy or power in the ultraviolet, visible, or infrared spectrum. Radiometric measurements are among the most difficult to make. The radiant power varies with position, direction, wavelength, polarization, and time, and the responsivity of most radiometers also varies with these parameters. In general, calibration and testing take place in two separate scientific disciplines: radiometry and photometry.

In radiometry, the physical quantity measured is the radiant power incident on an aperture or the portion of a surface. From this measurement and the geometry of the setup, several radiant power densities can be calculated. These include the radiant power incident per unit area (irradiance) and the radiant power incident or exiting per unit projected area and unit solid angle (radiance). In addition, two quantities typically used to characterize sources are the intensity of a source, which is the radiant power emitted by a source in a given direction per unit solid angle, and the total flux, which is the radiant power emitted by the source in all directions.

In photometry, the physical quantities of interest are similar to those in radiometry except that they are spectrally weighted by a function that approximates the spectral response of the human eye. The radiant power detected by such a "standard eye" is called the luminous flux. The standard unit of luminous flux is the lumen, and it is defined in terms of the radiant power emitted by a blackbody at the temperature of melting platinum. More specifically, a lumen is the luminous flux emitted per steradian in a perpendicular direction by 1/600 000 m^2 of a blackbody at the temperature of melting platinum. Finally, in terms of the SI base unit of luminous intensity, the candela is equal to 1 lm/sr.

Optical radiation measurements reduce to quantifying the radiant power or flux in terms of geometrical parameters such as distance from the source or emitter, and solid angle. Hence, radiometry and photometry are traced back to fundamental physics via temperature and time standards, where the temperature standards are used to measure the caloric heating of a detector due to incident flux, and the time standards are used to define geometrical quantities such as distance or angle via the definition of the meter in terms of the cesium clock.

Secondary reference standards in radiometry range from tungsten filament to arc-discharge lamps, depending on the spectral band of interest. Other working standards include gas lamps, detectors, blackbody ovens, and x-ray sources for the high-energy regime. Finally, radiometric calibration and testing are performed on window, filter, mirror, and baffle materials for transmittance and reflectance properties.

The most accurate laser power and energy calibration is fulfilled by standard calorimetry techniques. Detector calibration is also done using a beam splitter to direct equal amounts of energy from a standard laser source to a well-characterized detector and the detector under test.

3.5 Ionizing Radiation Measurements

Calibration of ionizing-radiation instrumentation falls into four general categories: electromagnetic radiation detection (x-rays, gamma rays), beta-radiation detection, alpha-radiation detection, and neutron detection (see RADIATION DETECTORS). Depending on the type of radiation and the source geometry, particular measurements most accurately describe the response of an instrument with that of a standardized source. For example, exposure rate (roentgens per hour) or flux density of electromagnetic radiation (from x-ray machine or accelerators), at a known distance from the source, should be measured. Alpha-radiation detectors are standardized in terms of activity, or activity per unit area, of the source with the reference geometry defined as either 2π or 4π. Beta-radiation detectors are characterized in terms of air or soft-tissue absorbed dose rate at the surface or at a specified distance from the source. And neutron detection instruments are standardized by the number of neutrons emitted per unit time and the average or effective energy of the neutron. In addition to the four main types of ionizing radiation, heavy particles and very high-energy particles that are generated by atomic beam collisions are also of interest. However, these sources of ionizing radiation require either indirect detection via detection of by-products (neutrons or photons that result from collisions between heavy particles in shielding or detector material nuclei) or proportional voltage or current detection via crystal scintillation or fluorescence.

Instruments are typically calibrated as transfer standards. Comparison of the instrumental response to the radiation field of an unknown source to that of a national or derived standard source should be performed to characterize the detector over the specified energy range of use. Periodic performance reassessments using check standards are then done to confirm continued satisfactory operation of the instrument.

A full range of photon-emitting radionuclides is available for electromagnetic-radiation detector calibration. Alpha, beta, and neutron radiation sources are also available as reference standard sources. It is critical that sources that provide a radiation field similar to that which is to be sampled in regular operation be used to perform the calibration. The radiation background at the calibration facility should be well characterized to assure that measurements are accurate and reliable. The environmental conditions should be noted, and instrumental response should be characterized as a function of pressure, temperature, and humidity, as many types of detectors are sensitive to changes in the environment.

3.6 Electromagnetic Measurements

The field of electromagnetic technology is extremely diverse, and so only a cursory glance at the multitude of disciplines and calibration standards will be given here. In general, exploitation of electromagnetic waves, either propagating through transmission lines or through free space, is the basis for one of the two subgroups of electromagnetic measurements. This subcategory includes measurements that focus on electromagnetic fields and antennas and the requirements as they relate to transmission and communication. The other subgroup of electromagnetic measurements deals with the more conventional quantities like resistance, voltage, current, charge, and power.

Electromagnetic field measurements occupy an extremely large spectrum of frequencies (10^6 to 10^{15} Hz). For practical purposes, two of the most important characteristics of the electromagnetic spectrum are the transparency of the atmosphere and the amount of background noise and its variation with frequency. Transmission efficiencies are high for frequencies below 1 GHz, and so most communication and microwave technologies have concentrated in this regime. At lower frequencies, below a few hundred megahertz, components are cheap, antennas are omnidirectional, and hence accurate measurements of components or characteristics of systems are rarely called for. Greater accuracy requirements exist for microwave systems. Frequency and power levels of microwave communication systems are enforced through regulatory decree, and so transmitter and receiver characterization is common. Antenna calibration is also prevalent, with particular emphasis on radiated power and polarization in the far field. With current trends moving toward digital communications and time-division multiplexing, it is increasingly important to characterize instrumental wave forms in the time domain. Hence, oscilloscope and spectrum/network analyzer calibration is an important adjunct activity to communication system calibration. Electromagnetic field-strength measurement is also of particular interest relative to electromagnetic interference (EMI). Depending on the nature of the fields present, EMI can be both hazardous to human health and compromising to proprietary information. Finally, a few other parameters of interest are impedance, attenuation, phase, noise, and voltage.

The second area of emphasis involves standards and methodology that pertain to measuring electrical quantities such as capacitance, current, voltage, resistance, charge, inductance, power, and energy in the frequency spectrum from dc to 10 MHz. These parameters are measured in terms of the so-called legal units, those embodied by the national physical standards or defined by them as a function of physical constants (see ELECTROMAGNETIC QUANTITIES, MEASUREMENT OF BASIC). These legal units are related to the SI system, as practical, via the seven base units from which all other physical parameters are derived. In practice, though, a set of four basic equations is used to define all six basic electrical quantities: $E = IR$ (Ohm's law), $Q = IT$ (Q is charge and t is time), $C = Q/E$ (C is capacitance, and $L = E(dI/dt)^{-1}$ (L is inductance). The other two quantities (energy and power) are realized by requiring the unit of electrical energy to be equal to the unit of mechanical energy and devising absolute electromechanical experiments involving force and length. A descriptive diagram of the derivation of electrical units is shown in Fig. 1.

3.7 Time and Frequency Measurements

Time is one of the base units of the SI measurement system. However, time interval and frequency, which is the dimensional reciprocal of time and is the derived unit, are the most commonly measured parameters. The time base unit is the second and it is currently defined as "the duration of 9,192,631,770 periods of the radiation corresponding to the transition between hyperfine levels of the ground state of the cesium-133 atom" (Blair and Morgan, 1972). All time and frequency measurements are traceable to this fundamental standard.

Time and frequency calibration involves a wide variety of tests and measurements with today's sophisticated instrumentation. Instruments such as the universal time-interval counter offer functionality in time measurement, pulse width, ratio of rise to fall time, frequency, period, phase, and event counts per time interval. The precision and accuracy of each of these functions, however, rely almost entirely on the quality of the time base to which each is referenced. Since cesium atomic-beam standards are expensive, many standards laboratories depend on long-range, low-frequency air-wave transmissions of a reference frequency to standardize their time base measurements. The National Institute of Standards and Technology provides radio linkage to the national reference frequency through the WWV and WWVH programs. The LORAN-C navigation system or Global Positioning System (GPS) can realize time-base accuracy with a simple slave oscillator and a trigger generator. The LORAN and GPS system's local trigger generator bears a relationship to a master cesium oscillator, which provides time base accuracies of 1 μs.

FIG. 1. The standards hierarchy used to derive the basic electrical units.

With an accurate time base, merely a simple electronic comparator/linear amplifier can provide frequency, phase, and period measurements with part per billion resolution. Hence, most calibration facilities rely on remote links to a cesium reference and thus use that link as an external reference input to bench-top counters, synthesizers, or analyzers.

4. PERFORMING CALIBRATIONS

In any measurement process, the ultimate objective is predictability: being able to make probability statements about past and future output from the process. If this predictability is not present, then the process will yield conclusions that are only temporal and local in nature, and that will lack the generality typical of scientific experimentation. To achieve such predictability, a measurement process must be "in control." This will be the case when the output from the process behaves like random sampling from some fixed distribution with fixed location and fixed variation.

4.1 Calibration Procedures

Calibrations are meant to be an accurate assessment of the relationship between a measuring device and a measurement standard. Hence, it is necessary to perform these measurements according to a set procedure so that measurements may be repeated at some later time. Calibration procedures should clearly define the objectives of the measurements to be made and how to realize those objectives. For example, "Certify the accuracy of the digital multimeter on the voltage function, over a measurement range of 0 to 1000 V, in the direct-current mode" might be a measurement objective. Once the measurement objectives are clearly defined, the procedure should identify the proper standards necessary to fulfill these objectives, how the standards/device under test should be configured (block diagram), what measurement techniques are applicable, how the data are acquired and analyzed, and a standard format for data presentation.

4.2 Calibration Setup

An integral part of any effective calibration procedure is a circuit (mechanical if the measurements involve mechanical stimuli like pressure or temperature) block diagram. The block diagram is often useful to facilitate efficient setup and to begin identifying potential error sources or measurement problems. The diagram should include things like instrument serial numbers so that standards are clearly identified. Critical connections should be clearly marked so that instrument damage is avoided. Integrity of connections (electrical or mechanical), thermal perturbations induced by making connections, electromagnetic interference, and any other potentially destabilizing contributions should be assessed and minimized where practical.

4.3 Making Measurements

With the setup assembled, taking data may involve turning dials and writing down numbers from a display, or it may be as sophisticated as a fully automated, computer-controlled data acquisition system. In either case, the data retrieval aspect of the procedure must be carried out with great care to minimize impact on data quality. Potential acquisition error sources are excitation errors, signal conditioning errors, recording device errors, transducer errors, probe errors, electrical connection errors, environmental effects, and data processing errors (averaging, filtering, etc.). All of these potential error sources must be considered when analyzing the data acquired by the measurement process. Eliminating or minimizing as many as possible by clever experimental design and careful measurement execution is recommended.

4.4 Analyzing the Results

In Sec. 2.4, calibration errors were defined in terms of the bias limit and the precision index. Once all elemental error sources are identified as bias limits and precision indices, they are combined to obtain the total bias limit and precision index (ANSI/ASME, 1985). Now all the additional information required to make an estimate of the measurement uncertainty is an estimate of the number of degrees of freedom of the precision index (see Glossary for definition of degrees of freedom).

For simplicity, a single number U is often needed to express a reasonable limit of error. The single number, which is some combination of bias and precision, must have a simple interpretation and be useful without complex explanation. For example, the interval $\bar{X} \pm U$ represents the bandwidth within which the true value is expected to lie. It is, however, impossible to associate the uncertainty with a rigorous confidence level because the bias limit is often based on judgment or past experience, while precision is calculated using statistics.

Although rigorous confidence levels are not available, two uncertainty intervals are widely used with coverages analogous to 95 and 99% confidence levels. Coverage indicates how often an interval estimate is expected to contain the true value (ANSI/ASME, 1985). Ninety-five percent uncertainty intervals provide 95% coverage of the true value. Two uncertainty intervals which provide these coverages are given by

$$U_{\mathrm{ADD}} = B + tS_{\bar{X}},$$

called the additive uncertainty, which provides ≈99% coverage, and

$$U_{\mathrm{RSS}} = [B^2 + (tS_{\bar{X}})^2]^{1/2},$$

called the root sum square uncertainty, which provides ≈95% coverage. Here B is the bias limit, $S_{\bar{X}}$ is the precision index of the mean, and t is the 95th percentile point for the two-tailed Student t distribution. Monte Carlo simulation of the uncertainty intervals has shown that for various bias error distributions, bias limits, and precision indices,

1. U_{ADD} provides approximately 99% coverage, and U_{RSS} provides approximately 95%

coverage, when neither bias errors or precision errors are negligible compared to one another; and
2. if either the bias or precision error is negligible compared to the other, both U_{ADD} and U_{RSS} provide 95% coverage.

5. INSTRUMENT MAINTENANCE

Maintenance is generally divided into three main categories: corrective, preventive, and predictive. The latter two must be the focus of any maintenance effort, as otherwise the system will tend toward substantial amounts of corrective maintenance. Corrective maintenance is essentially a reactive management technique that waits for instrument failure before any maintenance action is taken. This approach is also the most expensive because the loss of availability of equipment resources results in a loss of productivity. Preventive maintenance programs are all time driven; maintenance tasks are based on elapsed time or hours of operation. The mean time to failure or "bathtub" curve (Mobley, 1990) indicates that a system has a high probability for early failure, due to installation problems, followed by a relatively low failure probability period for an extended time, and that finally the failure probability increases sharply with elapsed time. Hence, scheduled maintenance is based on a mean-time-to-failure statistic. Of course, for calibration equipment the mean time to failure is generally when the instrument reaches its specification limit. Therefore, calibration intervals are adjusted such that the device under test or the calibration standard is still within specification 95 or 99% of the time at recalibration. Predictive maintenance refers to a management philosophy that is premised on monitoring or periodically intercomparing instruments or standards so as to be able to predict when an instrument will be out of its specification limits. This is a very useful management philosophy because it reduces corrective maintenance on lower-level standards or test equipment that results from standards being found out of tolerance.

5.1 Standards Calibration

Calibration of standards generally requires significantly greater attention to potential sources of error than does general-purpose measuring and test equipment. Calibration standards are relied upon for the most accurate of measurements and thus are very sensitive. Environmental or mechanical stress can compromise a measurement standard. For example, slight thermal or mechanical shock to a platinum resistance thermometer will shift its calibration curve. For this reason, the transfer standard was invented.

Calibration of the highest level standards is performed by national laboratories or other internationally accredited calibration organizations. These calibrations sometimes involve complex and rigorous characterization of instrumental performance (repeatability, linearity, etc.). Calibration procedures often invoke first principles of physical science, use state-of-the-art equipment and methodology, and are expensive and time consuming. In any case, environmental conditions and human interaction are strictly controlled to minimize uncertainty, and all but the intrinsic perturbations to the system are characterized to the greatest degree possible.

5.2 Calibration Intervals

Calibration intervals typically range from 6 to 60 months. Standards, however, are generally calibrated on an annual or biennial basis. The calibration interval can, in principle, be any length of time, but the idea is to optimize the usefulness of standards and measurement equipment by keeping the interval as long as possible without exceeding the target for out-of-tolerance occurrence at recalibration. The easiest way to determine optimum intervals is to let the calibration history for an instrument determine it. Choosing an annual recall interval is a safe starting place unless the instrumentation is to operate in a volatile environment. Calibration history will then tell whether it is prudent to lengthen or shorten intervals. As a rule of thumb, out-of-tolerance at recalibration twice in a row indicates that the interval is too long.

5.3 Storage and Care of Standards

Measuring and test equipment should be stored in a clean, dry place with due consideration for environmental conditions. Equipment should be protected, locked if necessary, while remaining readily available for use. During extended storage intervals, instruments should be clearly marked as to their calibration status. Instruments and equipment with multiple users should be logged and tracked to provide a history of instrument usage. Storage compatibility issues should also be addressed (e.g., corrosive chemicals should not be stored with instrumentation). The objective is to assure proper performance of precision measuring and test equipment, and so a thorough and handy usage history is necessary to minimize unwarranted recalibration.

6. FUTURE TRENDS

Enabling technologies such as modular and miniature instrumentation and graphical user interface (GUI) software are changing the face of measurement and test equipment. Historically, calibration standards were stand-alone instruments that occupied copious amounts of laboratory bench space and required highly controlled environmental conditions. Now, miniature, self-calibrating, and highly transportable/reconfigurable instrumentation is becoming reality.

6.1 Modular and Miniature Instrumentation

Through the development of the VXI (VME instrument interface) and MMS (Modular Measurement System) architectures, whole instruments can now be placed on a single circuit board. As technology progresses, these instruments will continue to shrink until digital multimeters, oscilloscopes, and other test and calibration equipment can be placed on a single chip. Micromachining and microlithography technologies are making possible the development of solid-state sensors for physical measurements such as pressure, temperature, acceleration, and flow as well. While manufacturing advancements provide the opportunity to package more and more powerful measurement systems in a smaller space, the communication and interfacing issues need to keep pace. Ultimately, what can be envisaged is the GUI depicting a virtual instrument—whatever instrument(s) is (are) needed for the particular calibration. These virtual instruments are created by using only the necessary assets from a core set of miniature source and sense instruments. Then, through multiplexing the core assets, multiple calibration setups can be realized via virtual instruments. These systems leverage size, speed, and extreme flexibility to actualize a multifunctional, working standard calibration system.

Finally, through the developments in micromachining and nanotechnology, solid-state microsensors will provide the means for implementing a philosophical change in calibration methodology. Transient calibration techniques can be developed where parameters such as pressure or temperature are sampled without long dwell times to allow the system to come into equilibrium. These techniques are, of course, only useful for certain applications, but their applicability may pervade low-level mechanical, thermodynamic, and electrical calibration of the future.

6.2 Self-Calibrating Instrumentation

The widespread availability of microprocessor technology, the advances in software, and the advances in imbedded memory have enabled instruments to become vastly more capable than those of a generation ago. The next generation of instruments will employ an even higher level of intelligence through the use of technologies such as fuzzy logic and expert systems. These technologies will facilitate instrument self-diagnosis and self-calibration through continuous monitoring of internal responses to self stimuli. Instruments will be able to respond to drifting of internal standard artifacts such as resistors or Zener diodes and either correct themselves or warn the operator that the calibration standard is approaching or out of the specified operating range.

6.3 Transport Standards

While the virtual calibration set is highly useful, it will continue to rely on reference standards to achieve traceability to international standards. An emerging technology that will facilitate accurate and efficient recertification of such a diverse array of miniature instruments is the multifunction transportable reference standard (MTRS). The MTRS will present a group of cardinal point reference artifacts (resistors, Zener diodes, dividers, solid-state strain-gauge pressure sensors, etc.) to the virtual instrument calibration set and through cross-checks and statistical techniques maintain the measurement accuracy. Spot checks can be done periodically and quickly at high accuracies since the MTRS can transfer directly from national secondary or primary standards through some sort of measurement assurance program.

GLOSSARY

Accuracy: Degree of conformity of a measure to a standard or a true value as determined by calibration.

Calibration: The process of comparing the response of some instrument to a standard instrument over some measurement range.

Coverage: The frequency with which an interval estimate of a parameter may be expected to contain the true value.

Degrees of Freedom: A sample of N values is said to have N degrees of freedom, and the first statistic calculated from those N values is also said to have N degrees of freedom. The degrees of freedom are reduced by one for each subsequent statistic calculated from the set of N values.

Error Limit: The limit of the random error based on a set of repeated measurements.

Fundamental Standard: Of or relating to a well-defined, naturally occurring process or one that is premised on basic physical principles. There are two fundamental standards: the cesium atomic beam and the triple point of water (the platinum-iridium kilogram is an artifact standard). Fundamental constants are often mistaken for fundamental standards; the speed of light, proton mass, and electron charge are all fundamental constants as defined by the SI system of units, but they are not fundamental standards because their accurate measure depends on circumstances which preclude sufficiently accurate agreement with the SI unit unless related through the fundamental standards of time and temperature or the kilogram artifact.

Laboratory Standard: An instrument that is calibrated periodically against a primary standard.

Metrology: The science that deals with methodology and systems of precision measurement.

Primary Standard: A fundamental physical standard or one maintained at the National Institute of Standards and Technology or another globally recognized standards laboratory.

Resolution: The smallest measurable input change an instrument is capable of displaying.

Student t Value: Value used to estimate the precision error limit for a given confidence level, obtained from tables with degrees of freedom for a given confidence level.

Traceability: The ability to trace the calibration of a measuring device through a chain of calibrations to a primary standard. Traceability does not guarantee accuracy; it only indicates documented calibration hierarchy.

Transfer Standard: A laboratory instrument that is used to calibrate working standards and that is periodically calibrated against the laboratory standard.

Uncertainty: The estimated error limit of a measurement or result for a given coverage.

Working Standard: An instrument that is calibrated in a laboratory against a transfer standard or laboratory standard and is used as a standard for calibrating measuring, test, or process instrumentation.

INTRODUCTION

Manufacturing, defined as the transformation of materials and information into goods for the satisfaction of human needs, is one of the primary wealth-generating activities for any nation (Chryssolouris, 1991). Manufacturing can be thought of as a system in which product design is the initial stage, and the delivery of finished products to the market is the final output. Since the field of manufacturing integrates many disciplines in engineering and management, it is useful to divide it in a way that facilitates the identification of issues and allows a scientific approach to the problems encountered. Manufacturing can be subdivided into the areas of manufacturing *processes*, which alter the form, shape, and/or physical properties of a given material; manufacturing *equipment*, used to perform manufacturing processes; and manufacturing *systems*, which are the combinations of manufacturing equipment and humans bound by a common material and information flow. Design and manufacturing interfaces should also be considered, since manufacturing always begins with a design such as a drawing, sketch, CAD file, or other way of communicating the features and characteristics of the product or subassembly that is to be manufactured.

Decisions regarding the design and operation of manufacturing systems require technical understanding and expertise, as well as the ability to satisfy certain business objectives. Thus, a combination of engineering and management disciplines is required to provide a decision-making framework for manufacturing. In general, there are four classes of manufacturing attributes that are considered when making manufacturing decisions: cost, time, quality, and flexibility (Fig. 1). In the context of manufacturing decisions, cost refers to the economic resources required to produce a product; time refers to the time required to produce a product; quality refers to the extent to which the product satisfies the customers' needs and expectations; and flexibility refers to the ease with which the manufacturing process can respond to changes in customer requirements, raw materials, etc. The four attributes manifest themselves, depending on the particular problem, in specific objectives, goals, and criteria.

A manufacturing decision is basically the selection of values for certain decision vari-

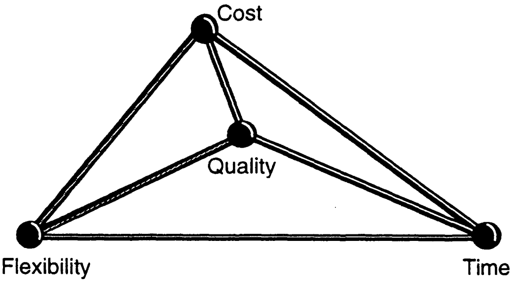

FIG. 1. The manufacturing tetrahedron.

ables related to either the design or the operation of a manufacturing process, machine, or system. Such a decision-making process is based on performance requirements, which specify the values of the relevant manufacturing attributes. In this light, the decision-making process can be regarded as a mapping from desired attribute values onto corresponding decision variable values. In order for this mapping to be scientifically founded, it must be based on *technoeconomical models*. This mapping essentially constitutes a modeling process wherein the levels of manufacturing attributes are related to the levels of different decision variables. For example, the value of an economic attribute for a turning process is determined from a technoeconomical model based on engineering analyses of the tool wear behavior (Metcut Research Associates, 1980).

The tetrahedral arrangement of manufacturing attributes emphasizes the interrelationship of these attributes. It is not possible simultaneously to optimize cost, time, flexibility, and quality. Rather, the overall outcome of a manufacturing decision is governed by trade-offs between the different manufacturing attributes. Assessment of these trade-offs requires a means of quantitatively evaluating each attribute. The more precisely defined these are, the easier it is to trade them off and make decisions. In industry to date, most quantitative measures in manufacturing refer to cost- and time-related attributes. Consequently, the trade-off between cost and production rate has been extensively treated. Thus, although cost- and time-related attributes remain extremely important for any manufacturing decision, emphasis must be placed on finding quantitative definitions for quality and flexibility, so that appropriate trade-offs among the four different classes of manufacturing attributes can be established in order to achieve a comprehensive treatment of manufacturing problems.

Costs related to manufacturing encompass a number of different factors, which can be broadly classified into several categories. Equipment and facility costs include the cost of equipment necessary for the operation of manufacturing processes, the facilities used to house the equipment, the factory infrastructure, etc. Materials costs include the raw materials for producing the product, along with tools and auxiliary materials for the system, such as coolants and lubricants. Direct labor costs are the costs needed for operating the equipment and facilities. Energy costs are required for the performance of the different processes. In some manufacturing industries, this cost may be negligible compared to other factors, while in others it contributes significantly to the financial burden of the manufacturing system. Maintenance and training costs include the labor, spare parts, etc., that are needed to maintain the equipment, facilities, and systems, as well as the training necessary to accommodate new equipment and technology. Overhead costs are the costs that are not directly attributable to the operation of the manufacturing system, but support its infrastructure. The cost of capital (or the cost to attain the required capital) may not be readily met within the manufacturing firm and therefore must be borrowed under specific terms. This classification provides a general framework of how cost issues can be addressed in the manufacturing environment by establishing a systematic way to measure the cost performance of different solutions.

In manufacturing systems, time attributes refer to both how quickly a manufacturing system can respond to changes in design, volume demand, etc. (discussed below) and how quickly a product can be produced by the system—usually expressed as the *production rate* of the system. Production rate affects, directly or indirectly, all other types of attributes. Higher production rates typically result in lower cost but possibly lower quality as well. Furthermore, to achieve high production rates it is often necessary to resort to automation, which may have an impact on the flexibility of the system. An example of such automation is a transfer line, which because of its fully automated part transfer mechanism and machining operations provides production rates on the order of one piece every 20 seconds, even for very complex parts, but is very inflexible.

For many decades, cost and production rate were the most important performance criteria in manufacturing, and manufacturers relied on dedicated mass-production systems to achieve economies of scale. However, as living standards improve it is increasingly evident that the era of mass production is being replaced by the era of market niches. The key to creating products that can meet the demands of a diversified customer base is a short development cycle yielding low-cost, high-quality goods in sufficient quantity to meet demand. This makes flexibility an increasingly important attribute of manufacturing. Flexibility, however, cannot be properly considered in the decision-making process if it is not properly defined in a quantitative fashion. The quantification of flexibility has been the focus of academic work, but industrial applications have been few. Academic research has focused on one-of-a-kind or small–lot-size production systems such as those found in the aerospace industry, but not on mass production systems. This is because the flexibility debate has concentrated on the ability of a manufacturing system to produce a spectrum of products quickly and economically. However, other aspects of flexibility (Browne *et al.*, 1984) are equally important such as *routing flexibility*, which is the ability to handle breakdowns and to continue producing a given set of part types; *volume flexibility*, which is the ability to operate profitably at different production volumes; and *operation flexibility*, which is the ability to interchange ordering of several operations for each part type.

A generic measure of flexibility that is nonetheless relatively easy to apply to realistic manufacturing situations is based on the premise that the flexibility of a manufacturing system is determined by its sensitivity to change. The lower the sensitivity, the higher the flexibility. High flexibility or low sensitivity to change brings three principal advantages to a manufacturing system. It is convenient to think of these advantages as arising from the various types of flexibility, which can be summarized in three main categories. Product flexibility enables a manufacturing system to make a variety of part types with the same equipment. Over the short term, this means that the system has the capability of economically using small lot sizes to adapt to changing demands for various products. Over the long term, this means that the system's equipment can be used across multiple product life cycles, increasing investment efficiency. Operation flexibility refers to the ability to produce a set of products using different machines, materials, operations, and sequences of operations. It results from the flexibility of individual processes and machines, the flexibility of product designs, and the flexibility of the structure of the manufacturing system itself. It provides breakdown tolerance, which is the ability to maintain a sufficient production level even if machines break down or humans are absent. This affects mass production in particular, where a large number of identical or very similar parts must be produced, and production quantity is often the most important indicator of manufacturing success. Capacity flexibility allows a manufacturing system to vary the production volumes of different products to accommodate changes in demand while remaining profitable. It reflects the ability of the manufacturing system to contract or expand easily. It has traditionally been seen as critical for make-to-order systems but is also very important in mass production, especially of high-value products like automobiles.

The quality of a product, broadly related to customer satisfaction, is often difficult to define in quantitative terms, since customer satisfaction depends not only on the actual features of a product, but also on its feasibility, maintainability, and a host of other factors that are often subjective and thus difficult to quantify. However, customer satisfaction can be traced to two major factors at the origin of a product: its design and manufacture. In manufacturing, quality typically refers to how well the production process meets design specifications related to the different features and properties of a product. The quality of a product is an aggregate of the quality of individual features and properties, which can be broadly divided into two major groups: geometric characteristics, and the physical and/or chemical properties of the materials that constitute the product.

Quality, pertaining to manufacturing systems, has many different aspects. When identical parts or products are mass produced, the repeatability of the manufacturing process becomes important, so that every item produced conforms to predefined specifications. This aspect of quality has been the subject of extensive studies in the area of statistical quality control. However, as manufacturing systems move toward low-volume or even one-of-a-kind production, the tools based on statistical methods may have to be adjusted, since the population of items that is needed for deriving statistically meaningful measures for quality may not be available.

Another aspect of quality concerns the life cycle of the product. If, after its release, a product is immediately unacceptable to the market, its design and overall features may be at fault more than its manufacturing. On the other hand, manufacturing quality becomes apparent after using a product for a period of time, through the wear behavior of the product's components.

Since manufacturing quality reflects the meeting by the manufacturing process of established expectations within tolerances, it is important to note that such tolerances may be overestimated or underestimated. An overestimation of tolerances leads to unnecessary cost during product manufacture and unnecessary pressure on the manufacturing system, while an underestimation of tolerances may lead to a malfunctioning product.

Measuring quality is critical for manufacturing, since it reflects the performance of the production process as a whole and facilitates the establishment of trade-offs between quality and other manufacturing attributes. Quality is measured from the most aggregate level, in terms of acceptance or rejection of a product, down to the elementary characteristics of a component. In general, the more aggregate the quality consideration, the less quantifiable it is and the more it relies on customer reports and subjective judgment. More elementary characteristics, for example dimensions, and physical properties, such as hardness and strength, are easier to quantify and therefore provide an easier measuring task for testing and inspection, which are usually carried out during the production process or immediately thereafter.

1. MANUFACTURING PROCESSES

A manufacturing process is defined as the use of one or more physical mechanisms to transform a material's shape or form. Manufacturing processes can be further divided into *discrete parts* processes and *continuous* processes. The metal-working industry, where many single items are produced, uses discrete-parts manufacturing. Chemical processing, used in, for example, the film- or fiber-making industries, often uses continuous processing.

Manufacturing processes can be classified into five broad categories. Forming or primary forming processes are processes in which an original shape is created from a molten or gaseous state or from solid particles of an undefined shape. During primary forming processes, cohesion is normally created among particles. Deforming processes are processes that convert the original shape of a solid to another shape without changing its mass or material composition. During deforming processes, cohesion is maintained among particles. Removing processes are processes in which material removal occurs during the process itself; cohesion among particles is destroyed. Joining processes are processes which unite individual workpieces to make subassemblies or final products. These include additive processes, such as filling and impregnating of workpieces; cohesion among particles is increased. Material properties modification processes are processes which purposely change the material properties of a workpiece in order to achieve desirable characteristics without changing its shape.

The selection of which process to apply to a particular material is influenced by a number of factors which affect cost, production rate, flexibility, and part quality. Probably the two most important factors are the lot size of the parts to be made and the physical properties of the material (e.g., the melting point). Small lot sizes require flexible processes, such as material removal processes, which are able to accommodate different geometric features, etc. Large lot sizes allow the use of primary forming or deforming processes; since tooling cost for such processes is high, a large lot size is required to amortize the cost. Metals have relatively high melting temperatures and therefore are usually processed in solid form using material removal and deforming processes. Polymers and composites have much lower melting points, allowing the use of primary forming processes, where the material is often in liquid state; however, secondary operations, usually grinding, are often needed to achieve the required dimensional accuracy and surface quality. Because these materials often contain abrasive fibers or fillers, they often exhibit abrasive behavior when conventionally machined. Ceramics are usually brittle, making them difficult to process in solid form with conventional machining techniques. With ceramics, primary forming processes are used to create the basic shape of the workpiece, and secondary operations (usually machining) are used to create the final shape and surface quality.

1.1 Primary Forming Processes

Primary forming processes produce a net shape either through solidification of a liquid or a vapor or through cohesion of solid particles. Forming processes can be used effectively on all major classes of engineering materials. Among the primary forming processes, casting has the most applications in manufacturing. Casting describes a family of processes in which molten material is introduced into a mold and then solidified. Metal casting processes are used when large parts, possibly having intricate shapes and internal cavities, are produced with mechanical properties such as high strength, brittleness, or hardness, which make these parts difficult to produce through other methods. Casting processes are limited in terms of surface quality, porosity, and, consequently, the strength of the parts produced. Generally, casting processes are used in production with relatively large lot sizes so that the high capital cost required to establish a foundry can be justified. It should be noted, however, that some casting processes are not capital- and investment-intensive.

Primary forming processes have found wide use in polymers and composite materials. Almost all processing techniques for these materials belong to the primary forming category and have a counterpart in processing metals and ceramics. In general, plastics can be molded, cast, formed, machined, and joined; and because they can be processed at much lower temperatures than metals, primary forming processes are very attractive for making components of plastics and composites.

The manufacturing process for plastics and composites often begins with raw materials in the form of pellets or powders, which are usually melted before the actual forming process begins. Plastic raw materials are also available as sheets, plates, rods, and tubing. Often, plastics used in producing composite materials are initially in liquid form. In addition, thermosetting plastics can be formed into their final shapes through chemical reactions as in reaction injection molding, thermoset molding, and thermosetting composites.

The applicability of forming processes is often constrained by the high cost and relative inflexibility of tooling. Forming dies and molds cost on the order of $10 000 to $100 000 and often require weeks to months of lead time to design and produce. However, the cost of the die can be distributed over the cost of producing a batch of parts; therefore, primary forming processes are economical when the lot size is large (on the order of 1000 parts and up). Also, forming processes often do not require highly skilled workers to operate since the tool and workpiece motions do not need to be programed, and so labor costs can be reduced relative to other processes.

Forming processes can achieve high production rates, with cycle times from seconds to minutes depending on part thickness. In general, casting and molding processes that use permanent dies machined from metals have lower cycle times than processes that use expendable foam, ceramic, or wax molds. However, expendable molds can produce intricate shapes and internal part features not available with permanent molds. Setup times for forming are on the order of eight hours, which makes casting and forming prohibitive for low-volume production.

Parts produced through permanent mold or die casting can achieve surface finishes of 1 to 2 μm R_a (roughness average), although typical cast parts require secondary removal processes such as grinding or EDM (electric discharge machining) to improve surface finish. Sand-casting processes can produce parts with up to 25 μm R_a surface roughness. Besides surface roughness, porosity in the cast or molded part due to entrainment of gas bubbles in the flow of molten material, and dimensional accuracy, are problems associated with parts produced by primary forming. The part quality can be influenced by process parameters such as the die temperature, cooling time, and cooling rate, as well as design of die or mold features such as sprues and conduits for molten material flow and mold cooling lines.

The flexibility of forming processes is limited by the kinematics of forming processes, which are constrained such that only one part geometry can be produced for a die geometry and the part geometry cannot be changed through workpiece-tool motions. However, forming processes have the potential to produce parts with very intricate geometric features, especially internal features, and workpiece thicknesses that can vary from under 1 mm to over 100 mm.

1.2 Deforming Processes

Deforming processes have a variety of applications in the industrial world. Components for automobiles, industrial equipment, and machine tools as well as hand tools such as hammers, pliers, and screwdrivers are some industrial applications of deforming processes. Containers such as metal boxes and cans, and fasteners such as screws, nuts, bolts, and rivets are other components created using deforming processes. The most commonly used materials in deforming processes are steel, carbon alloyed steel, stainless steel, and heat-resistant steel; nonferrous heavy and light alloys, such as aluminum, zinc, and copper; and titanium and heat-resistant nickel alloys. The significance of deforming processes can be best understood by considering that a medium-sized automobile has at least 150 pounds of steel in cold-formed parts.

Generally speaking, deforming processes used in the metal-working industry can be divided into *bulk* or *massive deforming* methods (Lange, 1985), such as extrusion, upsetting, or forging, and *sheet metal forming* techniques, such as deep drawing and bending. Irrespective of the type of deforming method, the stresses required for deformation are quite high, ranging between 50 and 2500 N/mm^2 [7–360 ksi (kilopounds per square inch)] depending on the method and the material. Because the entire workpiece, or a major part thereof, is deformed, the loads which result from a deforming process also are very high; for example, in a forging press loads may be up to 750 MN, or 85 kts. Comparing this with the heavier equipment for material removal processes, such as large planing machines, the load is a few orders of magnitude lower (20 kN or 2.3 tons) than the load which occurs in deforming processes.

Industrially applied deforming processes can be classified in a number of ways. One way to classify these processes is to examine the temperature present while the forming occurs. Following this criterion, one can distinguish between hot forming processes, which occur after the workpiece material has been heated, and cold forming processes, which occur without additional heating. Stress is another classification criterion referring to the amount of loading on the material when the deforming process occurs. The purpose of these classifications is to facilitate the training of people for the different processes, to provide uniform, reliable, speedy communication regarding issues of deforming processes, and also to provide some precise definitions of the different processes for use in process planning.

Deforming processes generally have relatively high tooling costs, similar to forming processes, because of the complicated die geometries required. Deforming methods are directly related to machining and metal-removing methods because the tools used for metal deformation are usually produced by machining processes, as a result of the small lot size (one-of-a-kind in most cases) and high precision required. Because the costs of tooling (up to $250 000 per die) and machinery (up to $200 000 per machine) are high, deforming processes are usually applied in lot sizes large enough to justify economically the high cost of the tools and machinery required. Since a deforming tool usually has a life of several million parts, the high tooling cost can be distributed over a large number of parts, so that the total manufacturing cost per part will be low for large batch sizes. Finally, highly skilled workers are usually not needed to operate deforming processes, and so labor costs are also relatively low compared with other manufacturing processes.

For large lot sizes, deforming processes have production rates up to 5000 parts per hour. Similar to primary forming processes, deforming dies require setup times up to several hours, making deforming processes impractical for small–lot-size production.

The range of surface finishes achievable through deforming processes is similar to that of primary forming processes, with surface roughness down to 0.8 μm R_a for extrusion and cold rolling. However, hot forming processes such as hot rolling, where the workpiece is preheated to an annealing temperature, generally yield much higher surface roughness (up to 50 μm R_a) and will require secondary finishing operations. One benefit of parts produced through deformation is that the deformation process produces work hardening in the workpiece, which increases the mechanical strength of the part. However, excessive material deformation may lead to crack and overlap formation in the workpiece.

Deforming processes have a relatively low degree of flexibility compared with other manufacturing processes, since the kinematics of deforming machines are constrained by either motion, force, or energy. The geometry of the part is governed solely by the tool geometry, as in the case of primary forming. However, since deforming dies must move relative to the workpiece, the geometric features that are producible are limited.

1.3 Removing Processes

Mechanical material-removal processes are the backbone of industrial manufacturing practice. These processes provide a great deal of flexibility, since the geometry of the part is defined by the shape of the tool and the kinematics of the tool and workpiece. The material-removal mechanism is a very important aspect of removing processes. There are four types of material-removal mechanisms: mechanical, in which mechanical stresses are induced by a tool to overcome the strength of the material; thermal, in which the thermal energy provided by a heat source melts or vaporizes the volume of material to be removed; electrochemical, in which the electrochemical reactions induced by an electrical field destroy the atomic bonds of the material to be removed; and chemical, in which chemical reactions are employed to destroy the atomic bonds of the material to be removed.

Removing processes typically have greater flexibility in terms of the lot size, workpiece geometry and shape, and part quality achievable compared with other manufacturing processes. The machine and tooling costs associated with material-removal processes are low compared with primary forming and deforming processes. Machines typically cost from \$10 000 for manual equipment to \$80 000 for CNC (computer numerically controlled) equipment, while tooling cost ranges from \$1 to \$100 per tool. However, the skill level involved for programing or manually setting the tool and workpiece kinematics is relatively high, and so labor costs for operating material-removal processes are correspondingly high. Therefore, machining processes are better suited for low- to medium-volume production, with lot sizes ranging from one to several hundred parts.

The production rates for machined parts are much lower than for casting or deforming processes, since the tool is required to make multiple passes over the workpiece surface to produce the final shape. The material-removal rate is dependent on the surface quality desired, the workpiece material, the cutting-tool material, and the cutting fluid used. For steels, the material-removal rates can range from less than 1 mm^3/min for a grinding process up to the order of 10 cm^3/min for a milling process. However, time required for workpiece setup and fixturing (on the order of several minutes to one hour) is generally much less than that for primary forming and deforming processes.

Surface quality and surface technology are clearly very important aspects of material-removal processes. Surface *texture* can be described in terms of surface roughness, macro effects such as imperfections, and geometric considerations such as tolerances. On the other hand, surface *integrity* refers more to microstructured effects such as microcracks and residual stresses. Surface effects are caused both by the process itself and by the workpiece material properties. These effects have a direct influence on the mechanical characteristics of the workpiece and eventually on the reliability of the component.

Material-removal processes are among the most flexible of manufacturing processes. Since the geometry of the finished part is defined by the geometry and the kinematics of the tool and workpiece, material-removal processes can produce parts with a wide range of sizes, shapes, and surface quality. Milling, turning, and grinding span a large segment of achievable surface quality, exhibiting their flexibility and popularity in industrial practice. The surface generation mechanism in milling and turning explains the great flexibility of these processes in terms of creating a variety of surface qualities through the selection of process parameters. Another reason for the flexibility of material-removal processes is the number of degrees of freedom incorporated into material-removal machines. Current numerically controlled (NC) machining centers have up to nine translational and rotational degrees of freedom for a given tool-workpiece combination. Even in drilling processes, which are limited to one degree of freedom, a range of hole depths can be produced without changing tools.

1.4 Joining Processes

Joining includes a number of processes such as welding, brazing, soldering, adhesive bonding, and mechanical joining (Kalpakjian, 1989; Shey, 1987; Schwartz, 1979). Each of these is an integral part of modern manufacturing operations, as most products are impossible to make as a single piece. Indeed, joining processes offer the ability to manufacture a product as individual components and then combine them into a single product, which may be easier and less expensive than manufacturing the whole product at once. Many products must be taken apart for maintenance, repair, or service, so it is beneficial to join the components so they can be easily dismantled and reassembled. Joining processes also allow the inclusion of features and properties in a particular product which may differ from the majority of the components used in the product.

The capital and tooling costs associated with most joining operations are relatively low compared with other processes, since most joining equipment is inexpensive. A typical welding machine ranges in price from \$5000 to \$50 000. However, the skill level of operators is high, especially in operations where parts with complex geometries are joined; therefore the labor costs associated with joining processes can be high. Other costs such as tooling (welding nozzles) and material (adhesive, filler, and operating gas) are relatively low.

Joining processes are very labor-intensive, especially for adhesive bonding or joining parts with complex geometries. Most joining processes require preprocessing of the joining surfaces to minimize surface roughness, and a period of time after joining for curing of the bond or cooling of the weld. These factors result in low production rates for joining processes compared with forming, deforming, or removing processes.

The quality of joints is limited by the lack of effective methods for nonintrusive joint evaluation. In welding, the weld pool formation is accompanied by the propagation of a heat-affected zone, in which the microstructure of the material is changed by heating. Other types of defects common in joints include porosity, entrapment of contaminants in the joint, incomplete fusion or penetration, crack formation, surface damage, and residual stresses. However, effective use of joining techniques can produce joints with mechanical strengths that exceed those of their joining members.

Joining processes also have a high degree of flexibility in part geometry and lot size. Since most welding tools have several degrees of freedom, a wide range of sizes and shapes of parts that may be joined can be accommodated.

1.5 Material Properties Modification Processes

The manufacturing processes introduced above are primarily concerned with changing the shape of a workpiece. However, since all manufacturing processes involve interactions between many phenomena, including mechanical, thermal, acoustic, and electromagnetic, there are invariably secondary effects of the processes, including alteration of material structure and composition, which are unintentional results. In this section, the processes introduced have the intended purpose of changing the physical properties of the material while maintaining the basic geometry of the part.

The practicality of many processes often depends on the physical properties of the workpiece materials. Heat and surface treatment methods can substantially influence the properties of these materials. These treatments are particularly useful with metals. Heat treatment permits the modification of the mechanical properties of metals, within certain limits, and is usually used to create suitable conditions for subsequent manufacturing operations and for the final use of the component.

The capital and operating costs of heat and surface treatment equipment can be high, with modern furnaces costing on the order of several hundred thousand dollars. Computer control on modern furnaces reduces the labor cost by minimizing the need for skilled human control of process parameters. The fuel or electrical consumption on furnaces is relatively high compared with other types of machine tools.

Since heat treatment processes require elevation of workpiece temperature, a significant amount of processing time may be required to heat the workpiece, maintain an elevated temperature, and cool the workpiece to room temperature. Also, the startup time for conventional furnaces may take several hours. As a result, heat treatment processes can constitute a significant portion of the total production time of a part. However, the improvement in mechanical properties of heat-treated parts may eliminate the need for using a more expensive material.

Surface and heat treatment processes are typically used to improve the quality of the part through material hardening (up to 65 Rockwell hardness C), relief of residual stresses, and coating of the workpiece with a material which has favorable properties. The treated region usually extends to 0.05–1 mm below the workpiece surface. Incorrect heat treatment of any metal alloy can lead to defects such as the formation of a coarse grain, surface burning, or surface decarborization. Coarse grains may be caused by overheating or by being held too long at the annealing temperature. Surface or skin decarborization occurs in steels as a result of the diffusion of carbon into the atmosphere because of excessively long annealing times. Often the burn structure is a defect which cannot be overcome. Heat treatment processes carried out at too high a temperature may lead to irreversible oxidation of the grain boundaries, which weakens their material cohesion, decreasing strength and rendering the material unusable.

Surface and heat treatment processes can accept a wide range of part geometries and sizes for processing, since there is no contact between a tool and the workpiece. However, in most conventional processes, the size of the part acceptable for processing is limited to the size of the oven or furnace used for treatment. Some state-of-the-art processes such as laser surface treatment eliminate this restriction by directing a heat source such as a laser beam at the workpiece and scanning the heat source along the workpiece surface.

1.6 Process Attribute Comparison

The applicability of the criteria that form the manufacturing tetrahedron discussed earlier to each class of manufacturing processes is shown in Table 1. The comparison illustrates the nature of the tradeoff between the manufacturing attributes for any manufacturing process. Selection of an appropriate process often depends on a balance of all four criteria based on the requirements for making a desirable product in an efficient and profitable manner. For example, if the primary concern is production rate, then primary forming and deforming processes should be considered. However, if many different part types with small batch sizes are to be produced in the same facility, then removing and joining processes are more appropriate. Finally, if the quality of the part is of prime concern, material removal and material property modification processes should be incorporated as secondary operations.

2. MANUFACTURING EQUIPMENT

Machines and manufacturing equipment are basically the "embodiment" of processes, while machine tools are the "building blocks" of manufacturing systems. The term "manufacturing equipment" covers a large variety of devices and machines, ranging from hand tools to complex automated machining centers, encountered in modern production facilities. This section emphasizes machine tools because they may be the most important elements of manufacturing systems, particularly in discrete parts manufacturing. Manufacturing equipment, and particularly machine tools, have been used in industrial production for over 100 years; the evolution during this period has been quite remarkable. Indeed, considering the example of the lathe (Fig. 2), one can notice that in the first decade of this century, a typical lathe was powered by a motor positioned outside of the machine itself. This configuration forced the machine to remain fixed at the site of installation and prevented easy relocation. In the 1920s, the motor became an integral part

Table 1. Characteristics of the classes of manufacturing processes.

	Forming	Deforming	Removing	Joining	Modifying
Cost	High tooling/ low labor cost	High tooling/ low labor cost	Medium tooling/ high labor cost	Low capital/ high labor cost	Medium to high capital/low labor cost
Production rate	High	High	Medium (milling) to low (grinding)	Medium (welding) to low (adhesives)	Low
Quality	Medium to low	Medium to low	Medium to high	Medium to low	High
Flexibility	Low	Low	High	High	Medium to high

of the machine, which allowed an easy relocation of the machine in case of a factory reorganization and also provided a stiffer machine that could achieve a higher production rate. In the 1960s, machine tools were produced with completely enclosed frame to obtain greater stiffness, and often included template and stylus for the purpose of copying a complex shape onto the workpiece. The lathes of the 1970s and 1980s became numerically controlled, with the ability to be programmed with the help of microcomputers (Figs. 3 and 4). There is a synergism between manufacturing processes and the equipment that performs them. Developments in manufacturing processes and materials have substantially influenced the evolution of machines. The introduction, for example, of new cutting-tool materials continuously increased the cutting speeds attainable in machining operations. Thus, machines had to be properly designed in order to accommodate the need for higher cutting speeds and production rates.

Manufacturing equipment, particularly machine tools, is the critical link between intermediate products formed from raw materials and finished discrete parts and components. These components are then assembled either into end products or into yet

other machines that will in turn make end products. Thus, virtually every manufactured product is built either directly or indirectly by machine tools (M.I.T., 1989). It is this position at the heart of the manufacturing infrastructure that makes manufacturing equipment and the machine tool industry so critical to a nation's manufacturing competitiveness and productivity. Furthermore, exporting has made the machine tool industry a global one; while less than 30% of world production of machine tools was exported 20 years ago, by 1976 exports were nearly 43% of production, and now they are close to half.

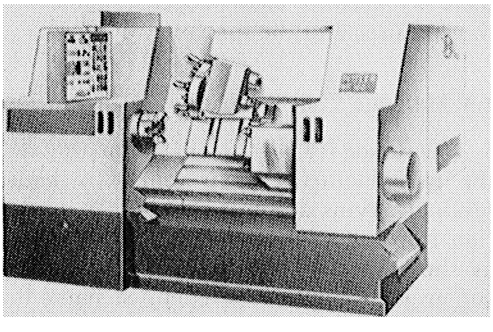

FIG. 4. Numerically controlled automatic lathe with drum turret (from Weck, 1984).

2.1 Machine Tool Types

In general, a machine tool can be defined as a nonportable machine, with an integral power source, that causes the relative motion of a tool and a workpiece in order to produce a predetermined geometric form or shape. This "narrow" definition primarily reflects the two major classes of machines: deforming (or forming) and removing (or cutting) machines. However, machines used for primary forming processes such as casting, and joining processes such as welding or assembly, can also be regarded as machine tools.

In order for machine tools to be successfully integrated into the production process, a number of criteria must be met. In modern manufacturing systems, quality is a major concern and may be the primary driving force in machine tool design, development, acquisition, and operation. Quality in machine tools falls into two categories: accuracy in geometric and kinematic terms, under static, dynamic, or thermal loading; and reliability, or the behavior of the machine over an extended period of time. Related to these characteristics are maintainability, work-space accessibility, and safety. Modern machine tools are expected to operate with accuracy on the order of microns in a wide range of loading conditions, some of which may exceed several tons. This accuracy, combined with the high velocity with which the machine tool elements must move in order to achieve required production rates, presents a formidable design and manufacturing challenge.

Cost is also an important factor, since machines typically represent a high capital investment which can reach into the order of billions of dollars for mass production systems typically in the automotive industry. Often, both cost and quality of the machine are determined by its degree of automation. Over-automated machines may be unreliable, while machines that are under-automated may have low production rates. Furthermore, the degree of automation often determines the degree of flexibility. Highly automated machines or systems such as transfer lines provide a very high production rate but limit product and operational flexibility. Thus, automation of machine tools should strike a balance between cost, quality (particularly reliability), and flexibility. In general, product flexibility is high among metal removing machines and relates to the "envelope" of the machine, namely the maximum and minimum dimensions of the parts that the machine can handle, and the accuracy range of the different motion axes of the machine.

Machines usually need to satisfy safety and environmental requirements. For example, machine tools that operate at high noise levels may be required to be encapsulated as a safety and environmental measure. Safety-related issues have the highest priority and can influence the design of a machine tool considerably. However, safety considerations often have a detrimental effect on the efficiency or productivity of a machine tool.

2.2 Machine Tool Design and Analysis

Machine tool design, in terms of overall structure and kinematics, is dictated primarily by the process to be performed by the machine. The design is also substantially influenced by the range of workpiece sizes, the required accuracy, operation mode (manual, semimanual, fully automated, etc.), maintenance procedures, cost, and a host of other factors related to the requirements and attitudes of the machine end user. Since machine tools are complex electromechanical structures which include many interconnected devices, their design involves a number of disciplines ranging from applied mechanics to ergonomics. This unique level of complexity, coupled with strict requirements in terms of kinematic accuracy, static and dynamic behavior, etc., causes the machine tool design process to rely heavily on empirical knowledge and expertise. Engineering analysis is typically confined to the identification of trends and the creation of a framework for machine design, instead of delivering exact solutions for the structure of the machine, the size of its components, etc. In general, stand-alone machines are designed to accommodate a variety of conditions in terms of workpiece size, etc., while dedicated machines such as transfer lines are designed for reliability rather than flexibility.

Examining the historical development of machine tool designs and their slow evolution, one must consider two factors: first, machines require a large initial capital investment, and second, the production and ultimately the revenues of the end user depend on the machine's proper functionality. An experimental, unproven machine design usually involves a high risk of not achieving the required production quotas, which may explain the conservative attitude of many machine tool builders throughout the world in terms of introducing radically new ideas in their machine tool designs. On the other hand, the lack of an innovative approach to machine tool design may lead to a loss of competitive advantage. The correct attitude in machine tool building is to strike a balance between new ideas for the future and well-proven designs of the past. Furthermore, since machine tool design substantially influences the production capabilities of the end user, there is a need for close cooperation between the end user and the machine tool builder.

2.3 Machine Tool Control and Automation

One reason for introducing automation into the manufacturing environment is higher productivity as a result of a higher production rate. In mass production systems such as those used in the automotive and consumer-goods industries, complex parts that would take a few hours to manufacture in manually or semi-automated systems can be made in seconds by automated systems such as transfer lines. Such "hard-wired" automation is designed to reduce material handling time, or the time the part spends between operations. In the metalworking industry, parts often spend only 5–15% of their time in added-value operations, while the rest is spent in handling and waiting. Automation may considerably increase the production rate of the system, but it also increases the required capital investment and substantially reduces the product, operation, and volume flexibility of the system.

Another motive for introducing automation is more consistent quality. This objective involves eliminating human errors and inconsistencies, which result in quality deviations. Manually performed manufacturing processes are influenced by the skills and abilities of the human operator, and so the quality of the finished parts also depends on the skill and ability level of the operator. Implementing automation for the purpose of consistent quality may reduce the flexibility of the system, however, since humans are one of the most flexible factors in the production process. Finally, better work content motivates the proliferation of automation. Repetitive or hazardous tasks can be automated to relieve humans. This "humanistic" automation also streamlines the production process, making it more efficient.

Since the introduction of automation provides higher productivity while, in general, reducing flexibility, considerable research and development have been devoted to the area of "flexible automation," which provides high production rates and consistent quality, while being flexible enough to accommodate a variety of tasks. Two results of these efforts are the establishment of Flexible Manufacturing Systems (FMS) and the introduction of robots that can be programed to perform different tasks.

2.4 CAD/CAM

The basis of any manufacturing effort is the design drawing. Painstakingly prepared drafts and blueprints are used in every step of a product's inception, design, and construction. But like the old-fashioned office, drafting is paperbound and is very labor intensive. Unlike the electronic data in a computer, paper drawings cannot be manipulated, processed, and quickly analyzed.

CAD can be most simply described as "using a computer in the design process." In the design process, a computer can be used in both the representation and the analysis steps. The application of CAD for representation is not limited to drafting. Three-dimensional wire-frame modeling, boundary representation (B-rep) modeling, and solid modeling are presentation methods available to CAD users. To aid in engineering analysis, there are packages that perform kinematic simulation and finite-element modeling for different engineering analyses. CAD systems frequently consist of a collection of many application modules under a common database and graphics editor.

A CAD system is a tool used to automate design work. Instead of using a pencil and paper, the designer uses a sophisticated computer graphics display. A light pen is used to draw on the monitor screen or to extract lines, curves, and shapes from the computer's memory. Solid shapes called from a computer library of geometric primitives can be assembled to form complex shapes. A CAD system can eliminate the tasks of searching through blueprint libraries, transcribing what has been drawn before, or redrawing existing figures or part assemblies. Using simple commands, a designer can display a cutaway of a part, a closeup view, or an exploded view of all the parts in an assembly. Using a CAD system, the complete geometry of a part can be visualized without the necessity of viewing different layers of a drawing. Any product or part that was drafted on paper can be drafted using a CAD system. Some CAD systems are more complex than others, and the design capabilities are limited by the machine itself. However, even the most limited CAD system typically offers significant productivity gains over traditional manual methods of drawing.

A CAD/CAM system is the application of a computer to the manufacturing process, in addition to its use in the design process. Similarly to CAD, CAM is a tool used to automate manufacturing. The manufacturing of a workpiece can be aided with computers at any stage of manufacturing, from the process planning to the system planning. Ideally, a CAM system can work in conjunction with a CAD system to allow a direct link (via computers) from the desk of a designer to the workbench of a shop floor. Current problems

with CAD/CAM systems involve the interface between the two systems. Different CAD systems have different methods of representing dimensions, and translation from CAD to CAM is difficult and often requires a human interface. This problem will diminish as improved methods of translating geometric representation for CAM systems develop and as CAD systems become more standardized.

2.5 Process Control

From a control perspective, a manufacturing process is easily modeled as an input-output (I/O) function as shown in Fig. 5. Notice here that this block includes both the actual material transformation process and the equipment supplying and modulating the transformation power. The outputs from any manufacturing process are by definition the geometry and properties of the product. The input is that set of equipment variables that have a clear and deterministic causal effect on the output, and the input-output relationship is parametrized by the characteristics of the workpiece material, the working environment or boundaries, and the basic characteristics of the equipment in use. The *raison d'être* for process control is the rejection or elimination of disturbances that typically arise from parameter variations; primary among these are the uncertainty and variation in the material properties. Uncertainties also arise from the inability to model precisely, in sufficient detail, the physics of most three-dimensional manufacturing processes.

From this process block, a generic manufacturing process control-block diagram can be drawn as in Fig. 6. The essential features of this diagram are the dominant time constant t_p of the process and the delay characteristics T_d of the feedback. The time constant represents either the process dynamics or the cycle time of the process for completion of a single product. The measurement delay is used to delineate various forms of process control. These are summarized in Table 2. While there are much more detailed differences among these various approaches (see, for example, Box and Kramer, 1990, where a detailed comparison of statistical process control and feedback control is presented), Table 2 illustrates that all processes are subject to some type of feedback control, either automatic or human operated, and even "no control" involves feedback in the form of customer complaints or warranty recalls.

Clearly, therefore, the choice of control method to be used involves factors such as the volume of parts (since low volumes cannot tolerate low control bandwidths, for example), the flexibility of the equipment, and the overall sensitivity of the process.

2.6 Sensing Techniques and Devices

The overall goal of automation for manufacturing processes necessitates the estab-

$T_d \sim$ months	Warranty recall

lishment of control loops by providing some feedback information about the state of the manufacturing process. This function is carried out by human supervision in conventional process control. With increasing automation, effective sensor systems are needed in order to achieve the automatic control, supervision, and error recovery tasks required to realize the full potential of intelligent manufacturing. Process sensors can be divided into three categories according to their function: tool monitoring, workpiece monitoring, and machine performance monitoring.

In the conventional case, most of the sensing functions are fulfilled by human perception and evaluation. The push toward untended machining and "lights-out" factories requires high levels of automatic machine monitoring. A sensor system must reach at least the level of effectiveness of the human sensing capabilities in order to replace a human operator. Sensors having sensing and processing capabilities equal to or exceeding those of humans can be called "intelligent" sensors.

3. MANUFACTURING SYSTEMS

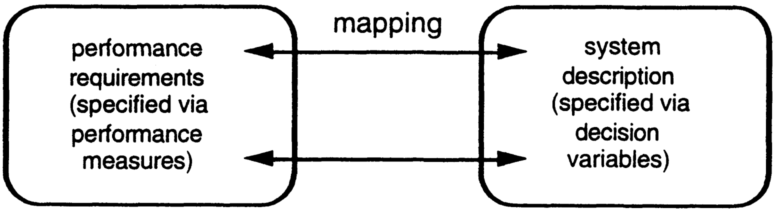
The manufacture of products in the modern industrial world requires the combined and coordinated efforts of people, machinery, and equipment. Thus, a manufacturing system can be defined as a combination of humans, machinery, and equipment that are bound by a common material and information flow. The materials input to a manufacturing system are raw materials and energy. Information is also input to a manufacturing system, in the form of customer demand for the system's products. The outputs of a manufacturing system can likewise be divided into materials, such as finished goods and scrap, and information, such as measures of system performance.

In general, manufacturing system design can be conceptualized as the mapping from the performance requirements of a manufacturing system, as expressed by values of certain performance measures, onto suitable values of decision variables, which describe the physical design or the manner of operation of the manufacturing system (Fig. 7).

A performance measure is a variable whose value quantifies an aspect of the performance of a manufacturing system. Performance measures are either *benefit* measures (the higher the better) or *cost* measures (the lower the better). Like manufacturing attributes, they can be divided into the four categories time, quality, cost, and flexibility. In general, a number of performance measures will be relevant for a given manufacturing system. However, these will differ from one manufacturing system to another.

Given performance requirements, the manufacturing system designer must describe a suitable system design. This design can be captured numerically by specifying the values of an appropriate collection of *decision variables*. An example of a decision variable is the number of each type of machine in a manufacturing system.

Designing manufacturing systems (mapping performance measures onto decision variables) is a difficult task because:



mapping
performance requirements (specified via performance measures)
system description (specified via decision variables)

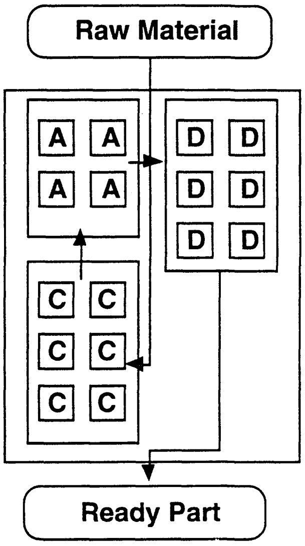
FIG. 7. The manufacturing system design problem.

- Manufacturing systems are large and have many interacting components.
- Manufacturing systems are dynamic.
- Manufacturing systems are open systems, which influence and are influenced by their environment.
- The relationships between performance measures and decision variables usually cannot be expressed analytically. Well-behaved functions do not apply.
- Data may be difficult to measure in a harsh processing environment.
- There are usually multiple performance requirements for a manufacturing system, and these may conflict.

Assuming that these difficulties can be surmounted, the next task is the construction of the actual manufacturing system. As this process is very capital intensive, it places a premium on the cost performance measures of the manufacturing system. No matter how worthy its performance in other aspects, a manufacturing system will never be constructed if it is not shown to be financially viable. The potential benefits of a well-designed production system include (Choobineh, 1986) low work-in-process; inventories; increased production rate; few fixtures, jigs, and tooling; improved product quality; reduction of floor space used; and reduced labor costs.

3.1 Design of Manufacturing Systems

In industrial practice, there are five general approaches to structuring the processing area: the job shop, project shop, cellular system, flow line, and continuous system. In a job shop, machines with the same or similar material processing capabilities are grouped together. The lathes form a turning work center, the milling machines form a milling work center, and so forth. The machines are usually general-purpose machines that can accommodate a large variety of part types. In this structure, the part or lot of parts moves through the system by visiting the different work centers according to the part's process plan (Fig. 8). Material handling must be very flexible in order to accommodate many different part types, and so it is usually done by manually controlled implements such as forklifts and handcarts. Within each work center, a number of machines can be used for a particular operation. This is advantageous for a number of reasons:



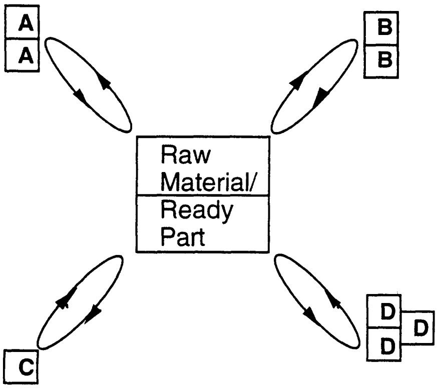
Machines/Resources are grouped according to the process they perform
Letters refer to individual machines/resources

FIG. 8. Schematic of a job shop.

1. Each operation can be assigned to a machine which yields the best quality or the best production rate;
2. machines can be evenly loaded; and
3. machine breakdowns can be accommodated easily.

These advantages are particularly evident when the job shop's work load includes a large variety of different parts with different process sequences. However, fully exploiting the flexibility of a job shop requires making and implementing complex decisions in real time. For example, when a machine becomes available after finishing an operation, which of the possibly many eligible operations should it perform next? Furthermore, lack of decision-making coordination among the work centers can impede the smooth flow of parts from work center to work center. This results in parts spending a long time in the job shop and creates high inventory levels.

In a project shop (Fig. 9), a product's position remains fixed during manufacturing because of its size or weight. Materials, people, and equipment are brought to the product as needed. Facilities organized as prod-



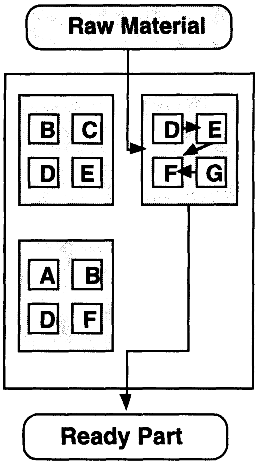
Machines/Resources are brought to and removed from stationary part as required

Letters refer to individual machines/resources

FIG. 9. Schematic of a project shop.

uct shops can be found in the aircraft and shipbuilding industries and in bridge and building construction.

In manufacturing systems organized according to the cellular plan (Fig. 10), the equipment or machinery is grouped according to the process combinations that occur in families of parts. Each cell contains machines that can produce a certain family of parts. The material flow within the cell may differ for different parts of a part family. Intracellular material flow can be performed either automatically or manually. By confining the path of each part to an individual cell within the manufacturing system (when possible), cellular systems enable each cell to be considered independently for detailed scheduling purposes, thus greatly simplifying this type of decision. Transportation times and the times spent in the system for the different parts are reduced compared to those of the job shop.

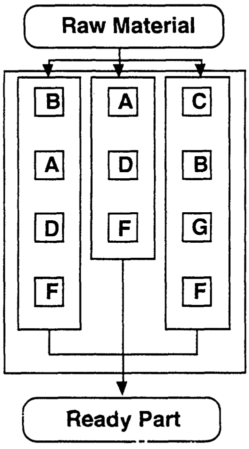


Machines/Resources are grouped according to the processes required for part families

Letters refer to individual machines/resources

FIG. 10. Schematic of a cellular manufacturing system.

The fourth way of structuring a manufacturing system is to create a flow line in which the machines and other equipment are ordered according to the process sequences of the parts to be manufactured (Fig. 11). A typical example is the transfer line, which is often used in the automotive industry. A transfer line consists of a sequence of machines each of which is dedicated to a particular operation or a particular part. Only one part type is produced at a time. Setup for the production of a new part type, if possible at all, takes hours or even days. The machines are linked by automated material-handling devices such as conveyors. The structure of a transfer line presupposes that there is a well-defined, rigid process sequence for the different parts, and that the lot size of each part is high enough to guarantee that the capacity of the equipment will be fully exploited and not wasted on setup.



Machines/Resources are grouped in lines according to the operation sequence of one or more part types

Letters refer to individual machines/resources

FIG. 11. Schematic of a flow line.

In the actual manufacturing world, these standard system structures often occur in combinations, or with slight changes. The choice of a structure depends on the design of the parts to be manufactured, the lot sizes of the parts, and market factors such as the required responsiveness to market changes. In general, job shops and project shops are most suitable for small–lot-size production, flow lines are most suitable for large–lot-size production, and cellular systems are most suitable for production of lots of intermediate size. Job shops are most suitable for the low-volume production of multiple part types that are very dissimilar. They possess general-purpose machines and flexible, manual material handling, which are ideal for this situation. Cellular systems are most suitable for the manufacture, in low-to-medium production volumes and lot sizes, of part types with enough similarity to be clustered into part families. Flow lines are best suited to the high-volume, high–lot-size production of a single part type or a few very similar part types. This is a consequence of dedicated machines and material-handling equipment.

Another substantial part of a manufacturing company's production facilities is the assembly system. Assembly systems can be categorized according to the motion of parts and workplaces. Stationary part systems are usually employed for large assemblies, such as airplanes, which are difficult to move around. Moving part systems can be divided into stationary workplace systems, in which parts are brought to stationary workplaces, and moving workplace systems, in which the workplaces move along with the parts.

The fundamental activity in design is decision making: The design of a manufacturing system is the process of deciding the values of the decision variables of the manufacturing system, where the decision variable might be, for example, the number of lathes. Methods and tools which are useful for making design decisions fall into three broad categories: operations research, artificial intelligence (*q.v.*) and simulation. The divisions between these categories are fuzzy. For example, simulation is often considered to be an operations research tool, while the mathematical programs of operations research are solved using search methods studied in artificial intelligence. The categories are an organization convenience; in truth, they overlap to a considerable extent.

3.2 Operation of Manufacturing Systems

The operation of a manufacturing system is the complex task of planning the material and information flows in the system. Proper material flow is what enables a manufacturing system to produce products on time and in sufficient quantity. It is a direct consequence of the system's information flows: *Command* information from human planners or from planning software prescribes the material flow in the system, while *sensory* information about the status of the system's resources is used to decide on the appropriate commands. The fundamental activity in the operation of a manufacturing system is thus determining the commands that prescribe the material flow in the system.

Command information flows can be organized into a bilevel hierarchy. High-level commands dictate the flow of materials *into* the manufacturing system. Therefore, they determine the system's workload—namely, how many of each type of part to manufacture in each time period. The time periods involved are typically long, on the order of days or weeks. For this reason, the decision-making activity of generating high-level commands is called *long-term planning*. Planning is concerned with determining the *aggregate timing of production* (when to produce and what quantities to produce).

Low-level commands dictate the flow of materials *within* and *out of* a manufacturing system. They determine which production resources are to be assigned to each operation on each part and when each operation is to take place. The role of lower-level commands is to resolve contention for the resources of a manufacturing system. This contention occurs among the parts released into the system as a consequence of long-term planning decisions. Since low-level commands control individual operations, they must be generated much more frequently than high-level commands. The time between commands is typically on the order of seconds or minutes. For this reason, the decision-making activity of generating lower-level commands is called *short-term dispatching*. Dispatching is concerned with the *detailed* *assignment of operations to production resources.*

Long-term planning and short-term dispatching are collectively labeled, in broad terms, as "production scheduling." We use the specific terms "(long-term) planning" and "(short-term) dispatching" when possible for greater precision.

Academic research in production scheduling has been based primarily on operations research techniques (see OPERATIONS RESEARCH) (more specifically, mathematical programming). Recently, many research efforts have employed artificial intelligence techniques, especially rule-based systems (see ARTIFICIAL INTELLIGENCE). Unfortunately, the use of academic results in industry has been minimal; many academic approaches make assumptions that do not reflect reality. Actual manufacturing environments are extremely variable, and usually cannot be rigidly classified into one of the classical scheduling models often assumed in academic research. In perhaps no other field is the dichotomy between academic research and actual practice more pronounced.

The academic literature contains an abundance of theoretical work on a number of classical scheduling problems. The entities to be scheduled are typically referred to as *jobs*. Usually, each job corresponds to an individual part. The individual production operations that make up a job are referred to as *tasks*. Classical scheduling problems can be categorized on the basis of requirements generation, processing complexity, scheduling criteria, and scheduling environment. *Requirements* are generated either directly by customers' orders or indirectly by inventory replenishment decisions. This distinction is often made in terms of an *open shop* versus a *closed shop*. In an open shop, all jobs are by customer request and no inventory is stocked; production scheduling becomes a *sequencing problem* in which tasks corresponding to the requested jobs are sequenced at each facility. In a closed shop, all customer requests are serviced from inventory and jobs are generally a result of inventory replenishment decisions. For a closed shop, production scheduling involves lot-sizing decisions associated with the inventory replenishment process in addition to sequencing. Depending on how the requirements are generated, the specification of the requirements may be termed as *deterministic* or *stochastic*. For example, in an open shop the processing time for each task of a job may be deterministic if it is known, or may be stochastic if it is a random variable with a specified probability distribution. Similarly, in a closed shop the customer demand process, which drives the inventory replenishment decisions, may be assumed to be stochastic or deterministic.

Processing complexity is concerned with the number of tasks associated with each job and is often classified as one-stage, one processor (facility); one-stage, parallel processors (facilities); multistage, flow shop; and multistage, job shop. In the one-stage, one processor problem, which is also known as the one-machine problem, all jobs consist of one task which must be performed on the one production facility. The one-stage, parallel processors problem is similar to the one-machine problem except that the jobs, which still contain a single task each, may be performed on any of the parallel processors. For the multistage problem, each job requires processing at a set of distinct facilities, where there is a strict precedence ordering of the tasks for a particular job. The flow-shop problem assumes that all jobs are to be processed on the same set of facilities with an identical precedence ordering of the tasks. In the job-shop problem, there are no restrictions on the task sequence for a job, and alternative routings for a job may be allowed. The $n/m/A/B$ notation is often used to represent processing complexity, where

n is the number of jobs. Each job is assumed to consist of a number of tasks.
m is the number of resources (machines).
A describes the flow pattern or discipline within the system. When $m = 1$, A is left blank. A may be
  F for the flow-shop case, i.e., the machine order for all jobs is the same.
  P for the permutation flow-shop case. Here not only is the machine order the same for all jobs, but the job order is the same for each machine. Thus, a schedule is completely specified by a single permutation of the numbers $1, 2, 3, \ldots, n$, giving the order in which the jobs are processed on each and every machine.
  G for the general job-shop case where there are no restrictions on the form of the technological constraints (constraints

on the order in which the machines may process the jobs or the order in which the jobs may visit the machines).

B describes the performance measure by which the schedule is to be evaluated.

As an example, *n/2/F/(total production time)* represents the *n*-job, two-machine, flow-shop problem where the aim is to minimize the total production time of the *n* jobs.

Scheduling criteria are measures by which schedules are to be evaluated, and may be classified broadly into schedule costs and schedule performance measures. Schedule costs include fixed costs associated with production setup or changeover, variable production and overtime costs, inventory holding costs, shortage costs for not meeting deadlines or for stocking out, expediting costs for implementing "rush" jobs, and costs for generating the schedule and monitoring the progress of the schedule. Common measures for schedule performance are the utilization level of the production resources, the percentage of late jobs, the average or maximum tardiness for a set of jobs, and the average or maximum flow time for a set of jobs.

Tardiness is the positive part of the difference between a job's actual completion time and its desired completion time. The flow time for a job is the difference between the completion time of the job and the time at which the job was released to the manufacturing system. In most production environments, the schedule evaluation is based on a mixture of both cost and performance criteria.

The *scheduling environment* deals with assumptions about the certainty of information regarding future jobs and can be classified as being static or dynamic. In a static environment, the problem contains a finite set of fully specified jobs; no additional jobs will be added to this set, and none of the jobs in this set will be altered. In a dynamic environment, the problem contains not only an initial set of known jobs but also additional jobs which arrive over future time periods. The scheduling problem in most production environments is stochastic and dynamic; however, most models for scheduling problems are deterministic and static (Graves, 1981).

Scheduling methods that either give some guarantee as to the insensitivity of the schedule to future disruptions or explicitly reflect the uncertain nature of the available information are the objective of control theory (Rodammer, 1988). Control theory attempts to command material flow in a way that is robust with respect to disruptions such as machine failures, operator absences, material shortages, and surges in demand (Akella *et al.*, 1984; Gershwin *et al.*, 1986), and with respect to the absence or inaccuracy of status information (Abraham *et al.*, 1985). Control theory views scheduling as a dynamic activity (Fig. 12) where the production scheduling problem is really one of understanding how to reschedule (Rodammer, 1988). The system under control operates on a sequence of inputs $u(t)$, yielding a sequence of outputs $y(t)$. The outputs at any time are a function of the state of the system $x(t)$, where the state $x(t)$ of the system is a function of the inputs $u(t)$. A general statement of the control problem is to determine a means to guide the system state (and thus the system output) through time according to some trajectory that satisfies the constraints of the system (e.g., maximum number of working hours per week) and that simultaneously satisfies some set of performance criteria.

The inputs to a manufacturing system include production orders, raw material and labor, disturbance inputs, and controlled inputs. Production orders specify the quantities of various jobs to be processed and the dates at which these jobs are due. Disturbance inputs include machine failures and labor outages, over which the scheduler has little influence. Controlled inputs include scheduling, maintenance, and overtime decisions, which the scheduler can regulate within bounds. The state of a manufacturing system defines the levels for all completed and partially completed jobs, the status of all machines (whether active, idle, or under repair), the availability of labor, and the inventories for all materials. Outputs of the manufacturing system may be defined as any portion of the state—for example, the inventory levels of all jobs ready for shipment on a specified date (Fig. 12).

Since the formulation of the production scheduling problem using control theory is relatively recent, adequate tools for solving it are still the subject of continuing research (Rodammer, 1988; Ho, 1984; Suri and Dille, 1984). Artificial intelligence (AI) techniques, in particular rule-based systems, have been

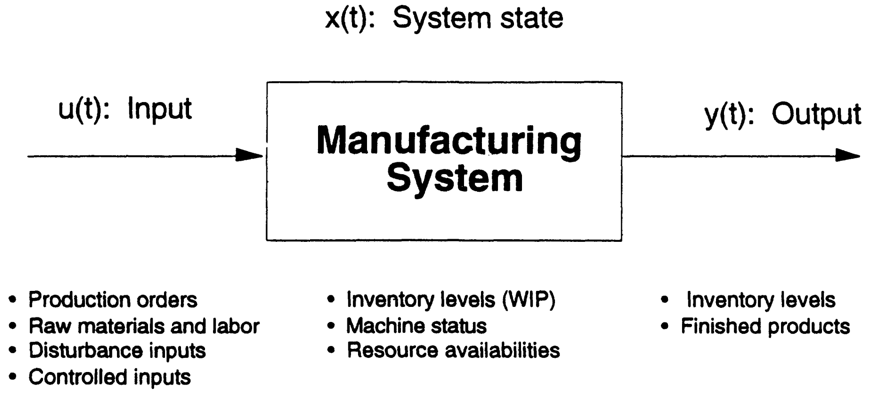


FIG. 12. A Manufacturing system from a control theory perspective (from Rodammer, 1988).

a recent focus of academic research in production scheduling. Rule-based systems seek to capture generic scheduling rules that are applicable to a wide range of situations. In general, these rules must be tailored to meet specific system requirements (Bensana *et al.*, 1988). Knowledge in a rule-based system can be classified into static knowledge (or data) and dynamic knowledge (or solution methods). Static knowledge includes all information about the manufacturing system itself (e.g., the number and types of machines) and the production objectives (e.g., the part types to be produced, along with their processing sequences, quantities, due dates, etc.). Dynamic knowledge describes available expertise about how to derive feasible schedules and consists of theoretical expertise, which refers to operations research techniques that deal with the management of time and resources; empirical expertise, which consists of heuristic dispatch rules; and practical dedicated expertise, which is provided by experienced shop floor supervisors who are aware of the constraints that have to be taken into account when preparing the schedule. In a rule base, these types of expertise are captured in the form of rules. They are invoked by higher-level rules that select a particular type of expertise on the basis of the status of the manufacturing system and the production scheduling problem to be solved.

In industry, it is customary to divide the operation of a manufacturing organization into three major levels (Fig. 13): strategic planning, operations planning, and detailed planning and execution (Anthony, 1965). At the strategic level, few decisions are made, but each decision takes a long time, and its impact is felt throughout the organization. At the detailed planning and execution level, many decisions are made, each requiring a much shorter time. Although the impact of each decision is local in time and in place, the great number of decisions, taken together, can have a significant impact on the performance of the organization. The characteristics of decisions at the operational planning level lie between those of the other two levels.

Strategic planning is performed by the top management of the organization. Several basic questions are asked and answered at this level, including "What is our business?" and "How will we compete?" At this level, the decision is made as to which manufacturing system structure (flow line, cellular system, job shop, project shop, or continuous system) is most consistent with the organization's overall strategy. Furthermore, a timetable is established for the major activities of the organization, such as the entry into a new market or the acquisition of additional manufacturing capacity. Finally, performance measures are established for the organization, such as return on investment, market share, earnings, growth levels, and so forth.

The resulting overall corporate strategy is used to guide the development of functional plans, primarily the marketing plan, the financial plan, and the manufacturing plan. The marketing plan specifies how the organization will compete in the marketplace. Included in this plan are forecasts of dollar sales and unit sales, and descriptions of distribution channels. Similarly, the financial plan

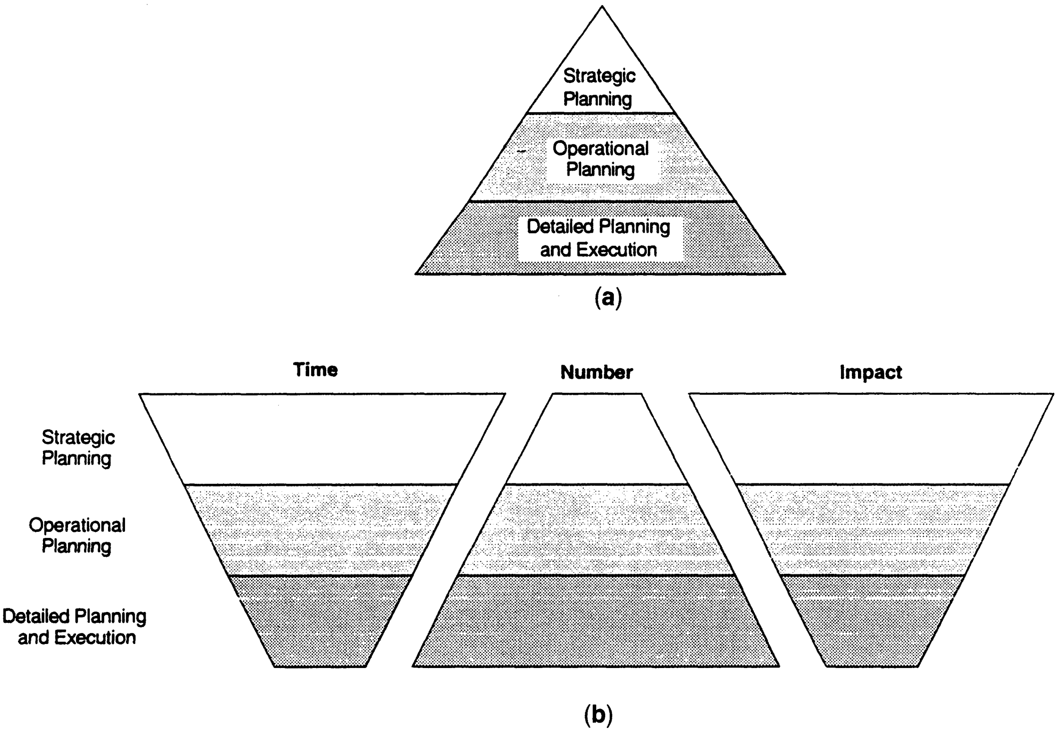

FIG. 13. (a) The levels of manufacturing operation and (b) the characteristics of decisions made at each level.

specifies the role that finance will play in the overall corporate strategy. Included are plans for cash flow and capital expenditures. Finally, the manufacturing plan specifies what manufacturing resources will be needed, how the resources will be deployed, and how much is to be produced. The output component of the manufacturing plan is stated in aggregate terms, such as annual or quarterly units of production, for each major product line (Berry *et al.*, 1979). This plan also sets guidelines and policies within which manufacturing is expected to perform. Ideally, any conflicts in strategies and policies among functions will be solved at the strategic level. Once acceptable strategic functional plans have been developed, the next step is to develop a more detailed operations plan.

In operational planning, the objectives of the strategic manufacturing plan are converted into more detailed and specific plans. One of the most important of these plans is the master production schedule (MPS). The MPS is expressed in specific product configurations, quantities, and dates and is frequently the key link between top management and the manufacturing facility. It is also a key link between manufacturing and marketing and serves to balance the demands of the marketplace against the constraints of the manufacturing facility.

The master production schedule is one of the inputs to material requirements planning (MRP). The other inputs to MRP include, for each type of final product, the existing inventory level, bill of materials, and the production time or order lead time for each individual component. A bill of materials lists the subassemblies of a final product and the individual components that constitute each subassembly. The output of MRP is a plan that describes the quantity of each individual component or subassembly to order or to begin producing in each time interval. Since the generation of the material plan requires a vast amount of data processing when many part types with possibly many layers of subassemblies are involved, it is usually handled by computer programs called MRP systems. MRP systems calculate material requirements on the basis of infinite capacity, meaning that the production and assembly times assumed for individual components and subassemblies do not incorporate waiting times due to resource contention.

Neither of the planning activities introduced thus far, master production scheduling and material requirements planning, incorporates any consideration of whether the manufacturing system has enough capacity to achieve the demanded levels of production. This is the role of capacity planning. Capacity planning provides projections of the capacity needs implied by the material plan, so that timely actions can be taken to balance the capacity needs with available capacity. In general, four variables may be adjusted to balance required and available capacity: inventory levels, the number of shifts worked, the quantity of resources used for production, and the amount of orders accepted for production. The first three options adjust the effective available capacity of the manufacturing system to fit the required capacity. The last option results in the modification of the master production schedule, which in turn results in a more feasible material plan. It adjusts the "required" capacity to meet the available capacity.

The third and final level of planning is the detailed planning and execution level. The shop-floor control system is the main operational system at this level. The shop-floor control system is responsible for detailed planning, such as determining the priority sequence of orders in a queue, and for monitoring the execution of the detailed plans, such as capacity use at the machine center (i.e. input/output control). The shop-floor control system is also responsible for collecting data from the shop floor and directing a flow of information back up to the operations planning level. After interpretation and aggregation, this information will pass from the operational level to the strategic level (Fig. 14).

Master production scheduling is a form of aggregate planning. Typically, it considers only finished products, not the individual components which make up those products. The objective of master production scheduling is to develop an aggregate production schedule that will meet seasonal requirements for finished products and at the same time minimize the incremental costs incurred. It is important to identify and measure these costs so that alternative master production schedules may be evaluated on the basis of total cost. Some costs that may be relevant are payroll costs; costs of overtime, second shifts, and subcontracting; costs of hiring and laying off workers; costs of excess inventory and backlog; and costs of production rate changes.

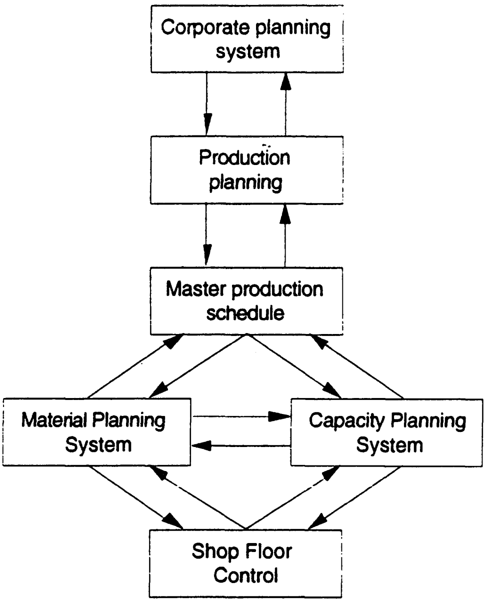

FIG. 14. Major components of the manufacturing planning system (from Melnyk, 1985).

The costs that are included in the total cost model should vary with changes in the decision variables. In a MPS, these decision variables typically denote the size of the work force to employ, the number of overtime hours to schedule, and how many of each finished product to produce during each time interval of some planning horizon. However, the behavior of cost with respect to changes in these decision variables is not necessarily easy to quantify. Often, approximations are made by assuming the costs to be linear or quadratic functions of the appropriate decision variables. This permits the use of optimization techniques such as linear programming.

3.3 Areas for Further Research

In manufacturing, the demand to develop more efficient manufacturing systems and processes will always exist, and currently there are numerous topics on which today's researchers are spending their efforts. Much of the effort is toward the advancement of computer-integrated manufacturing (CIM), especially in control, because as manufacturing systems become larger and as the processes become more complex, efficient control is possible only with the integration of computers. Also, many advancements in the field of artificial intelligence (AI) propagate and help to advance manufacturing, since AI tools are becoming more commonplace for industrial applications. Rapid prototyping, with the concept of "overnight" development of a product from the draftboard to the physical prototype, is another current research topic. A topic of high priority in research is the implementation of environmentally conscious manufacturing. As society slowly comes to the realization that the world has limited resources (and as governments are starting to enact environmental legislation), there is a need in industry to make current manufacturing practices more environmentally friendly. Today's researchers in manufacturing are making advancements in all these areas to satisfy the needs of today and tomorrow.

GLOSSARY

Brazing: Any of several joining processes similar to welding in which a high-temperature molten filler metal is distributed in a joint by capillary action. Note that melting of the base metal does not occur.

Casting: A process where a molten substance is poured into and solidifies inside a mold that is the negative image of the desired part shape.

Cellular System: A manufacturing configuration in which several different machine tools are grouped together into units called cells.

Computer-Aided Design (CAD): A process where computers are used to assist in the design of parts, often by manipulating three-dimensional computer descriptions of the part shape.

Computer-Aided Manufacturing (CAM): The use of computers to assist in manufacturing as in computerized process planning.

Computer Numerically Controlled (CNC): Employing a self-contained control system using a dedicated computer in conjunction with stored digital instructions.

Continuous System: A manufacturing system in which the product is continuous, rather than discrete. Often used in the chemical or textile industry.

Deforming Process: A manufacturing process where the shape of a part is altered while cohesion among the constituent particles is maintained.

Die: A generic term to describe tooling used to cut or form material.

Electric-Discharge Machining (EDM): A material-removal process that employs high-voltage electric discharges to ablate material.

Flexible Manufacturing System (FMS): An automated manufacturing system containing several different machine tools capable of making many different part geometries at various production volumes.

Flow Line: A manufacturing configuration in which the part is transported through a linear arrangement of machine tools that perform the manufacturing operations.

Forming: A manufacturing process in which the cohesion among the particles is increased so as to create a new part, e.g., casting.

Hardness: In manufacturing, defined as a material's resistance to mechanical indentation and thus closely correlated to the material yield stress. Units of measurement depend on the scale employed; Rockwell B, Rockwell C, and Vickers scale are commonly used.

Job: An individual part to be manufactured.

Job Shop: A manufacturing configuration in which several diverse machine tools are grouped together such that they may efficiently manufacture many different low-volume parts.

Joining Process: A manufacturing process in which two or more parts are brought together to create a new part, e.g., welding.

Lathe: A machine tool used for turning.

Manufacturing: The transformation of materials and information into goods for the satisfaction of human needs.

Material Requirements Planning (MRP): A plan (usually implemented through computer software) that describes the material requirements for the production of a part or a set of parts.

Master Production Schedule (MPS): A master plan for the production of a part or a set of parts. It serves as a link between management and the manufacturing facility.

Milling: A material-removal process in which a rotating cutting tool is applied to a part in order to create a desired shape.

Mold: The negative image of a desired part shape, used for casting operations.

Numerical Control (NC): A technique for controlling actions of a machine tool and similar equipment with a digital controller and numerical data.

Process Control: A method for ensuring that a manufacturing process produces useful parts by adjusting process parameters so that process outputs meet target values.

Project Shop: A manufacturing configuration in which the part remains stationary while materials and equipment are brought to the part in order to perform manufacturing operations.

Roughness Average (R_a): The arithmetic average of the absolute values of the measured profile height deviations taken within the sampling length and measured from the centerline.

Removal Process: A manufacturing process in which material is removed from the part in order to create a specified geometry, e.g., turning.

Resource: A machine capable of performing a manufacturing **task**.

Scheduling: The process of assigning tasks to manufacturing **resources**.

Simulation: In manufacturing, the representation of a manufacturing system by computers.

Soldering: A joining process in which the filler metal melts at a low temperature and is distributed through the joint by surface tension and capillary action. Note that melting of the base metal does not occur.

Task: An individual manufacturing operation; several tasks comprise a **job**.

Turning: A removal process in which a workpiece is rotated against a tool to form a desirable rotationally symmetric shape.

Welding: A joining process in which heat or pressure or filler materials are employed to achieve cohesion between two parts.

INTRODUCTION

The term *marine geophysics* applies to a branch of the geosciences in which a group of physically based techniques is applied to study the floor of the oceans and the subsurface layers beneath. Marine geophysical techniques *per se* are tools of the scientists; the objective of marine geophysical research is to apply these tools to the furthering of our understanding of the nature and evolution of the ocean basins of our planet. Marine geophysical techniques fall broadly into three groups:

1. high-frequency acoustics for mapping the seafloor;
2. low-frequency acoustics (seismic) to map structure beneath the seafloor; and
3. potential-field studies to map mass distribution and magnetic properties in the earth.

The three approaches provide different but complementary information that can be used by scientists to build an understanding of processes that shape ocean basins. The high-frequency acoustic methods give a measure of the shape of the seafloor and its acoustic response. Different geological features give different strengths of return, and thus the pattern of returned energy can be used as a proxy for a geological map of the seafloor. Low-frequency acoustic methods provide an image of the subsurface, allowing scientists to map the internal components of the crust. Here the sound propagation speed and scattered response of internal layers are used as proxy for geological structure. Potential-field methods can be used to derive estimates of the distribution of anomalous masses and the varying magnetization of deep rock layers. Acoustic methods rely on analyzing returns from sound energy transmitted into the Earth and hence are limited in depth to the depth of sound penetration. While information from potential-field methods is typically of lower resolution than that available from acoustic methods, these data can be used to deduce information about structure at much greater depth than is available from acoustic methods because gravity and magnetic fields are the integrated response to mass and magnetization distributions at all depths in the Earth.

Marine geophysical research has no central theme but rather has been applied to a

digital Encyclopedia of Applied Physics

very wide variety of problems specific to understanding the oceans. These range from the development of sediment accretion in zones of plate convergence, through the history of seamount construction, to rifting that leads to the rupturing of continents to form passive continental margins. One research area that has generated considerable interest in the last several years is in developing an understanding of the nature and evolution of midocean-ridge spreading centers. This topic area has seen extensive application of all three major classes of geophysical techniques, and we use this example here as a useful basis for discussion of marine geophysical methods and their applications.

The globe-encircling filigree of midocean ridges (Fig. 1) is the locus for generation of new oceanic lithosphere by the process of seafloor spreading. As part of this process, molten magma rises to the surface from the deep mantle, freezes, and forms the basaltic oceanic crust. The molten magma is generally thought to have been stored for some period of time in a shallow-level magma reservoir, or chamber, because the chemistry of volcanic rocks recovered from spreading centers is not consistent with magma having been in equilibrium with the parent mantle. The nature of the magmatic system is one problem that has drawn special attention, as it has become increasingly recognized that magma is delivered to the crust in a highly nonuniform way. Along the axis of a ridge, there exist regions that are much more volcanically active than others. The mechanism by which melt is focused in specific regions along the ridge is not well understood, and marine geophysical approaches, combined with geochemical studies of rocks recovered from the axes of midocean ridges, have proven particularly insightful in addressing this problem.

In the following, we present a discussion of tools and methodologies most commonly used in marine geophysical studies. The list is not intended to be inclusive of all marine geophysical tools, to avoid producing a simple listing of techniques. Following that, we describe some uses of these methodologies, using the example of midocean-ridge spreading systems as an area of current research focus. Again, we do not mean to suggest that this is the only, or the most important, focus

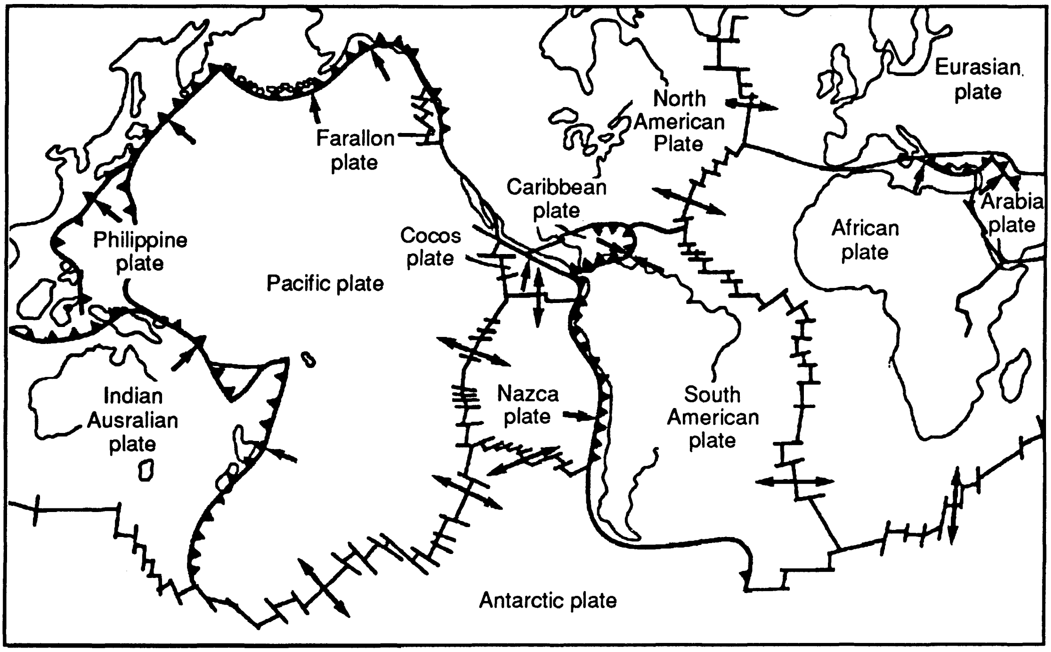

FIG. 1. Global distribution of lithospheric plate boundaries. Regions where new lithosphere is being created at midocean-ridge centers of seafloor spreading are shown with double arrows. The orientation of the arrow indicates the direction of relative motion of the lithosphere created at the spreading centers.

of research, only that it provides a convenient example.

1. METHODOLOGIES AND INSTRUMENTATION

1.1 Acoustic Imaging

Seafloor imaging involves the collection of two classes of acoustic data, bathymetric and side-scan sonar. Both data types are obtained using systems comprised of the same fundamental components: a transmitter that emits sound toward the seafloor, a receiver that detects reflected acoustic energy, and a timing device that records the time between transmitted and received signal. Both kinds of data are obtained using high-frequency sources that achieve minimal sub-bottom penetration. Bathymetric systems measure the time elapsed between transmitted and received acoustic pulses. Using the velocity of sound in seawater, travel times are converted to seafloor depths. Side-scan sonar systems measure the amplitude of energy backscattered from the seafloor, providing proxy information on bottom lithology and structure.

1.1.1 Bathymetric Systems Acoustic methods were first developed for measuring depth to the ocean bottom in the late 1920s. These early systems employed a single wide beam of sound insonifying an area of the sea floor with a "footprint" several kilometers in diameter (Fig. 2, upper illustration). This large area resulted because the beam sent into the ocean was not a narrow pencil of sound but had a conelike shape—the deeper the seafloor, the greater the footprint area. Any single depth point from such a system therefore represented an average depth in the insonified area, and the beamwidth fundamentally limited resolution of seafloor features. During the next 40 years, narrower beam systems were developed, providing improved resolution, but depth sounding remained limited to profiles of a series of single-point measurements (taken to be the center of the beam) beneath the ship.

In the 1970s, the first so-called multibeam systems became available. Instead of sending out a single beam of sound energy, these systems propagate sound from an array of transmitting devices on the hull of a vessel, typically arranged across the direction of travel of the vessel. With these instruments, a swath of seafloor transverse to the ship's track is insonified (Fig. 2, lower panel). The width of current multibeam swaths is 90° to 120°, so that the swath width on the seafloor is more than twice the water depth. This leads to efficient collection of virtually continuous high-resolution bathymetry by a survey strategy akin to mowing a lawn. The first multibeam system widely used for deep sea research was the 54° beamwidth Seabeam system, built by General Instruments Corporation, Westwood, Massachusetts (Renard and Allenou, 1979). Multibeam systems have become the standard tool for mapping the seafloor and have led to an explosion in our knowledge of its shape and properties.

Data obtained from multibeam systems are governed by insonification frequency, number of beams, beamwidth, and ping repetition rate. Operating frequency and beamwidth determine the system resolution, the number of beams and beamwidth control across-track data density and swath width, and the ping repetition rate governs the along-track data density. Choice of operating frequency, typically 12 to 16 kHz for deep-water systems and 30 to 200 kHz for shallow-water systems, is constrained by the absorption of high-frequency acoustic energy by seawater. The aperture or beam width, typically 1° to 3°, determines the size of the seafloor footprint insonified, and this area will vary with distance from nadir and with water depth. The density of information along the survey track is controlled by ping rate—the interval between successive acoustic transmissions. Present systems cannot process data for which more than one transmission is in the water column at the same time, and so ping rate is controlled by water depth. Thus, the data density along track is controlled by water depth and speed of the ship. Typically, then, the along- and across-track data densities are quite different, and data are usually averaged to roughly equalize densities.

Multibeam surveys typically involve a strategy to obtain essentially 100% coverage of the seafloor in an area of interest. Lines will be surveyed along an azimuth perpendicular to the dominant trend of seafloor features, with a few lines run parallel, or at another angle. Because swath width on the

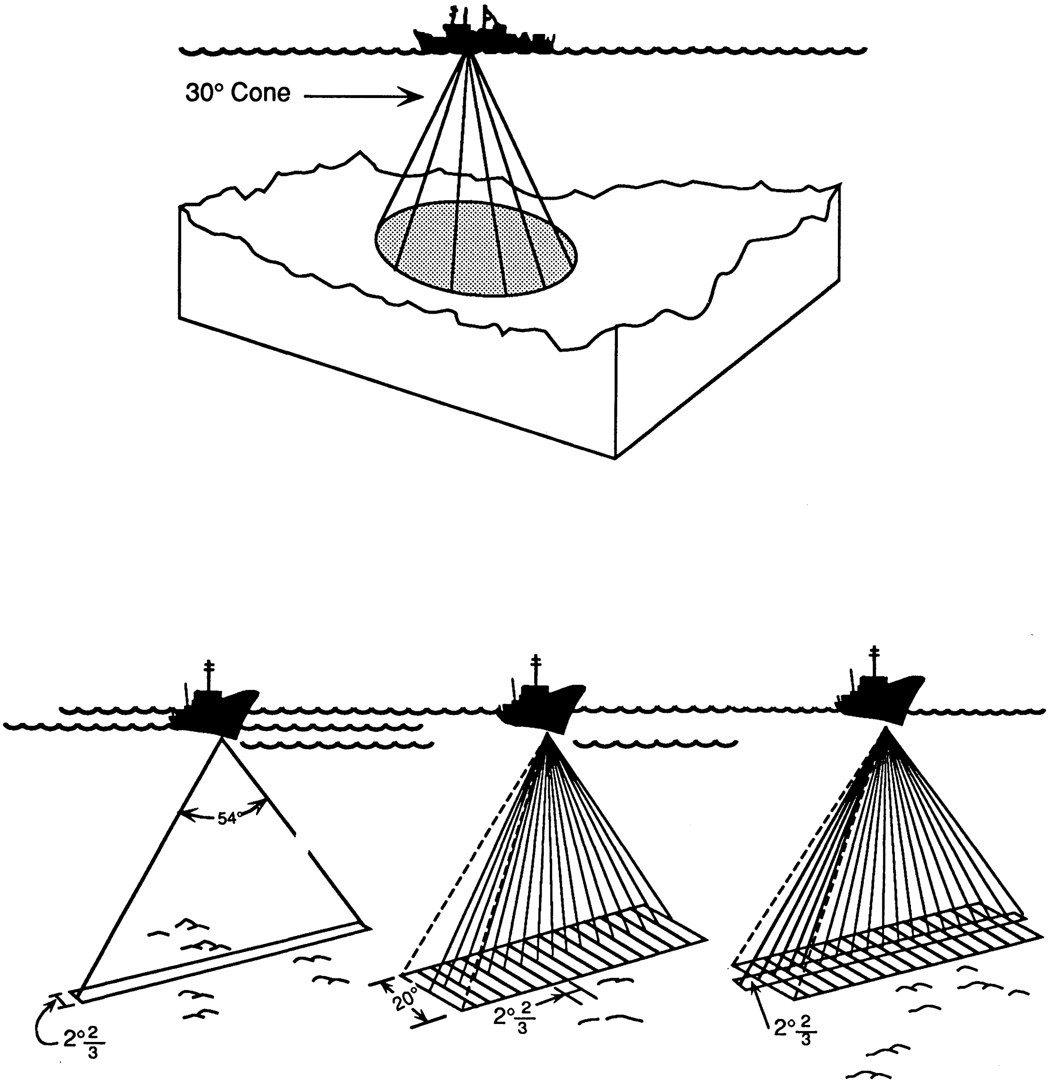

FIG. 2. The shape of the seafloor first became known in some detail by the use of single-beam echo sounders (upper illustration) which propagated a cone-shaped beam of sound from a single transmitter/receiver on the hull of a vessel and timed the return. Converting the time to the depth of the seafloor only required knowledge of the speed of propagation of sound in water, which is near to 1500 m/s in most oceans. The modern generation of bottom mapping tools are multibeam systems (lower illustration) which propagate a swath of sound energy into the water from an array on the vessel's hull. This achieves a rapid mapping of a wide region of the seafloor, so complete coverage can be obtained by a survey vessel tracking back and forth as if mowing a lawn. Figures after Renard and Allenou (1979) and Johnson and Helferty (1990).

seafloor is controlled by water depth (the greater the depth, the wider the swath), lines run at a uniform spacing will sometimes have overlapping swaths and sometimes will include gaps in coverage. These effects have to be accounted for by editing (or interpolation) in subsequent data processing. Navigation is usually achieved by Global Positioning System (GPS) satellites that effectively provide a constellation of celestial references giving very accurate position information on a virtually continuous basis. Data can be displayed as plots of contoured swath data, presented as contoured maps or as three-dimensional images such as the map of the East Pacific Rise (Plate 1).

1.1.2 Side-Scan Sonar Side-scan sonar systems recover information on seafloor properties, rather than its shape, by measuring the strength of returned acoustic energy as a function of time after an acoustic pulse is transmitted. The returned energy includes both backscatter (diffracted) and specular energy reflected off seafloor slopes. Backscatter results from the diffraction of sound due to seafloor roughness that is comparable in size to the wavelength of the acoustic pulse. Because rougher surfaces will diffract sound more efficiently than smooth surfaces, side-scan images can be used to distinguish different types of seafloor terrains (e.g., volcanic versus sedimented) (Fig. 3) In addition, side-scan imagery forms an excellent database for studying tectonic features such as faults where unsedimented scarps produce strong linear acoustic returns and shadows.

Side-scan sonar systems were first used to map geological features of the seafloor in the late 1950s, primarily on continental shelves. Use of these systems in deep ocean research did not begin until the late 1960s to early 1970s with development of instruments such as the long-range GLORIA side-scan sonar developed by the Institute of Ocean Sciences, U.K., and the Deep-tow system of the Scripps Institute of Oceanography.

Side-scan sonar systems are typically housed within a vehicle or "fish" towed be-

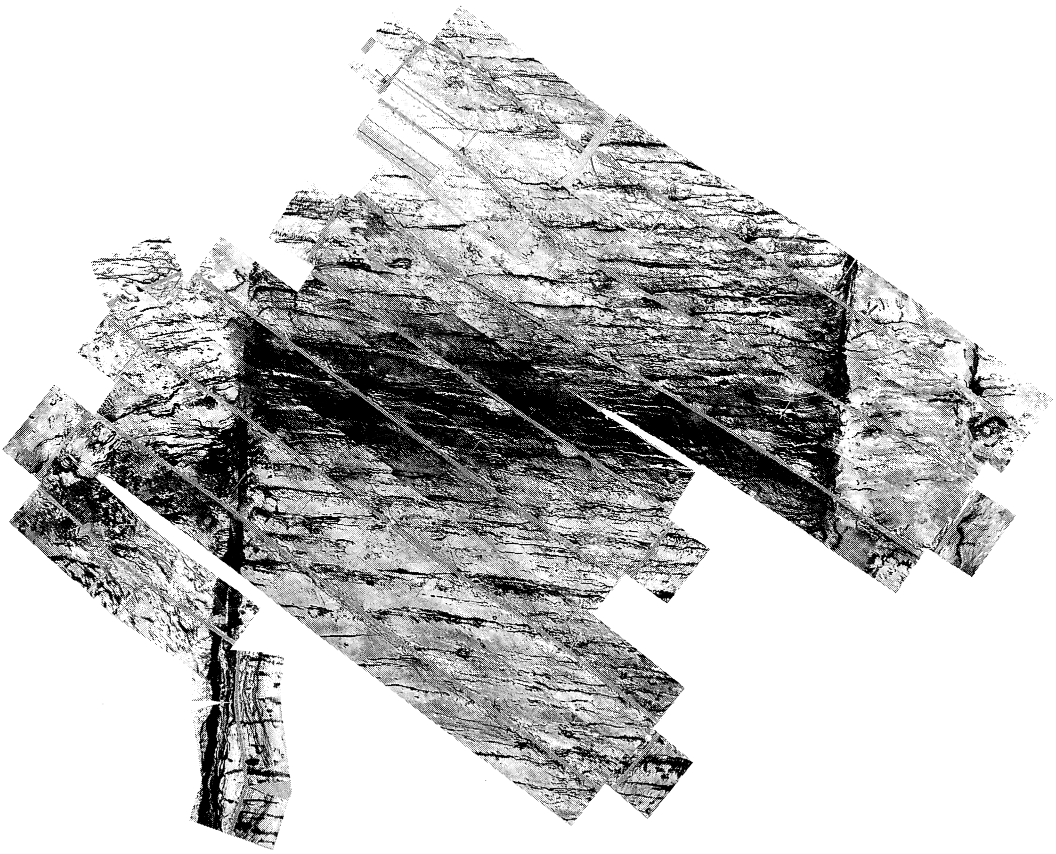

FIG. 3. A typical image of the seafloor made by a side-scan sonar system does not reveal the shape of the bottom (newer systems are able to recover bathymetric information also), but allows the texture to be revealed in detail. Dark and light areas correspond to areas of differing reflectivity. Strong, dark linear features correspond to faults that disturb the seafloor. The mid-ocean ridge is the dark region in the center of the map. Other dark regions are believed to correspond to regions of relatively young lava flows that have been recently extruded onto the seafloor. To first order, the dark, more reflective areas are thought to be formed more recently than the less reflective white areas, which may have a thin sediment cover. Tracks run by the ship follow grey strips of no data within the center of each swath. Data courtesy of K. C. Macdonald.

hind the ship (Fig. 4). A coaxial cable connects the fish to the ship and is used to transmit power and control signals down to the fish, and side-scan and fish attitude data are sent back. Towing the system, rather than having a hull-mounted design, decouples the instrument from ship's motion and reduces ship-generated noise. It also permits the instrument to be kept below the thermocline where water temperatures and hence velocities vary rapidly with depth. Both deep-towed (within 200 m of ocean bottom) and shallow-towed (within 200 m of the sea surface) systems are used. As with multibeam systems, the attenuation of high frequencies in seawater limits surface-towed systems to frequencies less than 30 kHz, whereas operating frequencies of 30 to 150 kHz are typical for deep-towed systems. Wider swaths are insonified with shallow-towed systems and at faster towing speeds, but lower-resolution data is obtained. For example, the SeaMARC II system, built by International Submarine Technology, Washington, and the Hawaii Institute of Geophysics, is towed at depths of ~100 m and at speeds up to 10 knots. It operates at 11 to 12 kHz with a total swath width of 10 km. In contrast, the Scripps's Deep-tow system towed at heights of 150 m off bottom gives a swath width of only 500 to 750 m. The operating frequency of this instrument is 110 kHz, and tow speeds are 1 to 2 knots.

The side-scan system is constructed of parallel linear transducer arrays that scan to either side of the tow fish. The same transducers are used for both transmission and receiving. Slightly different insonification frequencies are used to port and starboard to facilitate identification and rejection of returned acoustic energy from the opposite side of the fish, known as cross-talk. The transducer array emits a fan-shaped acoustic beam that is narrow in the along-track direction (1° to 2°) but wide in the across-track direction (over 50°), much like a multi-beam bathymetric system. Resolutions in both along- and across-track directions are determined largely by this spreading of the emitted beam (Johnson and Helferty, 1990).

A number of corrections must be applied to side-scan data before a meaningful image is produced. These include corrections for sound absorption in seawater and geometric spreading, both of which result in a progressive loss of acoustic energy for returns from greater distances from the fish. To compensate, a time-varying gain is applied, producing a constant average signal level across the swath. A slant-range correction is then needed to convert two-way travel time to horizontal distance from the ship's track to the acoustic target. This correction is based on the assumption that the seafloor is flat and horizontal, and this can give rise to considerable errors in positioning acoustic targets if seafloor relief is actually significant. Recent developments in side-scan sonar design have made possible the use of bathymetric information to place data correctly in space. The SeaMARC II and MR1 systems measure the phase difference between incoming acoustic energy recorded at a pair of transducer arrays mounted on each side of the fish. This phase difference is a measure of the angle of incoming acoustic energy and in conjunction with travel times can be used to obtain bathymetry (Blackinton *et al.*, 1983). At present, these bathymetric data are used during post-processing of select areas to locate side-scan data correctly (Reed and Hussong, 1989).

Image enhancement and analysis techniques similar to those used in digital processing of optical and satellite imagery can also be used in analysis of acoustic data. These include contrast and gain adjustments and filtering to emphasize specific features of interest. Some application of pattern recognition techniques or texture analysis has been made in side-scan processing and will likely see increased development and application in the future (Reed and Hussong, 1989). A wide range of visualization capabilities are presently being developed that will soon be applicable to side-scan imaging. For instance, the three-dimensional bathymetric image (Plate 1) can be "painted" with backscatter strength data to combine information on shape and reflectivity of the seafloor to aid marine geologists in interpreting these data types.

1.2 Seismic Methods

The central thesis underlying the use of seismic methods is that detectable properties of seismic waves are perturbed in their passage through the crust by changes in crustal parameters of interest. Analysis of perturbations in the seismic wave field should then yield information on these parameters. Two

FIG. 4. The technology for creating a side-scan image typically involves the use of a towed "fish," which emits an acoustic signal from an array of transducers. Side-scan images measure the strength of the returned energy from the seafloor rather the shape of the seafloor, but some information on the seafloor depth is required to place the side-scan information (here shown as the data pixel) on the seafloor. Note that the "footprint" of individual beams changes with distance from the fish. Different side-scan fish are towed near the surface or near the seafloor to achieve very high resolution. The latter are referred to as deep-tow instruments and must be towed very slowly (less than 2 knots) to ensure that they stay near the bottom. Figure from Johnson and Helferty (1990).

different techniques are commonly employed. In the first, properties of the seismic wave field are used to infer the distribution of seismic-wave propagation speed in the subsurface. In the second, the direct response of the earth to seismic energy is used to create an image of structure. The first approach derives a quantitative estimate of a particular physical parameter. The second achieves a visualization of the Earth from which quantitative information is not readily available. In both cases, the information recovered is a *model* of Earth structure that is much simpler than we believe the real Earth to be. The specific model parametrization and resolution achieved depend on experimental design, data type, and analysis techniques.

1.2.1 Crustal Velocity Distribution from Seismic Kinematic Data To observe the seismic wave field, recording instruments are placed either on the seafloor [ocean bottom seismometers (OBS)] or deployed near the sea surface (sonobuoys or towed hydrophone arrays), and a near-surface seismic energy source (airguns or explosives) is discharged at numerous locations away from the receiver(s) [Figs. 5(a) and 5(b)]. Less common types of experiment involve seafloor shots and receivers [Fig. 5(c)], or surface shots fired to borehole receivers [Fig. 5(d)]. When towed hydrophone arrays are to be employed, both source and receiver can be moved simultaneously to create an expanding spread profile (ESP) [Fig. 5(e); Stoffa and Buhl, 1979]. Expanding spread profiles acquired with large-volume, tuned, multi-airgun source arrays and multichannel hydrophone receiver arrays can achieve an essentially continuous wave-field sampling over source–receiver offsets of up to 100 km. In each configuration, the objective is to record the seismic wavefield at many different distances from the origin point of a seismic source. Changes in seismic travel times and wave form with increasing range from the source can be analyzed to recover information on crustal velocities.

Techniques for estimating one-dimensional $V(z)$ structure rely on a commonly used theoretical abstraction of elastic-wave propagation in terms of wave fronts and their outwardly directed normals, called rays, such as those drawn schematically in Fig. 5. Seismic rays relate closely to classical descriptions of light in terms of geometric optics. If velocity continuously increases with depth, rays that originate from the source nearly vertically will penetrate more deeply than those originating at shallower angles. The depth to which a ray penetrates is described as its turning-point depth. Figure 6 shows rays traced through a structure typical of the crest of the East Pacific Rise spreading center. This includes an interval where velocity decreases with depth because of the presumed presence of a body of near-liquid magma. Rays that penetrate into this region do not have turning points because they bend toward the vertical.

Estimates of $V(z)$ can be derived from two approaches. In *forward modeling,* a trial model function is prescribed, and kinematic variables such as travel times are calculated for that model. Predicted values are compared with observations, and by iterative trial and error modification of the model and recalculation of the kinematic variables, observed and calculated versions can be brought into approximate coincidence. The process can be made interactive by use of modern workstations, and model velocity functions that generate travel-time predictions that visually satisfy the data quite well can be established very quickly. A second approach is to solve directly for the parameters of the unknown earth model using travel-time information as input. The basic principle involved is that the ray parameter (the inverse of an arrival's horizontal component of velocity) of any ray characterizes that ray throughout its entire path. This means that the ray parameter measured at the surface of the earth is the inverse of the velocity of the seismic wave in the earth at the ray's turning-point depth. A velocity model can be constructed from turning-point depths of a suite of ray parameters measured from seismic arrivals.

Construction of a $V(z)$ model by travel-time techniques gives information with variable resolution in depth. An instructive way to visualize travel-time resolution limitations is by turning-point density (Fig. 6). Rays traced through the Vera *et al.* (1990) model of the East Pacific Rise axis show many ray turning points within a small depth interval in some regions, with associated rays returning to the surface in a dense pattern. Turning-point density is sparse in other parts of the model. Since estimating $V(z)$ involves calculating turning-point depths, intervals that include

FIG. 5. Marine seismic refraction experiments typically involve the collection of seismic arrivals that have traveled from a source (shown here as the star symbol) to either a single receiver or several receivers. In each case, the seismic wavefield is recorded at numerous distances from the source. The passage of seismic energy through the subsurface can be represented by lines that trace the path of propagation of a seismic "ray"—a convenient descriptive construction that is used to visualize the paths taken by seismic energy perpendicular to the wave fronts of seismic energy. The experimental configurations shown in (a) through (e) can be used to provide one-dimensional estimates of the velocity structure of the crust. Arrays of instruments are used to determine two- and three-dimensional estimates of velocity structure.

many turning rays will be better resolved than those with fewer turning rays. Regions of steep velocity gradient show densely spaced turning rays and act to focus energy to the surface, while low-velocity gradients have few turning rays and defocus energy. Because rays do not turn in low-velocity zones, no information on such an interval is directly available there. Low-velocity zones are an extreme example of the important general rule of thumb regarding model resolution—no arrivals, no resolution. Magma chambers and the adjacent regions of solid rock at elevated temperature are expected to exhibit lower

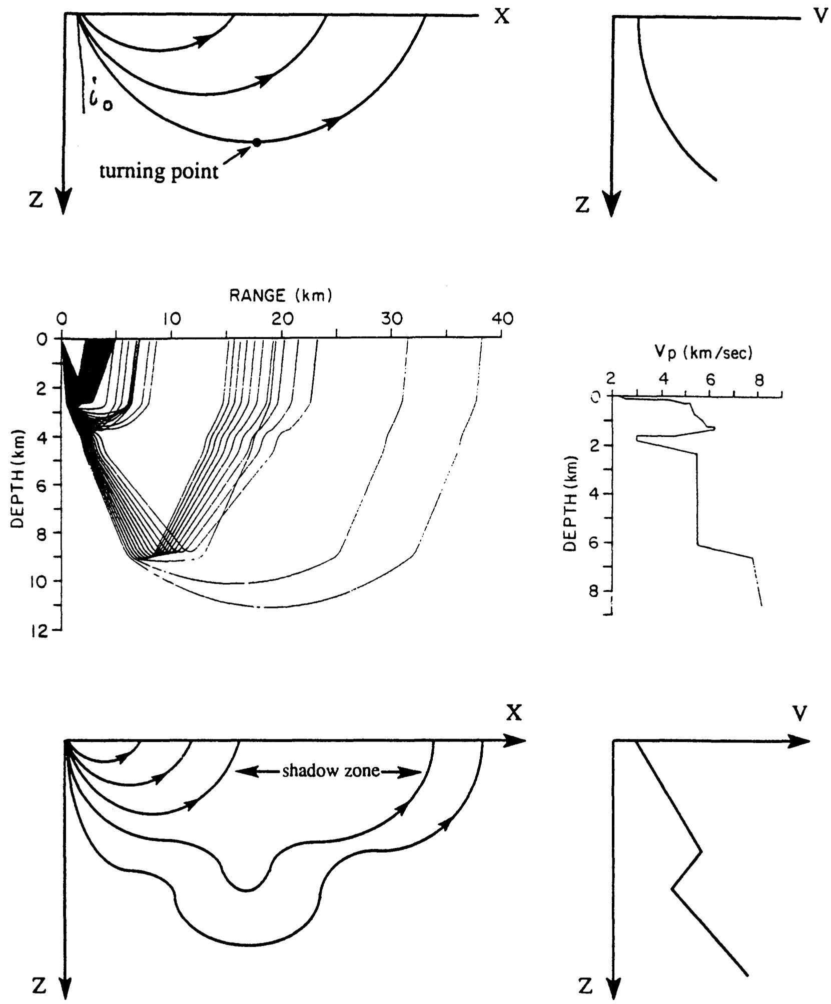

FIG. 6. When seismic energy penetrates into the earth, it is typically bent back toward the surface and travels in a path that is roughly like a semicircle. There is a turning point where the energy begins to travel back up to the surface. These turning-point depths can be estimated by measuring properties of the recorded wavefield and a profile of seismic velocity as a function of depth (middle illustration, right-hand side). If the crust includes a region such as a liquid magma body where velocity decreases, seismic rays are bent down into the crust and do not begin turning back toward the surface until they again enter an area of increasing velocity. These low-velocity zones present considerable interpretational difficulties for seismic data analysis.

velocities than the surrounding rocks. Hence, travel-time inversion alone is incapable of recovering information on one of the most fundamental and important features of mid-ocean ridges. We rely on methods that use different aspects of the seismic wave field, such as described below, to define these features.

Estimates of two- and three-dimensional velocity structure, including low-velocity regions, can be derived from observations using spatially distributed arrays of instruments and sources [Figs. 5(f) and 5(g)] and the application of tomographic techniques of analysis. Sources are fired across a distributed array of seafloor instruments so that many rays pass through a particular crustal volume of interest (Fig. 7, top panel). The analysis does not calculate depths to a particular part of a ray path, but estimates a velocity distribution (Fig. 7, bottom panel) consistent with total travel times from many source–receiver combinations. In a tomographic analysis, an initial, very slowly vary-

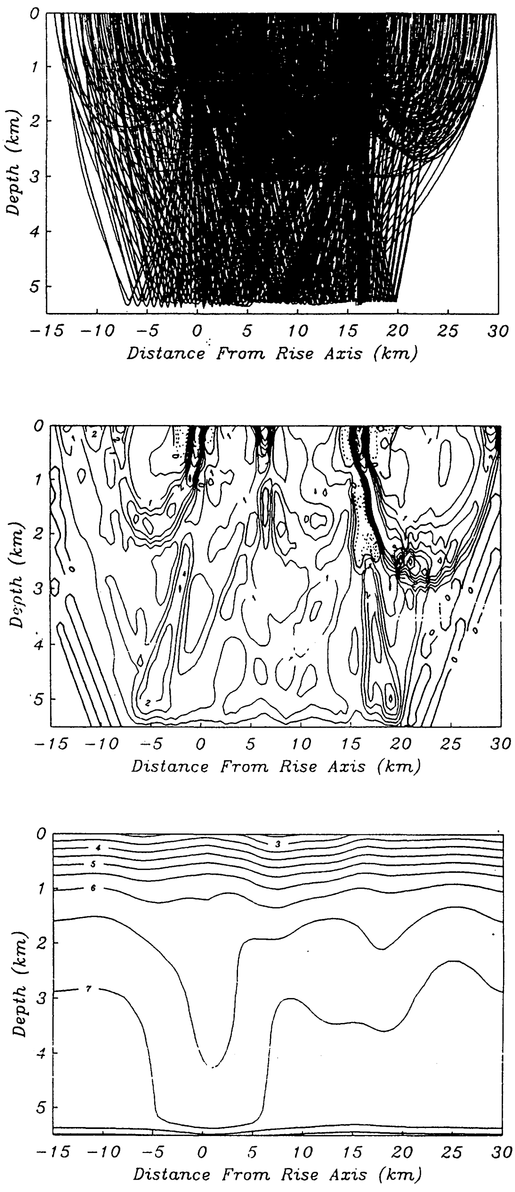

FIG. 7. Tomography uses the travel times of a suite of seismic rays that cross one another (top panel) from recordings of surface shots made by several instruments, typically deployed on the seafloor. The analysis leads to an estimate of the two-dimensional crustal velocity field as in the bottom panel (or three-dimensional if a spatially distributed array of recording instruments is deployed). Note the broadly defined region of lower velocity in the central part of the figure. This corresponds to a region of magma and hot rock associated with the zone of crustal formation beneath the ridge axis. Resolution of the velocity structure depends on the density of crossing rays and is illustrated in the middle panel. Illustrations are from Caress *et al.* (1992).

ing two-dimensional $V(z,x)$ model is specified, rays are traced through the model from known source locations to known receiver locations, and associated travel times are calculated (Fig. 7, top panel). The objective is to modify the velocity model iteratively until observed and calculated travel times come into acceptable agreement. This is essentially the forward modeling approach, but applied by a process that assesses the extent of misfit and modifies the model until the misfit is reduced to an acceptable amount.

Resolution can be calculated from the response of synthetic impulsive velocity perturbations. Spikes in the velocity field are inserted, and a partial derivative matrix associated with the preferred model is used to try to recover the spike, yielding a model δv (Fig. 7, middle panel) in which the information density, as represented by the contour density, is a reasonable proxy for resolution. This can be done over the entire model space to give an estimate of model resolution throughout the space of interest (Caress *et al.*, 1992). What is immediately apparent is a repetition of the result stated earlier—resolution is controlled by ray density. In a tomographic analysis, resolution relies on rays crossing from different source–receiver configurations. There is often a simple trade-off between velocity and dimension—small structures with large velocity perturbations have an almost identical effect to larger bodies with smaller velocity anomalies. However, since tomography uses transmitted rays, information on low-velocity zones *can* be directly recovered.

1.2.2 Crustal Velocity Distribution from Seismic Wave Forms

Ray-based methods used in travel-time analyses embody substantial simplification to propagation phenomena that inherently restricts information gained from travel-time analysis. The seismic signal is treated as being of infinite frequency and wave fronts as discontinuity surfaces. Practical seismic sources emit complex signals with frequency content usually ranging from around 4 to 60 Hz, with peak at 10 to 15 Hz. Amplitude, phase, and frequency content of these signals are modified in their passage through the crust by properties that affect travel times by irresolvably small amounts, or not at all. Wave-form studies can therefore add information not available from seismic travel times or can improve on the resolution available from travel-time methods.

Wave-form information is most commonly employed by iterative forward modeling using the same approach as that employed for forward modeling of travel-time data, except that the "complete" seismic response is calculated. Several methods are available, and a useful basic discussion of them is given by Mooney (1983). The most extensively used class of synthetic seismogram methods is transform methods, in which the elastic wave equation is doubly transformed (space and time) to yield an ordinary differential equation that is solved for displacement potentials in terms of p (horizontal slowness), z (depth), and ω (radial frequency) by standard approaches (Aki and Richards, 1980). A synthetic seismogram is generated by double inverse transforming this solution. Many different synthetic seismograms can be created depending on how the transforms and inverse transforms are taken. The most commonly used are reflectivity (real slowness integration followed by frequency; Muller, 1985) and WKBJ (frequency integration followed by real slowness integration; Chapman, 1985). The most powerful synthetic seismogram computation uses the finite-difference (FD) method (Kelly *et al.*, 1976; Stephen, 1983). In this approach, the wave equation is approximated by a low-order discrete-difference equation and applied to a medium that is subdivided (gridded) into numerous very small elements in which the differencing approximation holds valid. Complex structure can be readily included by assigning different properties to elements of a finely subdivided model. Thus, models can be made two- or three-dimensional, and anisotropy can be modeled. The great penalty of FD methods is the enormous computation time required, because the medium must be gridded on a scale that is very small compared to a seismic wavelength, and the wave equation solved at a correspondingly large number of points.

Once the synthetic response of the model has been computed, a comparison is made to observed data, misfits are noted, and model adjustments are made until a satisfactory fit is obtained. A typical comparison of observed and synthetic seismograms using the reflectivity method is shown in Fig. 8 (Vera *et al.*, 1990).

Wave-form analysis provides a route to deriving estimates of seismic attenuation, a parameter that cannot be obtained from travel-time data. Anelastic attenuation describes the degree to which seismic energy is absorbed, primarily through internal friction that causes dissipation of the energy into tiny amounts of heat. Attenuation factors in common crustal rocks vary by a much greater range than exhibited by either p-wave or s-wave velocities. This is because attenuation is more sensitive than the bulk elastic properties to factors such as porosity (including the shape of pore spaces), presence of fluids, and temperature. Attenuative properties of crustal rocks near their solidus probably range through an order of magnitude, perhaps five times the range of the elastic property changes in the same region. Attenuation is the energy loss per cycle (through anelastic processes) relative to peak energy at a given frequency (Aki and Richards, 1980) and must be estimated from changes in seismic wave forms. One approach—the spectral ratio method (see, for example, Jacobson and Lewis, 1990)—involves comparison of seismic pulse spectra after propagation through the earth with the same pulse before propagation. Wilcock *et al.* (1992) extended this approach by using a spectral method to estimate attenuation of wave forms, which they map into the distribution of crustal attenuation of the East Pacific Rise axis using a velocity model and ray paths derived from tomographic analysis of seismic travel times (Fig. 9).

Like travel-time analysis, wave-form analysis can be treated as an inverse problem. Wave-form inversion involves an iterative search for a model parametrized in terms of p- and s-wave velocities and density that best fits observed travel times and wave forms of observed seismic data. In one approach, a starting model is chosen that adequately describes the long-wavelength or background parameters, perhaps using a travel-time inverse model. The associated synthetic seismogram is calculated and compared to an observed seismogram. A quantitative measure of misfit between observed and calculated wave-form data is made for the entire seismogram, and used to calculate how to perturb the model structure in such a way that a new synthetic seismogram, calculated

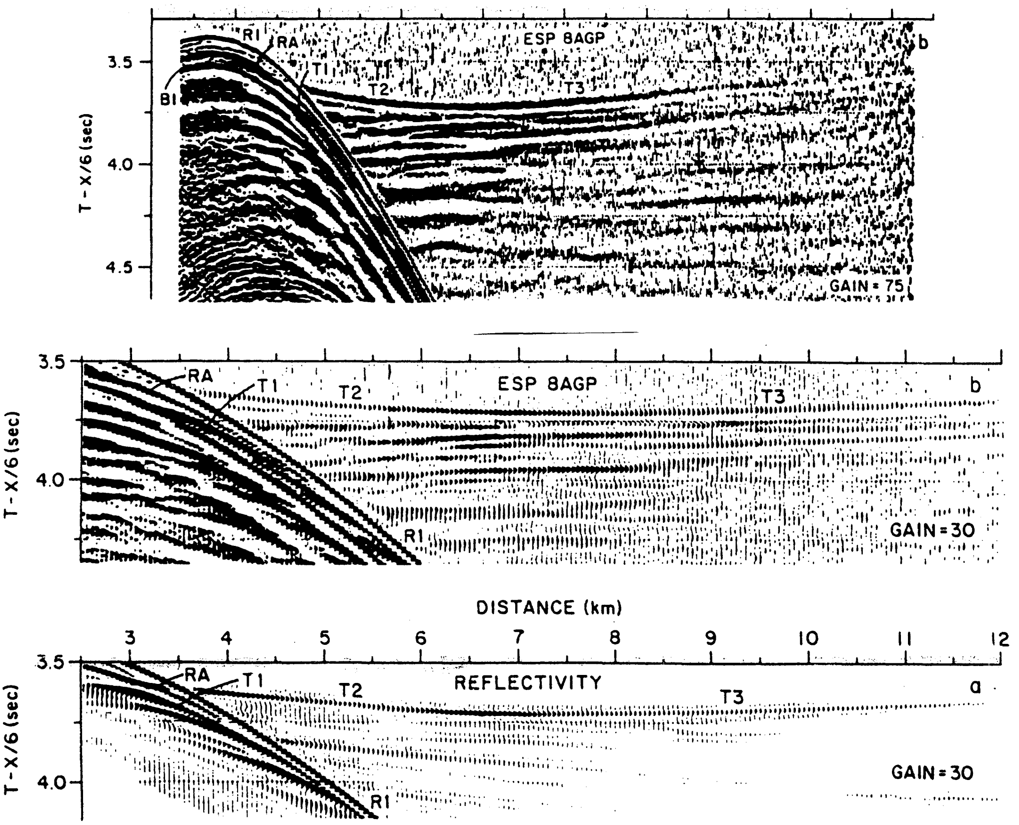

FIG. 8. A typical ESP seismogram recorded on the East Pacific Rise is shown in the top panel, and an analysis using reflectivity synthetic seismogram methods is shown in the lower two panels. The middle panel is a detail of the observed data, and the bottom panel shows the seismogram calculated for the structure shown in Fig. 6 (middle panel, right-hand side). Note that most of the important features of the observed data have been simulated in the calculated synthetic data. Illustrations are from Vera *et al.* (1990).

for the perturbed model, will produce an improved fit to observations. Least-squares criteria for misfit can be used provided the initial model is suitably close to the final model. As in travel-time tomography, it is necessary to calculate a large matrix of partial derivatives of the synthetic seismogram with respect to model parameters. In wave-form inversion, this is a huge task since it involves computation of the full synthetic response. Use of wave-form inversion for study of the oceanic crust has largely been limited to use of the refracted wave field calculated by the WKBJ technique (Carey and Chapman, 1988; Shaw and Orcutt, 1985).

A recent advance in model-space search schemes involves the application of methods borrowed from life sciences. The genetic algorithm (GA) is an approach that works on groups of models rather than a single model and proceeds in a very different way from traditional parameter-estimating schemes. Model parameters are represented in binary form, and the search begins with a random population of models called chromosome by analogy to a biological form. The correlation between synthetic data generated from these models and observations is calculated as a measure of the "fitness" of each model. Then the processes of selection, crossover, and mutation are performed on the models in sequence. Selection involves copying models in proportion to their so-called fitness. The selected pairs of chromosomes (models) then exchange bit strings at some crossover site within the model string. The population then experiences mutation whereby a bit is randomly swapped in a chromosome's bit string. Following these three steps, the models are compared to the old generation of models and

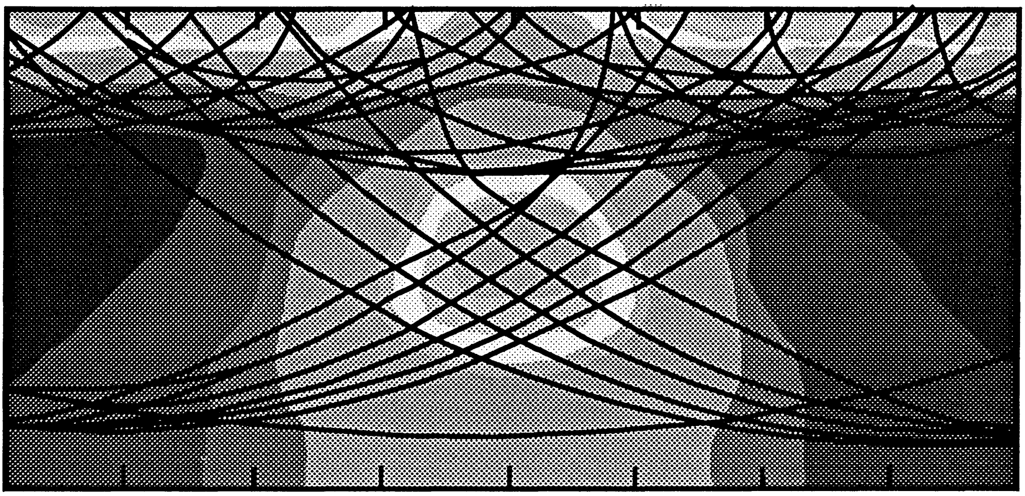

FIG. 9. Seismic waveforms can be used to derive estimates of the attenuation properties of the crust. This illustration from Wilcock *et al.* (1992) shows how the region of magma and hot rock can be identified using the extent to which rocks attenuate seismic energy. The most lightly shaded areas are the most strongly attenuating. These data, together with the results of tomographic studies that give the velocity distribution beneath the ridge, are clarifying the structure beneath fast-spreading centers and providing insight into the process of seafloor spreading.

accepted or rejected based on the same fitness measure. The procedure repeats until all models are almost equally fit.

1.2.3 Seismic Imaging Using the Scattered Wave Field The basic principle in this approach is that seismic energy propagating at near-vertical take-off angles will, on encountering changes in elastic properties on a spatial scale that is small relative to the seismic pulse length, be scattered by them and returned to the surface. This scattered response can be used to construct a visualization of short-wavelength structure often called a reflection image. Energy sources and hydrophone arrays (streamers) for reflection experiments are the same as those used to create refraction seismograms, but both are towed from the same vessel. The source is fired at regular intervals corresponding to fixed along-track increments, usually less than 50 m. Hydrophone arrays of up to 6 km in length, containing as many as 1000 individual hydrophones, are used, together with source arrays of 60 or more airguns firing total volumes of more than 10 000 in.^{3}. The experiment produces an essentially continuous insonification of the subsurface because the receiving array moves only a small fraction of its length between shots.

Each shot fired during an experiment creates a seismogram with a fixed source geometry and a suite of regularly spaced traces, one for each hydrophone group in the streamer—usually 60 to 240 traces. To produce a reflection image from field recordings, traces are regrouped ("gathered"), corrected for varying source–receiver distance, and summed ("stacked"). Gathering is done so that summed arrivals have come from approximately the same reflection points. Each regrouped seismogram is a small common-midpoint experiment in which maximum range is the streamer length. Time corrections to gathered seismograms are made to align traces, which are then summed to enhance signal-to-noise characteristics. The correction attempts to bring arrivals observed at all ranges to the travel time they would have were they recorded at an offset of zero—the correction appropriate for situations where the subseafloor structure is nearly horizontal is called a normal move-out (NMO) correction, and a different type of correction, known as dip move-out (DMO), is applied if structure is complex or steeply dipping. In both cases, the correction is equivalent to a transformation to zero offset. In theory, summation of traces after trace alignment produces signal-to-noise enhancement by a factor equal to the square root of the number of traces summed.

Reflection seismograms obviously have an appearance that matches our expectation of what a profile of the Earth's interior might look like, and really qualify to be described as an *image* (Plate 2). It is not a direct representation of subsurface structure, but rather its acoustic response. An image is produced by reversing propagation effects by downward wave-field projection or extrapolation ("migration"). Several wave-field extrapolation methods have been developed, all of which involve several stages of data manipulation, and all are very demanding of computer time (Yilmaz, 1987). The velocity field must be known very well (and may not be). Most extrapolation methods involve some form of approximation to the full wave equation to make computations tractable. Most, for instance, allow only mild lateral variations. Extrapolation methods are similar to synthetic seismogram methods. Kirchoff integration methods operate in the time domain and are the simplest methods. A popular transform method operates on data in the frequency-wavenumber (FK) domain but is strictly applicable only when no lateral velocity variations are present. Finite-difference migrations can account for mild lateral variations (Claerbout, 1985). To perform extrapolation in a completely correct way requires use of the full wave equation, must operate on pre-stack data, and must account for refraction of rays across boundaries. The FK and FD extrapolates are the most commonly used in studies of oceanic crust.

1.3 Potential Fields

1.3.1 Studies of the Gravity Field Variations in the strength of the earth's gravitational field provide information on geologic structures associated with inhomogeneities in the distribution of mass within the Earth. The magnitude of the gravitational acceleration at the Earth's surface is about 980 cm/s^2, but varies both because of the shape of the Earth (a measurement taken at the equator is further from the Earth's center of mass than is a measurement taken at the pole) and because of local inhomogeneities in the Earth's density structure. The standard unit of gravitational measurements is named the Gal in honor of Galileo and has a value of 1 cm/s^2. However, a more useful unit for geophysical applications is the milliGal (mGal). Gravity at the earth's surface is then slightly less than 10^6 mGal. Gravity anomalies resulting from geological structures are generally less than about 50 mGal but can be as large as a few hundred mGal.

Gravity measurements made during geophysical surveys, whether on land or at sea, are almost invariably relative, rather than absolute. Determination of the difference in gravity between several locations is much simpler, faster, less expensive, and, until very recently, more accurate than actually determining the value of gravity at each location. A survey therefore needs to be "tied in" by including measurements at locations where the absolute value of the gravity field is known. For marine surveys, this is done in port prior to and following the survey.

Gravity surveys at sea are made difficult because the vessel is subject to large accelerations caused by wave motion. A moderate-sized ship, such as commonly used in marine surveys, can be subjected to accelerations of up to 100 000 mGal, or 10% of the earth's gravity. Since gravimeters cannot distinguish accelerations due to gravity from those due to the ship's motion, it is necessary to suppress or remove these environmental accelerations to isolate the much smaller variations in gravity resulting from geologic structure. This is commonly done by passing the gravity measurements through a low-pass filter. Gravity variations resulting from geological structures are commonly a kilometer or more across. Since a ship traveling at 10 knots (a common cruising speed during surveys) travels about 300 m in a minute, any gravity anomaly resulting from geological structures will have a period of several minutes. On the other hand, ship motions typically have a characteristic period of the order of 10 to 30 seconds, and average to zero (since the ship remains on the sea surface). Thus, by passing the gravity signal through a low-pass filter that suppresses signals at periods shorter than 2 to 3 minutes, vertical ship motions can be effectively removed. Marine gravity measurements can be obtained with an accuracy of about 1 mGal, while gravity measurements on land can be made with an accuracy of about 0.01 mGal.

There are two basic type of meters presently in use, beam gravimeters and forced-feedback accelerometers. A beam gravimeter

[Fig. 10(a)] consists of a beam, one end of which is free to rotate in a vertical plane. The force of gravity on the free end of the beam is balanced by a zero-length spring, i.e., one for which the relationship between elongation and applied force acts as if the spring had zero length when unloaded. For such a spring, a small change in gravity produces a large deflection of the beam (Harrison, 1960; Worzel and Harrison, 1963). The sensor for a forced-feedback accelerometer gravimeter [Figure 10(b)] is an inertial-navigation grade accelerometer. The sensor consists of a proof mass wrapped in a coil and constrained to move along the vertical axis between two permanent magnets. The mass is maintained at its null position by a balance between gravity and the electromagnetic force induced by a current through the coil. Changes in the position of the coil are detected by a feedback loop, which regulates the current in the coil to drive the proof mass back to its null position. The current through the coil, averaged over 1-s intervals, is monitored to determine changes in the vertical acceleration. Both types of gravimeter record accelerations along their vertical axis. They must therefore be kept level to detect changes in the Earth's gravity field correctly, and this is accomplished by mounting the gravimeter on a gyrostabilized platform.

To make gravity measurements suitable for interpretation, effects not related to geological structure have to be removed. Gravity changes with latitude because the Earth is not a perfect sphere and because it is rotating. The latter effect enters because the net force experienced by a body at the surface of the Earth is the sum of a downward "gravitational" force due to the earth's mass and an upward "centrifugal" force due to the rotation of the earth. The centrifugal acceleration is dependent on latitude because a body's distance from the Earth's spin axis and therefore its velocity vary with latitude. The motion of the ship also alters the centrifugal acceleration. This is referred to as the Eötvös effect (after Hungarian geophysicist Baron Roland von Eötvös). It can be as large as 90 mGal for normal ship speeds, much larger than the magnitude of most geological anomalies in deep-water areas.

Gravity variations are defined in terms of an anomaly, being the difference between the measured and the expected value of gravity at a location. The difference between a gravity measurement at sea level and the expected gravity at that latitude, after making

an Eötvös correction, is referred to as a "free-air anomaly". This is the most commonly used anomaly for marine studies. Gridded bathymetric data sets from swath mapping surveys have also made possible the use of a "mantle Bouguer anomaly" (Prince and Forsyth, 1988). Calculation of this anomaly involves correction for the gravity effect of bathymetric relief (water-crust interface) plus the effect of the crust-mantle interface achieved by assumption of a constant-thickness crust (usually 6 km). Examples of use of these types of anomalies are discussed below (see Plate 4).

Marine gravity surveys are generally carried out with lines run perpendicular to the expected trend of the feature being surveyed. Until recently, interpretation has usually assumed that the structure being investigated is two-dimensional. The gravity anomalies resulting from two-dimensional model bodies can be easily calculated (Bott, 1960; Talwani *et al.*, 1959) and interpretations made based on forward modeling procedures much like those described for seismic methods. The application of multibeam swath mapping systems since the early 1980s has resulted in surveys which include complete (or nearly complete) bathymetric coverage of sizable areas. This has allowed three-dimensional variations in structure to be explicitly included in gravity modeling. These are usually calculated with Fourier transform techniques (Parker, 1973).

1.3.2 Magnetic Field Studies The Earth's external magnetic field is very near to that expected from a bar magnet with its poles roughly corresponding to the earth's rotational poles. This was recognized in the sixteenth century by Gilbert, who wrote in his treatise *De Magnete* that "*magnus magnes ipse est globas terrestis*" (the Earthly globe itself is a great magnet). The approximate coincidence of rotational and magnetic poles has been used for navigation for hundreds of years, since it implies that a magnetized compass needle will point toward the pole. This dipolar nature of the field means that its direction relative to the earth's surface varies with position on the earth. The field is oriented in a vertical direction at the poles (down at the north pole, up at the south pole) and is horizontal at the equator. The field is specified by the "inclination" or "dip" (the angle with the horizontal), the "declination" (the angle between the horizontal component and true north), and magnitude of the total field. The SI (mks) unit for magnetic intensity is the tesla, which is defined as 1 Wb/m^2 (or as 10^4 G to use a more familiar unit). A more useful unit for discussing the earth's magnetic field is the nanotesla (nT), often called the gamma (γ). The earth's magnetic field varies from about 30 000 to 60 000 nT. Magnetic anomalies resulting from geological structures are commonly a few hundred nT, but may be as large as several thousand nT.

The magnetic field arises from electrical currents within the core. The interaction of these currents with fluid motions in the liquid outer core (caused by thermal convection) and the rotation of the Earth can result in a feedback mechanism or dynamo, so that the Earth's magnetic field is self-sustaining (Backus, 1958; Bullard and Gellman, 1954; Elsasser, 1956; Herzenberg, 1958; Parker, 1955). Magnetohydrodynamic models suggest that the earth's field consists of a very strong (perhaps 100 to 500 Oe) internal toroidal field confined to the core and a much weaker external poloidal field, which results from distortions in the toroidal field and is the magnetic field observed at the surface.

As in the case of gravity-field studies, magnetic-field values are treated as anomalies with respect to a reference field. For magnetic studies, an empirical reference field is determined by a spherical-harmonic analysis of magnetic measurements at numerous fixed locations around the world. These International Geomagnetic Reference Fields are determined at a particular time and are referred to by the epoch for which they are valid, for example IGRF 1985. Since the secular variation is reasonably smooth, predictive models are used to interpolate between the times represented by them and to extrapolate from the most recent IGRF to the present. In addition, the anomalous field must take account of secular changes due to two forms of variations in the external field phenomenon. One is the diurnal or daily variation associated with the pattern of ionospheric currents following the sun. These are generally smoothly varying and reasonably small (30 to 50 nT). The second type of variation is the much higher-amplitude, shorter-period, irregular disturbances known as magnetic storms that frequently occur at times of vigorous sunspot activity and are accompanied by spectacular auroras and disrupted radio communications. It is frequently impossible to collect useful magnetic data during magnetic storms.

As was the case with gravity studies, the advent of swath map surveying in the 1980s has led to the collection of densely sampled grids of magnetic data. With the assumption that the magnetization is in a single direction (or 180° from that direction), these grids of data can be inverted to give the distribution of magnetization of the crustal rocks (Macdonald *et al.*, 1980; Parker and Huestis, 1974).

For most marine studies, the magnetic-field strength only is measured, and the instrument used is a proton precession magnetometer, which uses nuclear magnetic resonance to determine field strength. Protons making up the nuclei of hydrogen atoms in water possess a magnetic moment that causes them to try to align along any external magnetic field. Since the Earth's field is fairly weak, this tendency is more than overcome by thermal agitation, which constantly disorients the protons. The magnetometer basically consists of a bottle of water with a coil around it. A large current is passed through the coil to create a strong magnetic field, several hundred times as large as the Earth's field, and this aligns proton spin axes in the same direction. When the current is stopped, the applied field is removed, and the protons sense only the Earth's field. They will try to reorient themselves along the Earth's field, and, for a short period of time, until thermal agitation disorients them, the protons will coherently precess around the Earth's field. The precession frequency is directly proportional to the external magnetic field strength and can be measured by the induced current. Proton precession magnetometers therefore determine the intensity of the total magnetic field.

Magnetic anomalies arise because the Earth's field can *induce* a magnetic moment in magnetic materials by causing the spins of free electrons to align along the magnetic-field direction. In addition, many rocks contain ferromagnetic minerals that can acquire a *permanent* or *remnant* magnetization when they originally form. The rock magnetization, whether induced or permanent, produces a magnetic field. The anomaly associated with local structure results from the interaction of the Earth's field with the field generated by the magnetized body. Hence, even when a body is magnetized along the direction of the Earth's field, the associated anomaly will vary with location on the Earth. The total intensity magnetic anomaly over a spherical body magnetized in the direction of the Earth's field will be positive and symmetric at the magnetic poles, while at the equator, the anomaly will be symmetric and of the same magnitude but have negative amplitude (Fig. 11). At intermediate latitudes, the anomaly will be asymmetric or skewed. For the same reasons, the anomaly depends on the body's orientation. A north-south profile perpendicular to and across the center of a linear feature that is oriented in an east-west direction near the equator will show a large negative anomaly. If the body is rotated 90°, so that it is oriented in a north-south direction, an east-west profile perpendicular to and across its center will show no magnetic anomaly.

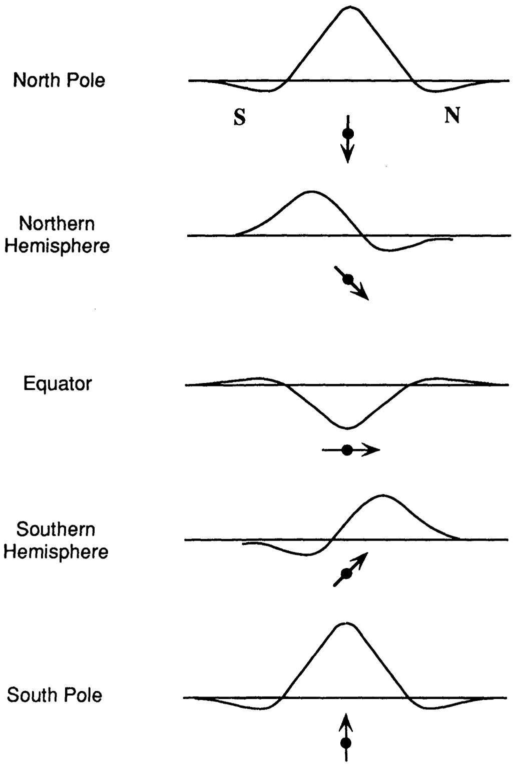

FIG. 11. The magnetic response of a buried object with magnetic properties varies according to its position on the Earth because the anomaly produced results from the interaction of the present field with the magnetic field of the body that may have been acquired at a very different time when the Earth's field was oriented differently from today's field. Even if the body is magnetized in the direction of the present field, the anomaly produced varies with latitude.

2. MARINE GEOPHYSICAL METHODS AND THE STUDY OF MIDOCEAN RIDGES

The midocean-ridge systems of the world's oceans are the locus of creation of new seafloor through a complex system of processes that involves melting of underlying mantle to produce magma, and transport of magma through a low-porosity mantle to the surface, where it freezes to form oceanic crust—a layer of igneous rock about 6 km thick that floors virtually all the world's ocean basins. The rate of crustal production, or spreading rate, is measured from the pattern of magnetic anomalies. This use of marine magnetic anomalies to establish the age of the seafloor and hence the rate at which it was created is axiomatic to the modern era of understanding of the ocean basins and their mechanism of formation. Magnetic anomalies can be used to establish the age of the seafloor because the Earth's magnetic field periodically reverses its polarity. Igneous rocks acquire a permanent remanent magnetization in the same direction as the Earth's field at the time they cooled. Seafloor formed when the magnetic field is reversed will acquire a magnetization that is 180° different from that acquired when the field is in its present, "normal" direction. Reversals during the past 45 Ma have occurred irregularly, averaging roughly 200 000-yr intervals. The irregularity of the reversals creates a distinctive pattern to a sequence of anomalies (Fig. 12) that can be correlated between areas of the same age and, once the dates of the reversals are known, can be used to assign ages to the seafloor (Heirtzler *et al.*, 1968; Cande and Kent, 1992). Three-dimensional magnetic surveys have been carried out in a number of settings. Macdonald *et al.* (1980) and Sempere *et al.* (1987) studied the transition from normally to reversely magnetized crust. They found that the transition is sharp, linear, and quite narrow. This implies that reversal of the field takes place over a relatively short period of time, and that the zone in which new crust is created at intermediate and fast-spreading ridges is narrow and spatially stable.

Oceanic crustal thickness is only 20% of that of the continents. This was not recognized until the 1950s, when the first seismic experiments were carried out in the deep oceans. Furthermore, these early seismic experiments found that oceanic crustal thickness was almost invariant throughout the world's oceans. While it has more recently been shown that thickness varies more than the resolution of earlier experiments allowed us to appreciate, the variation is still small and is not well understood. One of the thrusts of marine geophysical research at present involves attempts to understand how oceanic crust is formed and the controls on crustal generation processes. It has recently become apparent, for instance, that the rate at which crust is produced by seafloor spreading at ridges profoundly affects *some* aspects of the crust-generating process but has little effect on others. We will use this research area as a vehicle for describing one way in which the marine geophysical measurements described above are used as a tool for research.

2.1 The Shifting Paradigm I: Controls on the Form of Midocean Ridges

The existence of an extensive ridge system in the world's ocean basins was first recognized in the early part of the century when ships engaged in stringing telephone cables across the Atlantic found systematic evidence for significant shallowing in the middle regions of the ocean. By the 1970s, through compilation of many widely spaced crossings of ocean basins made by ships carrying single-beam bathymetric systems, it had been discovered that ridges like the Mid-Atlantic Ridge were present in essentially all the oceans, though not always located as centrally as the Mid-Atlantic Ridge. With the parallel recognition that ridges were the site of lithospheric generation, there emerged a conceptual picture of the ridge system as a quasilinear zone of generation of new lithosphere, save for a few places where very large offsets, fracture zones, were present.

The modern era of exploration of the ridges can be thought of as beginning when multibeam swath mapping systems were first deployed to provide systematic maps of the axial regions. Aspects of the ridges' shapes that had been hinted at from the earlier data became clearer, and their importance became profoundly understood. One of the most revealing findings was that the axial region of ridges spreading at fast rates (around 10 cm/yr) displays a distinct topographic high, while those spreading at rates around 2 cm/yr or less exhibit a distinct topographic depression (Plate 3). The nature and cause of this great difference appear to relate to the changing balance of forces that combine at the midocean ridge. Another finding is that the ridges are far from quasilinear features, but instead are finely divided into *spreading segments*—individual cells of the ridge that are effectively isolated from their neighbors. The offsets associated with fracture zones were recognized to be part of a multimember family of offsets that exhibit remarkably different form in different ocean basins.

The creation of new lithosphere is funda-

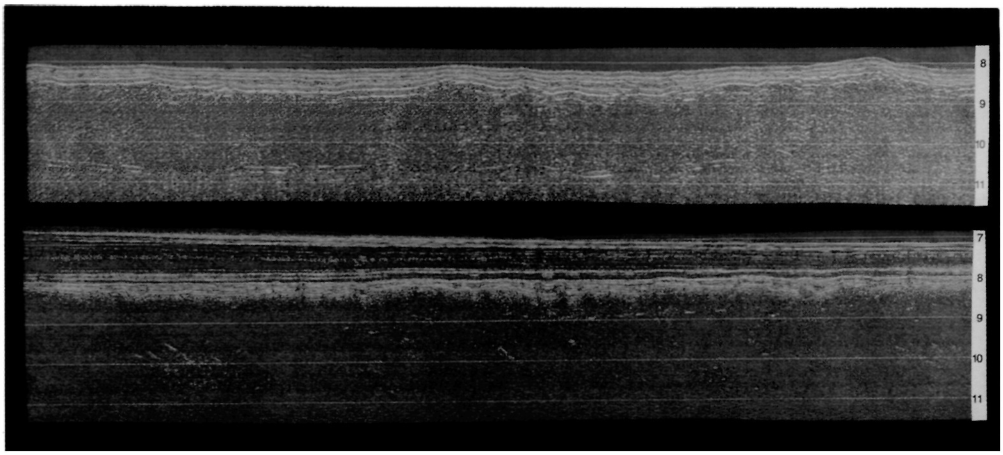
Vol. 9 – PLATE 1. Typical renderings of the shape of the seafloor include three-dimensional representations of the midocean ridge such as the one shown in the upper panel, a region at the East Pacific Rise. The ridge is the elevated area in the center of the diagram. A seamount is seen on the far left of the map. Note that the general trend of the seafloor topography forms a typical linear pattern approximately parallel to the trend of the ridge axis. This map was produced using the Hydrosweep swath mapping system of Atlas Electronic. The lower panel is a plan view contour representation. The area of its three-dimensional figure is shown in the rectangle.



Vol. 9 – PLATE 2. Seismic images of crust produced by seafloor spreading at ridges creating crust at very different spreading rates. In the upper panel, crust produced at the fast-spreading East Pacific Rise shows almost no internal structure but has a distinct base that is the Moho. By contrast, the slowly-spreading Mid-Atlantic Ridge creates crust that is densely structured with dipping features within, but has a poorly resolved base. These differences relate to the differing balance between magmatic production and tectonic stresses in the two settings. These differences are also apparent in the topography of the ridges (Plate 3).

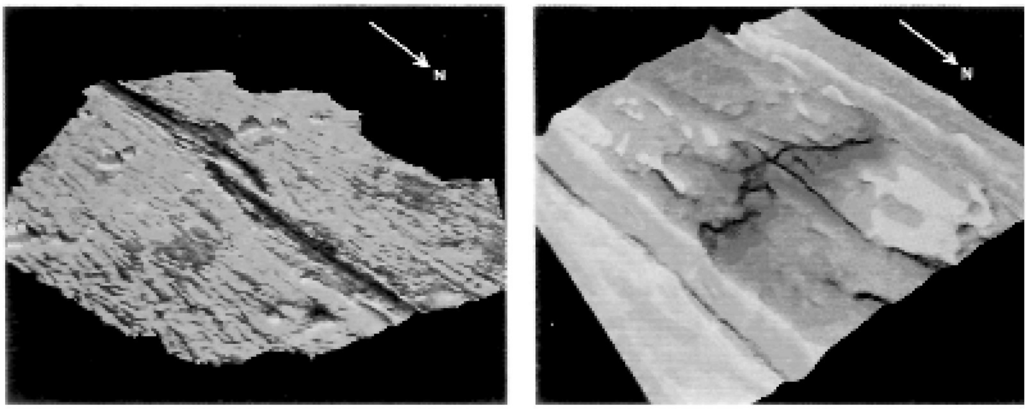
Vol. 9 – PLATE 4. The gravity response of a slowly-spreading ridge such as the Mid-Atlantic Ridge (upper left) can be expressed as a free air anomaly (upper right), but when expressed as a mantle Bouguer anomaly (see text for description), a remarkable circular anomaly pattern is revealed (lower left). These are believed to be the expression of zones of upwelling mantle containing a high percentage of magma. When the large-scale thermal structure of the ridge is subtracted, the circular anomalies become elongate perpendicular to the ridge, perhaps marking zones of a thick and a thin crust produce near to, and away from, upwelling centers. Illustrations from Lin *et al.* (1990).



Vol. 9 – PLATE 5. A typical feature of fast-spreading ridges is the overlapping spreading center (OSC). This is a region where two portions of the ridge run in parallel for a short distance (left-hand image). These features migrate along the ridge axis, as one of the parallel limbs grows at the expense of the other. Strong magnetic anomalies associated with crustal formation at the dying ridge tip form a roughly "V"-shaped pattern that tracks the past motion of the OSC. Illustration from Macdonald and Fox (1990).

SEISMIC PROFILES: SOUTHERN EAST PACIFIC RISE

Vol. 9 – PLATE 6. Perspective rendering of two seismic images of the axial region of the East Pacific Rise (Detrick *et al.*, 1993). The longer line runs along the very summit of the ridge crest. One feature of interest in these data is the axial magma chamber (AMC) reflection that appears as a tiny bright event beneath the ridge in Plate 5. In the profile obtained along the summit of the ridge, we see that the AMC, although small in cross section, displays a surprising continuity along the length of the ridge.

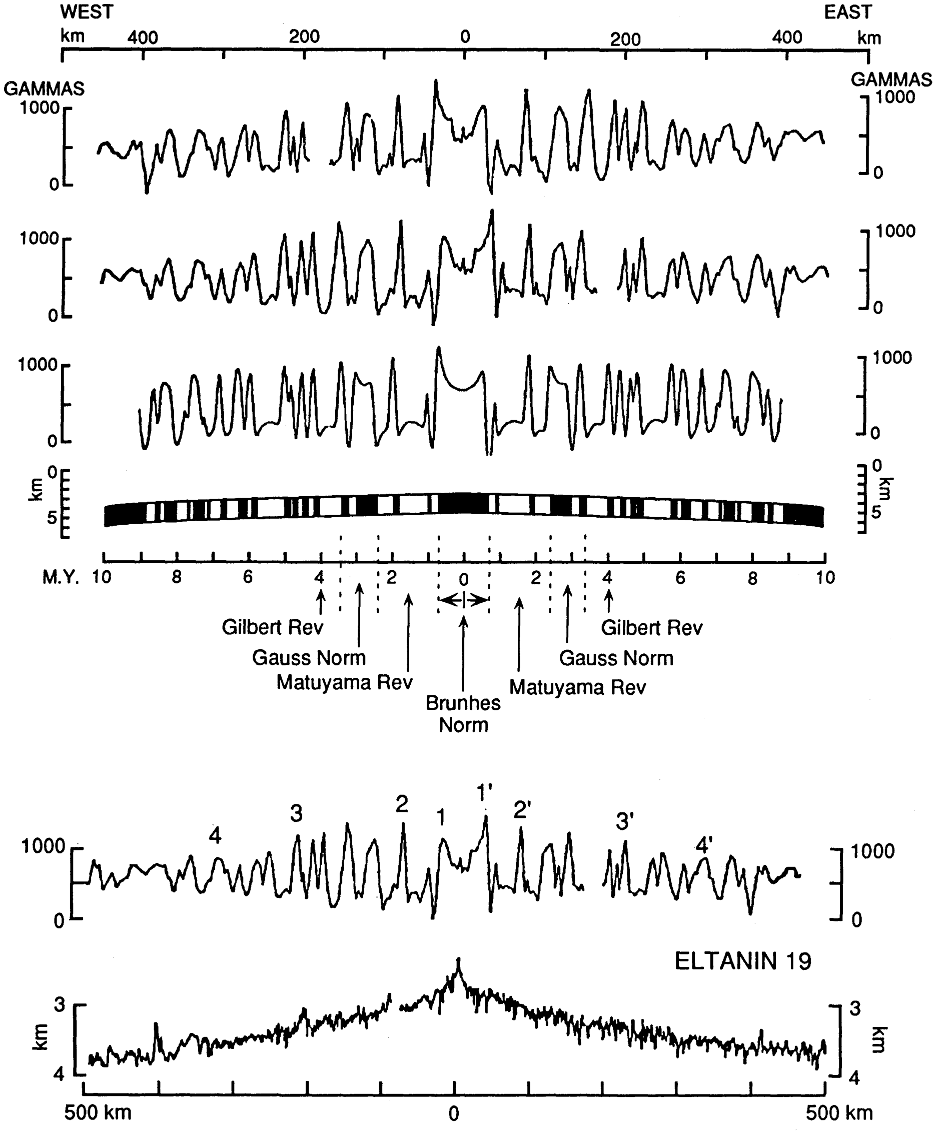

FIG. 12. The pattern of magnetic anomalies recorded over a midocean ridge shows a symmetric pattern that is the response of rocks magnetized in alternating directions (black and white regions of the magnetization model beneath), as the Earth's magnetic field has reverses in polarity with time. These anomalies can be dated and used to establish the history of seafloor spreading.

mentally a magmatically driven process. As plates separate, the underlying mantle rises upward, and a small fraction melts by decompression. The melt separates from the matrix of the still solid mantle and moves toward the surface at a faster rate than the mantle itself. The melt is not completely free to move because the mantle does not contain free pathways, and the partly trapped melt causes buoyant forces to be generated that assist the mantle in its upward motion. This buoyancy-driven flow is critically important because its form and strength depend on the temperature field of the spreading region, which in turn depends on spreading rate—the environment of a slowly spreading ridge is cooler on average than that of a fast-spreading ridge. Buoyancy-driven flow is expected to be stronger and more three-dimensional at slowly spreading ridges than at fast-spreading ridges. The role of mantle flow may therefore be critical to understanding the differences between fast- and slowly spreading ridges.

Another important difference is that slowly spreading ridges are associated with significant earthquake activity, while fast-spreading ridges have only very minor activity. This means that mechanical stresses associated with creation of new lithosphere at slow rates are greater than those associated with spreading at fast rates. Why should that be? Again the reason can be related to the temperature-field differences of the two systems. Fast-spreading centers are hot, and hot material, subjected to stresses, yields plastically without breaking. Slowly spreading ridges are relatively cold, and the rocks are brittle by comparison with the softer, more pliable hot rocks of fast-spreading regions, and, when subject to stress, they will often break. When rocks break, they create faults in the crust, and the rock-breaking process gives rise to earthquakes. It is believed that this accounts for much of the difference in axial topography of the ridges.

The axial depression of slowly spreading centers is created as the response of the crust to mechanical stresses that are trying to pull the crust apart. This stretching causes faulting as the crust extends laterally. The depression is a rift valley, much like those that underlie the lakes in East Africa where the African continent is also subject to extension. The great difference here is that the crust at a spreading center is being created and deformed at essentially the same time. Most investigators believe that the process is episodic—crust is created by injection of magma at irregular and largely unknown intervals. As the new magma body cools, it becomes increasingly rigid and able to sustain mechanical stresses. During cooling, the axial region is continuously subject to extensional stresses, and so the crust will deform initially by plastic flow and then by faulting as the crust becomes more rigid. Thus, the degree to which the crust experiences faulting is largely governed by the periodicity of magmatism. It is widely accepted that magmatism is almost continuous at fast-spreading ridges, and, because of this, the crust of the axial regions remains hot and pliable there. At slowly spreading centers, considerable time probably elapses between magmatic pulses, and this allows mechanical deformation to create the faulted rift valley that characterizes these features.

At fast-spreading centers, the axial region is characterized by a distinct topographic elevation that rises above the regional level of the seafloor. Side-scan sonar imagery in the axial region allows investigators to map volcanic flows of different ages using the property that different-aged material will have a different extent of sediment cover, and this will affect the backscatter properties differently (Fig. 3). The same data show the pattern of faults and fissures as linear bands of intense reflectivity. In conjunction with other work, side-scan studies have shown that the zone of active volcanism and faulting at the crest of the axial ridge is surprisingly narrow, only 5 to 10 km wide (Bicknell *et al.*, 1988; Macdonald and Luyendyk, 1977). In fact, most of the volcanism occurs in a depression first described as an axial summit graben and now more typically described as the axial summit caldera (ASC). This feature is only a few hundred meters to perhaps a kilometer wide (Fig. 13). This observation has proven to be a major puzzle to investigators. Melt is generated at depths in the mantle of about 60 km, over a region perhaps a hundred or so kilometers in breadth. That melt emerges at the crest of a ridge over a region that is so small relative to the zone of melt generation suggests that a mechanism exists that can efficiently focus melt into the region of the ridge axis. A considerable amount of theoretical modeling has been carried out in an effort to explain this process, but the models require the input of unknown parameters such as the viscosity and permeability of the mantle. Each different parametrization leads to a different theoretical pattern of flow. To investigate the problem, a large-scale experiment is planned for a very fast-spreading region of the southern East Pacific Rise, in which seismic and electrical methods will be used to map the pattern of flow. Electrical methods have not been widely employed in studies of the oceanic lithosphere, but they hold great promise since they are able to sense the presence of melt more directly than seismic methods because the differences in electrical conductivity of liquid and solid phases of the same material are much larger than the corresponding differences in seismic wave speed for these same materials.

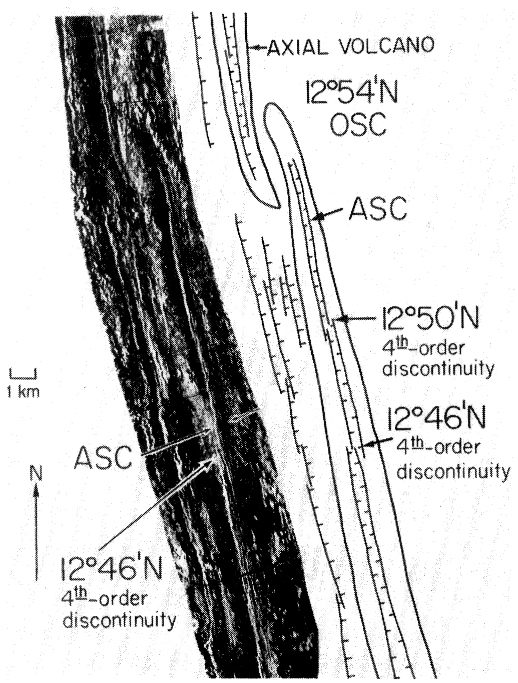

FIG. 13. Side-scan sonar image of the axial region of a fast-spreading ridge and its interpretation. Images like these show the narrow region only a few hundred meters wide called the axial summit caldera (ASC in the illustration) within which most recent volcanic eruptions are confined. Data from Macdonald *et al.* (1993).

The migration of melt to the surface probably does not occur in a sheetlike fashion, but instead the melt rises in a series of relatively isolated plumes. It is now widely held that this focused upwelling is largely responsible for the segmentation of ridge morphology that swath mapping surveys have made apparent. One particularly powerful line of evidence comes from gravity observations (Lin *et al.*, 1990). When mantle Bouguer anomalies are calculated for regions of the slowly spreading Mid-Atlantic Ridge, they reveal remarkably circular patterns that can be associated with the morphological segments (Plate 4). These patterns identify low gravity values, suggesting that they are associated with deficiencies in mass beneath the centers of spreading segments. Because melt is less dense than the parent mantle, the gravity lows may well represent areas of melt concentration in upwelling plumes.

While the inferred plumelike rise of magma to the surface beneath the centers of spreading segments reveals fundamental structure of the deep mantle beneath, the present behavior of deep-mantle processes beneath the boundaries between segments may tell us about the time history of magmatic processes. Swath mapping has shown that there is a rich variety of discontinuities between individual spreading segments, and these take different forms for ridges spreading at different rates. At fast-spreading centers, these include regions where portions of the spreading system actually run in parallel for a short distance [Plate 5(a)]. These overlapping spreading centers (OSC) are very common on the East Pacific Rise, where they have been extensively mapped. The combination of detailed swath mapping and magnetic surveys shows that OSCs are not stable structures, but move along the ridge axis—apparently one limb of the OSC typically dominates over the other and lengthens while the other shortens. Evidence for this comes in the form of an apparent wake of deep seafloor left behind by the motion of the OSC, together with a striking pattern of magnetic anomalies. In Plate 5(b), we see that the ridge parallel lineations generated by the seafloor spreading process are overprinted in the central part of the map by a band of magnetic highs that is almost orthogonal to the trend of the ridge axis. This high magnetization is believed to result from chemical processes associated with the cooling of magma in a region that is relatively starved of magma, such as might occur on the dying limb of an OSC. The observation that the band of magnetic highs is not quite orthogonal to the ridge but forms a "V" shape suggests that the location of the position of the dying limb has moved in time. The overall motion is tracked by the shape of the wake and is to the south, but irregularities in the V show that there may have been an initial step to the north. This implies that one limb may dominate for a period of time and give way to the other.

2.2 The Shifting Paradigm II: Magma Chambers at Midocean Ridges

In that they appear as near proxies to geological cross sections, seismic reflection images have become a commonly used and extremely powerful tool in our quest for understanding the physical processes associated with seafloor spreading. A typical reflection image of the fast-spreading region of the East Pacific Rise south of the Garrett Fracture Zone (Fig. 14) reveals the structure beneath the elevated spreading axis that is well described from bathymetric mapping (see Sec. 2.1). The most distinct feature of the subsurface is a layer that approximately parallels the seafloor except immediately under the axis, where it shallows considerably. This reflection event lies at the boundary between rocks with relatively low velocity and a higher-velocity layer as determined from analysis of common-midpoint gathers that form part of the processing steps for creating the image, and from travel-time and wave-form analysis of expanding spread profile refraction data obtained in the same area. The boundary between slow and fast layers appears to be extremely sharp and has led to considerable speculation over the responsible geological mechanism. The problem is that the rock units themselves cannot vary very significantly. The rocks are all derived from the melting of mantle, so that we do not anticipate extreme variation in rock type—all the rocks that form the crust are basically basaltic in composition. What then can give rise to such an extreme change in the near surface?

Most investigators believe that the change relates to the mechanical state of the layers and not to rock type. At the ridge axis, lava is extruded to the surface, where it forms a highly fractured layer. Lavas are erupted at temperatures in excess of 1000 °C into water that is at effectively 0 °C, and the result is that they cool very rapidly and are usually very highly fractured. Rocks that solidify at deeper levels in the crust cool slowly and are less fractured. Because of this, the seismic velocity of rock layers near the surface does not represent the velocity of the rock itself but a combination of the rock and the material filling the cracks and fractures. In fresh lava at the surface, the cracks are filled with water, and the seismic velocity measured from the surface is much less than that of the extruded basalts themselves. The slow surface velocities are therefore thought to be indicative of the high degree of fracturing of the extruded sequences. The strong reflection is widely thought to mark the base of a layer of extruded lava, beneath which lie relatively unfractured intruded rocks that never came into direct contact with seawater. The boundary is then regarded as the mechanical interface between highly fractured and less fractured rocks. The very distinct nature of the boundary is surprising, however, since it might be expected that the degree of fracturing would diminish progressively with depth,

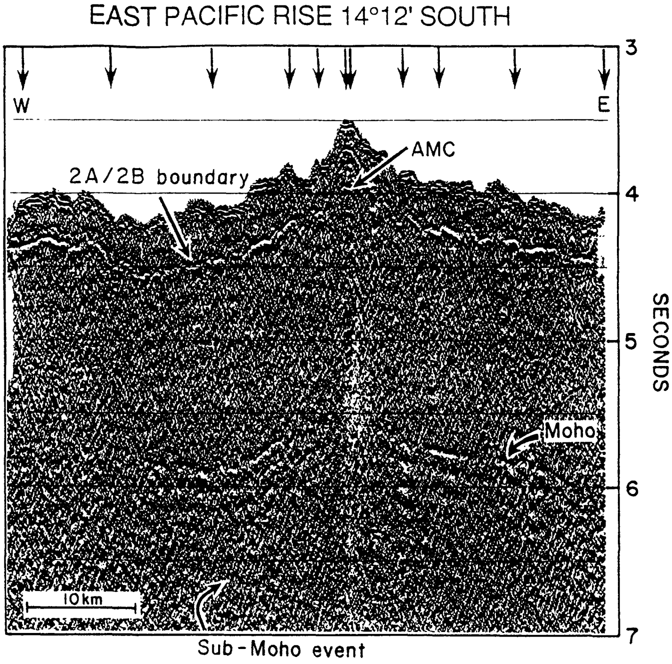

FIG. 14. Seismic reflection image across the crestal region of the East Pacific Rise, where the spreading rate is as fast as is known from any current ridge. Features revealed in the image are discussed in the text.

rather than change abruptly. Furthermore, the rapid deepening of the boundary down the flanks of the ridge axis has no agreed-upon explanation. One explanation is that it may be caused by off-axis extrusion of lava. There is some evidence in side-scan images that lava units flow down the flank of the axial high, but this explanation seems to contradict the evidence that *most* volcanism is confined to the narrow axial summit caldera. Another explanation is that the mechanical boundary may move down in the crust with time as a result of the effects of hydrothermal circulation that might drive a cracking front down into the crust. This mechanism, too, has not been substantiated.

At deeper levels, beneath the strong event in the image, we see the base of the crust marked by the Mohorovičić discontinuity, or Moho, and deeper still are indistinct features that may represent structure within the mantle. The reflection image also detects a tiny bright signal from just below the rise axis. The strength and spectral properties of the reflection suggest that it is the response of a body with much lower velocity than its surroundings and may therefore mark the top of a liquid magma body, the axial magma chamber (AMC). This feature is much smaller than any structure resolved by travel time or attenuation tomography (Fig. 7 and 9), and this testifies to the resolution potential of the reflected wavefield. The magma body, resolved by reflection images, is so small, in fact, that the term "chamber" seems barely applicable. It is typically not more than 1-km wide, and the thickness of the melt layer (judged from modeling refraction seismic data, and the spectral characteristics of the AMC reflection itself) may be less than 100 m.

Despite being very small and probably very thin, the AMC is surprisingly continuous along the axis of the rise. Plate 6, from Detrick *et al.* (1993), shows intersecting crossings of the southern East Pacific Rise on which the AMC is clearly visible. Although it is only 1 to 2 km wide at most, the AMC shows along-axis continuity for several tens of kilometers. The seismic reflection images therefore lead to the suggestion that the AMC might better be regarded as a high-level sill-like structure than as a chamber *sensu stricto.*

No reflection is observed from the base of the AMC or from its sides. Thus, although the reflection image gives a high-resolution image of one part of the structure, it fails to provide information on the larger structure surrounding the AMC. Because the reflection method images the response to relatively sharp changes in density and/or wave speed, what may be implied is that the lens of liquid magma has sides and a base that are too gradational to appear in the reflected response of the crust. Results of travel time and attenuation tomography reveal a region of reduced velocities that is much broader than that represented by the reflection image of the AMC, and this may imply that the AMC reflection arises from a thin pool of liquid magma that lies atop a broader zone containing traces of melt or perhaps solid rock in which the temperature has been raised by proximity to the region of melt.

If the pool of liquid magma is indeed very small, the crust cannot form by the simple process of solidification of magma since this would only account for a comparatively small amount of material. The crust above the magma chamber is formed by dike injection and lava eruption, but the crust beneath requires a different process. Recent models of oceanic crustal formation put forward by Phipps Morgan and Chen (1993), and similar models of Quick and Denlinger (1993), offer an explanation. These models use numerical techniques to calculate the temperature, crustal flow, and strain fields for models of spreading centers in which the crust is produced by a magma lens that is arrested in its upward descent when it reaches a freezing horizon controlled by hydrothermal cooling. The lens will reach shallowest levels in crust produced at fast spreading rates and be absent in crust forming at slow rates, consistent with the seismic reflection observations of magma-chamber characteristics. Figure 15 compares the calculations for three spreading rates. One critical prediction of this model is the great difference in crustal strain patterns predicted for the different spreading rates. The overall geometry of the strain field is similar in that we observe greater strain in the lower crust with elongated strain ellipses dipping toward the axis, flattening out as the Moho is approached. In fast-spreading crust, the crustal strain is very large, while at slow rates the strain is moderate.

If we were to somehow introduce strain markers into the crustal sections, they would

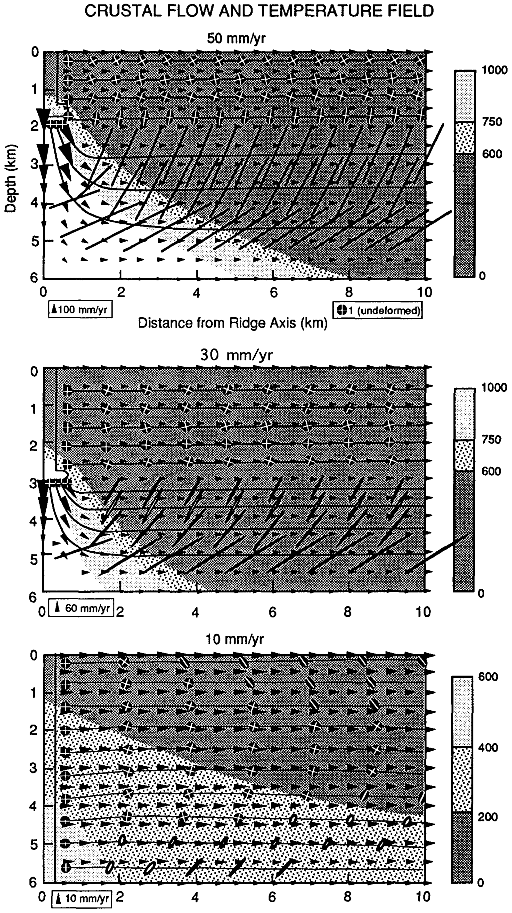

FIG. 15. Temperature, crustal flow, and strain fields calculated by Phipps Morgan and Chen (1993) using numerical simulation techniques to account for the creation of oceanic crust from a small magma body located within the crust. The crust above the magma chamber is produced by dike injection and volcanic eruption, while that below forms from the magma body and flows into the shape defined by the strain markers. These trace the shape of crustal layering and show a strong dependence on spreading rate (fastest is shown at the top, slowest at the bottom). Some of the differences in the seismic images of fast- and slowly-spreading crust (Plate 2) may be attributable to this mechanism of crustal accretion.

be deformed into the "stretched ellipses" shown in Fig. 15. In an actual ridge setting, this means that solidifying lower crustal rocks experience greater ductile strain at fast-spreading ridges than at slowly spreading ridges. Thus, crustal layering would be "strung out" to a much greater extent at fast-spreading centers than at slowly spreading centers and hence produce thinner layering. This may provide a key to understanding some of the differences in reflectivity of slow- and fast-spread crust (Plate 2). When layering is present of the type believed to constitute the features in the crust of the western North Atlantic, the response of the layers depends very strongly on its thickness. Obviously, a pathological case is established when the layer has zero thickness and hence cannot be resolved regardless of the wavelength of the seismic source. As layer thickness increases, its detectability does not simply improve as the thickness increases. In fact, a tuning phenomenon occurs in which reflections from the top and bottom of a thin layer can interfere constructively and produce a combined reflection that greatly exceeds the strength of the reflected response of either interface forming the layer. It is not unreasonable to assert that, given the noisy data field in which these images are created, crustal layering may *only* be detectable if it is developed at thicknesses near to the tuning thickness. One possible explanation for the differences in crustal reflectivity between slow-spread and fast-spread crust is not that the layering is absent in fast-spreading crust, but that the strain associated with crustal generation at a fast-spreading ridge is so large that any layering that develops is strung out so thinly that it becomes greatly less than the tuning thickness. The layering may be present, but seismically undetectable.

GLOSSARY

Airgun: Device that uses the discharge of compressed air to create a source of acoustic energy for marine seismic experiments.

AMC (Axial Magma Chamber): A strong shallow feature recognized in seismic reflection images of the axis of fast-spreading mid-ocean ridges such as the East Pacific Rise. It is believed to represent a thin pool of liquid magma that is the reservoir for lava eruptions at the ridge axis.

ASC (Axial Summit Caldera): A narrow, shallow, nearly linear depression in the summit of fast-spreading midocean ridges. Recognized in high-resolution sonar images of the seafloor, it is thought to represent a type of caldera collapse structure.

Bathymetry: The shape of the seafloor defined from the results of echo sounding experiments. Can be represented as profiles or contours or in perspective renderings.

DMO (Dip Move-Out): A seismic-image enhancement process used in conjunction with others to create clear images of the subsurface in areas of complex structure.

Eötvös Effect: The change in apparent value of gravitational acceleration caused by the motion of the platform on which the measurement is being made.

ESP (Expanded Spread Profile): A technique for acquiring wide-angle marine seismic data using two vessels, in which the midpoint position between the vessels is maintained fixed as the vessels separate, one discharging a seismic source while the other receives the seismic transmissions.

Free-Air Anomaly: The simplest means of expressing the gravitational effect of density heterogeneity in the earth. Obtained by removing a standard reference field from observed values reduced to the same plane as the reference.

Gather: A term originating in the oil exploration industry to describe the reorganization of seismic data from the geometry in which they were recorded to one more suitable for image processing.

Genetic Algorithm: A procedure for estimating unknown parameters from a suite of measured quantities related to the unknowns. Based on testing a population of models defined by test parameter strings by processes of selection, crossover, and mutation that are analogous to those of biological systems. Currently becoming used in seismic inversion.

GPS (Global Positioning System): A navigation system that uses a constellation of military satellites with accurately known positions as the basis for highly accurate, continuous position information.

Gravimeter: Device for measuring the strength of the Earth's gravitational field. Those used at sea rely on the principle of a balance beam or feedback accelerometer.

Induced Magnetization: The magnetic field of a rock body that is caused by the interaction of the Earth's field with magnetic minerals within the rock.

Lithosphere: The outer shell of the Earth (including crust and upper mantle) that deforms in a relatively rigid manner. The mosaic of plates that move across the face of the Earth is formed of lithosphere.

Magnetometer: Device for measuring the strength of the Earth's magnetic field. Most marine instruments use the forced precession of protons in the Earth's field as the basis for the measurement.

MBA (Mantle Bouguer Anomaly): The anomalous gravity field that remains after removing the effect of the shape of the seafloor and an estimate of the shape of the crust–mantle interface.

Midocean Ridge: Elongate, mountainous structure that occurs in most ocean basins and is the locus for creation of new lithosphere by seafloor spreading.

Migration: A term used in seismic-reflection image enhancement that refers to a process by which image geometry is positioned to portray structure in the earth more accurately.

Moho: A shorthand term for the Mohorovičić discontinuity that is the seismically defined interface beneath which propagation velocity exceeds 8.0 km/s, normally taken to be that in the mantle. Moho is therefore usually considered to represent the crust–mantle interface.

Multibeam Echo Sounder: Device for measuring the shape of the seafloor using sound transmitted from an array of transducers on the hull of a vessel. These send a wide swath of sound into the ocean that insonifies a swath of the seafloor, allowing for the efficient mapping of large areas of the seafloor.

NMO (Normal Move-Out): The process of correcting seismic data recorded on an extended array of receivers for the effect of transmission times to different parts of the array.

OBS (Ocean Bottom Seismometer): Device for recording seismic information either from artificial sources such as airguns or explosives, or from earthquakes. They typically comprise an external sensor attached to a pressurized instrument package that rests on the seafloor during recording.

OSC (Overlapping Spreading Center): Feature of fast-spreading midocean ridges in which two parts of the ridge run nearly parallel for a distance of as much as 50 km.

Ray: A construction used in seismic data analysis to describe the passage of seismic energy through the earth.

Remnant Magnetization: Magnetic property of a rock acquired at the time of its formation that it holds independent of the present magnetic field.

Seafloor Spreading: The process by which new lithosphere is created at midocean ridges through the upwelling of mantle and its partial melting and cooling.

Side-Scan Sonar: Device for measuring the strength of the return of acoustic energy from the seafloor in a broad swath. Strong returns and shadows provide a proxy for structure and geological formations.

Spreading Segment: A morphological portion of a midocean ridge, typically centered around an elevated portion of the axial depth, that is believed to be centered over an isolated, plumelike region of mantle upwelling. Segments are thought to be independent units of the ridge, communicating little with adjacent parts of the ridge.

Stacking: Term used in seismic-reflection image processing to describe the summation of signals from numerous parts of a recording array following NMO or DMO correction. Typically precedes migration in data processing.

Swath Mapping: Used in acoustic studies of the seafloor to describe the insonification of a wide region of the seafloor by arrays of transducers mounted either on the hull of a vessel or on a towed instrument package.

Synthetic Seismogram: The calculated seismic response of a specified Earth structure. Used as a guide to the interpretation of observed seismic data and as a basic for the inversion of seismic observations.

Tomography: A method of analysis of seismic data that applies to data obtained from arrays of instruments recording wide-angle information. The method creates a two- or three-dimensional estimate of the structure by optimizing travel times to all instruments from all the shots fired during the experiment. Resolution is related to the number of ray paths that cross one another.

5.1
Introduction

Measurements of mass and density have had commercial importance since antiquity. With the rise of modern physics, beginning with Newton, mass (or density) became one of the fundamental quantities used to describe the natural world. In the eighteenth century, Lomonosov in Russia and Lavoisier in France demonstrated that mass is conserved in chemical reactions. Analytical balances soon became the one piece of equipment common to all chemistry laboratories. Balances have remained essential tools of physics and chemistry even though our understanding of mass has changed greatly since the time of Lavoisier.

The first section of this chapter is devoted to mass measurements. After some basic principles, the unit of mass in the International System of Units (SI) is defined, and research toward a redefinition in terms of physical constants is mentioned. Practical considerations in the specification of secondary mass standards are introduced. Balances, the essential tools that allow comparison of one mass with another, are then discussed. We conclude the section with the link between the laboratory standard of mass and the mass of astronomical bodies or subatomic particles.

The second section, on density measurements, reviews the most widely used techniques for the accurate determination of this quantity.

5.2
Mass

5.2.1
A Few General Principles

A parameter called *mass* appears in fundamental equations of physics. Instead of defining this quantity, we take the view that the equations themselves show how the mass ratio of any two entities can be measured.

Newton recognized that the quantity now called *mass* fulfilled two roles in his physics: as the proportionality constant between force and acceleration (inertial mass) and as a parameter in describing the force of gravitation (gravitational mass). We may further distinguish two types of gravitational mass: active mass, responsible for generating the gravitational field, and passive mass, influenced by the field. In Newtonian physics, the two types of gravitational mass are identical, but

Handbook of Metrology. Edited by Michael Gläser and Manfred Kochsiek

ISBN: 978-3-527-40666-1

their experimentally observed equivalence to inertial mass appears fortuitous.

The postulate that the ratio of inertial mass to passive gravitational mass is the same for all objects is now known as the *weak equivalence principle or the universality of free fall* (see, e.g., Misner, Thorne, and Wheeler, 1973). The principle may safely be assumed for the practical measurements described later.

According to special relativity, the rest mass of an object is not simply the total rest mass of all its parts. The rest mass also includes a contribution E/c^2, where E is the sum of all internal potential and kinetic energies and c is the speed of light. Thus, for example, the Coulomb energy within an atomic nucleus contributes to its rest mass (e.g., about 0.4% in the case of gold). It is the total mass energy that is conserved, and there is no mass measurement that can distinguish between the individual components of rest masses and energies.

In general relativity, mass plays the role of generating the curvature of space-time.

5.2.2
SI Unit, Relation to Atomic Mass

The SI provides a practical framework for the precise measurement of physical quantities. The kilogram is among the base units of the SI and is now unique in that its definition remains tied to an artifact (BIPM, 2006):

> *The kilogram is the unit of mass: it is equal to the mass of the international prototype of the kilogram.* 3rd General Conference of Weights and Measures (CGPM), 1901.

The international prototype, the artifact referred to, is a cylinder made of an alloy of 90% platinum and 10% iridium. Since its fabrication in the 1880s, it has been stored and used at the International Bureau of Weights and Measures (BIPM) in Sèvres, France, according to provisions of the Convention du Mètre (BIPM, 2006). The national laboratories of most industrialized countries are equipped with 1-kg prototypes that are copies of the defining artifact. The mass in kilograms of these national prototypes is traceable through calibration at the BIPM to the international prototype. It is then the task of the national laboratories to calibrate standards whose masses are multiples or submultiples of 1 kg for the requirements of science, industry, and commerce.

In essence, the mass m (in kilograms) of any object is the ratio m/m_0, where m_0 is the mass of the international prototype. Operationally, the desired ratio is achieved by a chain of calibrations:

$$\left(\frac{m}{m_n}\right)\left(\frac{m_n}{m_{n-1}}\right)\cdots\left(\frac{m_i}{m_j}\right)\cdots\left(\frac{m_1}{m_0}\right) \tag{5.1}$$

where intermediate ratios involve secondary standards. Every intermediate ratio m_i/m_j in the chain represents a measurement (or series of measurements) and thus contributes to the uncertainty of the final result. Intermediate ratios involving artifacts whose mass ratio is not nominally unity or whose densities are not nominally equal pose particular problems, as discussed later (Sections 5.2.3 and 5.2.4).

In the case of other base units of the SI, such as the meter, it became clear long ago that the original artifact standard was noticeably unstable when compared with a ‘‘natural’’ standard, such as the wavelength of light emitted in certain atomic transitions. An analogous situation has yet to be confirmed as regards the kilogram. However, the precision with which 1-kg artifacts can be compared

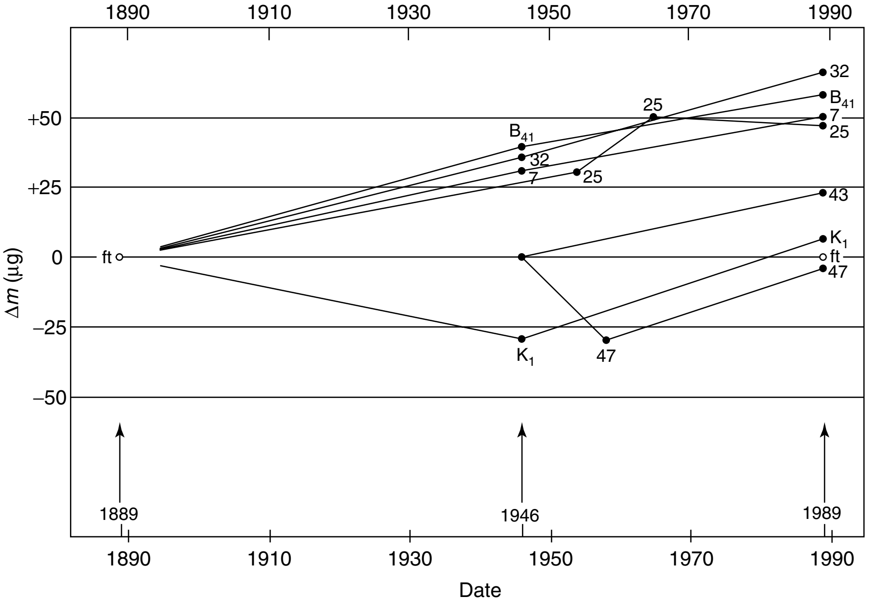

Fig. 5.1 The change in mass of seven similar artifacts since their first calibration, always with respect to the mass of the international prototype of the kilogram. The mass of the latter is defined to be 1 kg. The artifacts numbered 43 and 47 were first measured in 1946; the others in 1889. Courtesy of the Bureau International des Poids et Mesures.

is about 1 μg (1×10^{-9}), and one can easily see that a group of Pt/Ir kilogram artifacts made at the turn of the nineteenth century is slowly drifting with respect to the international prototype (Figure 5.1; Girard, 1994). It is conceivable, though unsubstantiated, that the entire group is drifting with respect to the constants of nature (Quinn, 1991). Several schemes are being pursued with a goal of checking the stability of the international prototype with respect to physical constants (Mohr, Taylor, and Newell, 2008). As yet, none of these schemes has achieved a precision sufficient to interpret the drifts shown in Figure 5.1. However, redefinition of the kilogram in terms of a physical constant, such as Planck constant, *h*, would already benefit electrical metrology and some areas of physics (Mills *et al.*, 2006). Redefinition of the kilogram, if it occurs, would maintain historical continuity.

Atomic masses can be measured to high precision relative to the mass of carbon-12 (Audi, Wapstra, and Thibault, 2003). The SI mole is the unit of "amount of substance" linking macroscopic and atomic mass: 1 mol of unbound atoms of carbon-12 at rest in their ground state has by definition a mass of exactly 0.012 kg. Each such atom has a mass of exactly 12 atomic mass units (u). The number of entities in 1 mol of any specified substance is the Avogadro constant N_A(6.022 141 79(30) $\times 10^{23}$ mol^{-1} (Mohr, Taylor, and Newell, 2008)), numerically equivalent to the number of atomic mass units in 0.001 kg. Hence, a measurement of the Avogadro constant to sufficient accuracy (and repeated at regular intervals) would provide a practical means of realizing the kilogram in terms of the mass of a single atom of carbon-12. Since the value of the molar Planck constant, $N_A h$, is already well known, redefinition of the kilogram could also be made in terms of h (Mills *et al.* 2006; Mohr, Taylor, and Newell, 2008).

5.2.3
Mass Balances (General)

The mass ratios in Equation (5.1) may be determined to high accuracy by the use of analytical balances. In principle, these devices are transducers whose output can be related to the difference in mass between two objects. For the smallest uncertainty, the two objects are nominally equal and the range of the transducer (or on-scale range of the balance, to use more traditional terminology) is a small fraction of the mass of each object.

The balance capacity puts an upper limit on the nominal mass of each of the objects no matter how small the difference between them. The use of such a transducer requires a companion set of mass standards that can be assembled to approximate the mass of the unknown.

Modern analytical balances have on-scale ranges equal to their capacity. This is a major convenience. If the scale is linear, it can be calibrated with a single mass standard. However, demonstrating linearity requires additional standards, so that even these balances achieve lowest uncertainty when used to compare the mass of nominally equal objects.

The existence of narrow-range mass transducers is sufficient to create standards whose mass is any multiple or submultiple of 1 kg. For instance, it is possible, using a sensitive balance, to demonstrate that 10 artifacts are approximately equal in mass and that the 10 taken as a group have a mass approximately equal to 1 kg. Thus, the mass of each of the 10 artifacts is nominally 100 g. Corrections to the nominal mass can be calculated by taking the balance readings into account. The uncertainty in each correction is ultimately determined by the precision of the balances that were used (see, e.g., Prowse and Anderson, 1974).

5.2.4
Need for a Buoyancy Correction

Weighings carried out in air (or any other fluid) will require correction for buoyancy. If comparison weighing is done in air of density ρ_a, then the unknown object acts as if its effective weight were $m(\text{eff})g$:

$$m(\text{eff}) = m - \rho_a V \tag{5.2}$$

$$= m(1 - \rho_a/\rho) \tag{5.3}$$

where V is the volume of the object, ρ is its density, and g is the gravitational acceleration in the laboratory. For simplicity, assume the weighing is done on a linear balance whose scale range equals its capacity. The balance output is routinely calibrated weighing a standard of known mass m_s, with nominal value near the capacity. The calibration procedure adjusts the scale output to read (m_s), where {} indicates the numerical value of the quantity within the brackets. However, the balance has actually responded not to m_s but to the weight $m_s(\text{eff})g$

$$m_s(\text{eff}) = m_s(1 - \rho_a/\rho_s) \tag{5.4}$$

where g is the local gravitational acceleration and ρ_s is the density of the standard. Consequently, m is related to its balance reading $\{y\}$ by

$$m = \{y\}\,\frac{(1 - \rho_a/\rho_s)}{(1 - \rho_a/\rho)} \tag{5.5}$$

The quantity $\{y\}$ is often referred to as the *apparent mass of the unknown object*. The local gravitational acceleration is the same for the standard and unknown and thus does not appear in Equation (5.5) as long as the centers of mass of the two objects are at the same elevation (the relative gradient of g is about $-3 \times 10^{-9}\ \text{cm}^{-1}$ at the surface of the earth). The buoyancy terms are more problematic, especially when one is weighing materials much less dense than the standard. Since ρ_s is typically $8000\,\text{kg m}^{-3}$ and ρ_a is about $1.2\,\text{kg m}^{-3}$ in laboratories at sea level, the correction for air buoyancy is, for example, roughly 0.1% for water.

The air density in a given laboratory whose temperature is controlled to within a few degrees will be mainly a function of ambient air pressure and thus will not vary beyond 5% of its average value. Air pressure is a function of elevation so that the mean air density in laboratories at 1600 m above sea level is about $1.0\,\text{kg m}^{-3}$. For lower uncertainty, the density of air can be computed from an equation of state whose input parameters are temperature, barometric pressure, relative humidity (or dew point), and atomic fraction of carbon dioxide (Picard *et al.*, 2008). A simplified version of this equation (OIML, 2004a) is adequate to achieve an uncertainty within 0.01% in air density:

$$\rho_a = \frac{0.34848p - 0.009(hr) \times \exp(0.061t)}{273.15 + t} \tag{5.6}$$

with ρ_a in kilograms per cubic meter, and where the air in the balance case has the following measured parameters: barometric pressure p (hectopascal or millibar), temperature t (degree Celsius), and relative humidity hr (percent).

5.2.5
Specification of Secondary Standards

The SI unit of mass is disseminated by means of secondary standards. Analytical mass standards are readily available commercially in denominations from 1 mg to 50 kg. Summations up to 400 tons of much larger artifacts may be needed to calibrate force transducers such as strain-gauge load cells. Because of the difficulty in their manipulation, large masses are most easily calibrated at the point of use (Bray, Barbato, and Levi, 1990). In recent years, there has been a growing need for standards with mass smaller than 1 mg. Production of such standards, previously left to the ingenuity of the individual user, is now being taken up by a number of national metrology institutes.

Mass standards used in legal metrology, named *weights*, are manufactured to specifications set by each country, usually in accordance with Recommendation R111-1 of the International Organization of Legal Metrology (OIML, 2004a). Thus, the mass of artifacts of a particular class are specified to be within certain maximum permissible errors, as shown in Table 5.1. If the user needs to know the mass to better accuracy, then each artifact must undergo calibration so that individual deviations from the nominal mass can be known.

The need for buoyancy corrections to weighings in air has led to conventions for the construction of weights. OIML, specifies the following convention (OIML, 2004b).

1. An artifact of mass m_s and density ρ_s has a conventional mass m_c defined as

$$m_c = m_s \frac{(1 - 1.2/\rho_s)}{(1 - 1.2/8000)} \tag{5.7}$$

It is the conventional mass that is referred to in Table 5.1 and in typical

Tab. 5.1 Maximum permissible errors for three best accuracy classes of weights, as recommended by the OIML.

Nominal value	Class E$_1$	Class E$_2$	Class F$_1$
50 kg	25 mg	80 mg	250 mg
20 kg	10	30	100
10 kg	5.0	16	50
5 kg	2.5	8.0	25
2 kg	1.0	3.0	10
1 kg	0.5	1.6	5
500 g	0.25	0.8	2.5
200 g	0.10	0.3	1.0
100 g	0.05	0.16	0.5
50 g	0.03	0.10	0.3
20 g	0.025	0.08	0.25
10 g	0.020	0.06	0.20
5 g	0.016	0.05	0.16
2 g	0.012	0.04	0.12
1 g	0.010	0.03	0.10
500 mg	0.008	0.025	0.08
200 mg	0.006	0.020	0.06
100 mg	0.005	0.016	0.05
50 mg	0.004	0.012	0.04
20 mg	0.003	0.010	0.03
10 mg	0.003	0.008	0.025
5 mg	0.003	0.006	0.020
2 mg	0.003	0.006	0.020
1 mg	0.003	0.006	0.020

reports of calibration, although the mass m_s may be given as well. To limit confusion, m_s is sometimes be referred to as the *true mass* or *vacuum mass* of the standard if it is reported along with the conventional mass. The user is normally expected to treat the artifact standard as if its mass were m_c and its density were 8000 kg m^{-3}. From Equations (5.4), (5.5), and (5.8), this fiction does not propagate as error provided $\rho_a = 1.2\,\mathrm{kg\,m^{-3}}$. In general, however, the use of conventional mass does introduce an error e given as

$$e \approx m_s(1.2 - \rho_a)\left(\frac{1}{8000} - \frac{1}{\rho_s}\right) \qquad (5.8)$$

Recommendation R111-1, therefore, contains a second specification.

2. The density ρ of an artifact standard must be such that a deviation in ρ_a of 10% from the assumed value of 1.2 kg m^{-3} will lead to an error that does not exceed one-fourth the absolute value of the maximum permissible error given in Table 5.1.

The introduction of conventional mass and density is intended to simplify the data analysis of routine weighing near sea level. The convention must, of course, be abandoned if its use will lead to serious error, for instance, if mass standards are used in vacuum.

The magnetic properties of secondary mass standards are sometimes of interest to experimentalists. Austenitic alloys of stainless steel and plated brass (where it meets the density requirements) are the most often used materials. The best grades of stainless steel have relative permeabilities less than 1.004. Common grades of brass and 18/8 stainless steel are much worse.

5.2.6
Analytical Balances

5.2.6.1 Design Considerations

The design of analytical balances has evolved significantly due to the perfection of electromagnetic servocontrol. The basic mechanical configuration is, however, traceable to ancient origins: two pans suspended symmetrically from the ends of a horizontal beam. The operating principle, shown schematically in Figure 5.2, is that a mass imbalance between the two pans creates a net torque on the beam so that its equilibrium angle is no longer zero. The sensitivity S is

$$s \equiv \frac{d\phi}{dm_2} = \frac{L}{m_1 l + (m_2 + m_3)h} \tag{5.9}$$

which will depend on the total load if the three pivots are not aligned. The most important design features of this type of balance are reviewed by Quinn (1992) and Speake (1987).

The so-called top-loading balances are designed with the pans above the beam. In order that an object produces the same torque no matter where it is placed, the pan must be guided so that it does not rotate with the beam. This can be accomplished by using twin beams in the form of a parallelogram. For large masses, the pan may be additionally equipped with a self-leveling mechanism. This design, though allowing unimpeded access to the pan, did not become practical for high-precision balances until the advent of servocontrol.

5.2.6.2 Servocontrol and Automation

The convenience and practical precision of balances are improved by automation and servocontrol. One can, in fact,

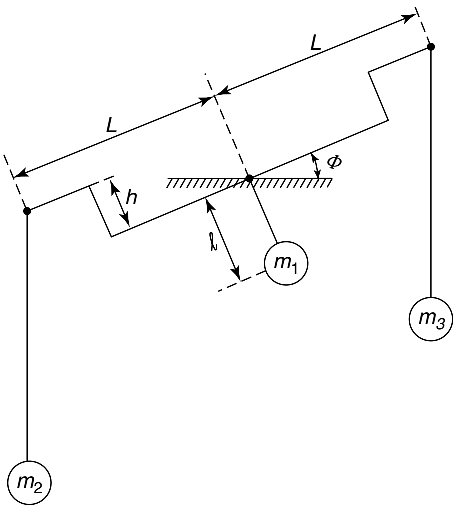

Fig. 5.2 Schematic of an equal-arm balance without servocontrol. The three pivot points are represented by solid circles. The mass of the beam is m_1 and is centered a distance ℓ below the central pivot. The loads on each pan are represented by m_2 and m_3.

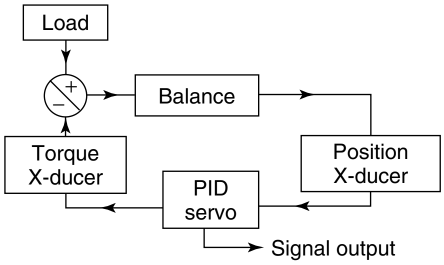

Fig. 5.3 Typical arrangement of a servocontrolled balance. The load, which would cause an unserved balance beam to rotate, is compensated by an electromagnetic torque transducer.

consider electronic balances as servocontrolled, modified versions of the balances presented above (Schoonover, 1982). Figure 5.3 shows a typical control loop where the balance is seen to be a transducer that converts a torque imbalance to an angular deflection that is itself converted to a voltage. An amplifier acting through an electromagnetic transducer supplies feedback to maintain the beam at constant angle. To optimize accuracy and transient response, the feedback signal is typically a linear combination of a force proportional to the angular deflection, its time integral, and its time differential (PID feedback).

There are several practical benefits of servocontrol. The rotation of the beam can be greatly restricted so that relatively robust leaf springs (also known as *flexure strips*) can replace delicate knives at the pivot points. The beam can be maintained precisely horizontal, thereby rendering the balance immune to spurious horizontal forces. The sensitivity of the unservoed balance can be adjusted until a tilt of the balance case causes the beam to tilt through exactly the same angle. A balance adjusted to this "autostatic" condition is relatively immune to common sources of mechanical noise (Speake, 1987). Finally, the on-scale, linear range of the balance can be greatly increased. Quinn (1992) describes a servocontrolled balance with a precision of order 0.05 μg for loads up to 2 kg. Speake (1987) derives fundamental theoretical limitations to balance precision. Commercial balances are now available that can compare 1-kg mass standards to a precision of 0.1 μg in air or vacuum.

Commercial balance manufacturers include a variety of convenience features in servocontrolled balances. The most common of these are automatic or semiautomatic scale calibration and suppression of the zero drift. Depending on the sophistication of the balance and its accessories, complete weighing operations can be fully automated.

5.2.6.3 **Force**

Analytical balances cannot distinguish the gravitational force on a mass from other vertical forces. In the case of air buoyancy, corrections can be applied and error avoided. Other forces must be made negligible. Of these, the principal concerns are moving air and electrostatic and magnetic interactions.

Thermal effects are minimized by keeping the objects to be weighed in good thermal equilibrium with the interior of the balance. Otherwise, a convection cell can be created that may result in serious systematic errors (Gläser, 1999).

Electrostatic problems often occur when one is weighing good insulators such as fused silica or poly(tetrafluoroethylene). Equipping the balance pan with a Faraday cage of stable mass can eliminate such problems, as can exposing the insulator to ionized air.

The weighing to small uncertainty of permanent magnets or even ferrous materials is often troublesome. To elucidate a problem, the object in question can be weighed in various orientations on the balance pan to see whether the results are independent of such maneuvers. If not, the object can be suspended well below the pan of the balance in hopes that the unwanted interaction is between the object and a part of the balance itself.

That analytical balances are blind to the origin of the force that they sense can be turned to advantage. Thus, laboratory balances are commonly used in measuring phenomena such as surface tension and magnetic susceptibility. Since the pan of a servocontrolled balance is maintained at fixed position with respect to the laboratory, measurement of forces that vary strongly with position is convenient with these balances.

5.2.7
Microbalances

5.2.7.1 Analytical Type, Adapted to Microweighing

Although modern analytical balances can have standard deviations of less than 1 μg, microbalances have traditionally been used for different types of measurements than those required of normal analytical balances. Typically, microbalances have relatively small capacity but precisions of 1 μg or better. They will operate in vacuum or controlled atmospheres and are often used to follow the evolution in mass of a sample that is undergoing some physical or chemical change.

5.2.7.2 Vibrating Transducers

Some commercial microbalances measure inertial mass. Typically this is accomplished by relating the change in the frequency of a mechanical resonance to the change in mass of the resonant system. In special cases, it is possible to design transducers that measure inertial mass to picogram sensitivity. The most widely known example is the quartz-crystal microbalance (Ward and Buttry, 1990; Lu and Czanderna, 1984). In this case, the piezoelectric effect is exploited in order to excite the shear resonance in a plate of AT-cut quartz. The resonant frequency f_0, usually about 10 MHz, decreases by an amount f that is proportional to the mass per unit area m/A loading the free surface. The mass sensitivity of such a device is approximated by a relation first derived by Sauerbray (1959):

$$\Delta m/A = -4.42 \times 10^6 \Delta f/f_0^2 \qquad (5.10)$$

with $\Delta m/A$ in kilograms per meter square, for AT-cut quartz.

The field of MEMSs (micro-electromechanical systems) and NEMSs (nano-electromechanical systems) is burgeoning, and devices with attogram (10^{-18} g) precision have been reported.

5.2.8
Astronomical and Subatomic Mass

The product Gm_E, where m_E is the mass of the Earth, is approximately equal to gr^2, where r is the Earth's radius and G is the gravitational constant. Cavendish's measurement of G was popularly known as *weighing the Earth* in recognition of the role of G in relating planetary and other astronomical masses to laboratory standards. More generally, a small satellite in an elliptic orbit of semimajor axis a and angular frequency ω about a mass m will, in the appropriate limits, obey Newtonian mechanics:

$$m = \frac{a^3\omega^2}{G} \tag{5.11}$$

Thus, for example, the mass in kilograms of the Sun can be known. The currently recommended value of G (Mohr, Taylor, and Newell, 2008) is $6.674\,28(67) \times 10^{-11}\ \mathrm{m^3\ kg^{-1}\ s^{-2}}$.

It is difficult to accurately determine the mass of celestial objects having no observable satellites. Consider the asteroids, for example. It is sometimes possible to infer the mass of the largest asteroids from observations of gravitationally perturbed neighbors. Otherwise, even more indirect methods must be used: the volume of the asteroid is estimated from its brightness (assuming a value for albedo), and the mass is then estimated by assuming a value for the asteroid's density.

The mass of subatomic particles may be found by applying the conservation laws of energy and momentum. The acceleration in electromagnetic fields of either the particle itself or its decay products may be measured, as well as the energy and momentum of emitted photons. By the nature of these measurements, the mass is most directly reported in electron volts (eV), an energy unit that is outside the SI. To convert electronvolts to kilograms, it is necessary to multiply by a factor equal to the numerical value of the elementary charge, e, divided by c^2 (Mohr, Taylor, and Newell, 2008).

5.3
Density

The density ρ of an infinitesimal volume dV of material of mass dm is

$$\rho = \frac{dm}{dV} \tag{5.12}$$

In the SI, density is a derived quantity with units of kilograms per cubic meter. Depending on the application, it may be convenient to measure the density of the unknown relative to a known density (most usually that of water). Alternatively, one may measure directly the mass and volume of the unknown. The latter technique is, of course, the only method of determining a reference density directly in terms of SI units.

5.3.1
Measurements Based on Buoyancy

Buoyancy methods rely on Archimedes' principle, just as do the corrections for air buoyancy described in Section 5.2.4. Immersion of the sample in a liquid results in a buoyancy "correction" so large that the density of the sample may be thus determined with respect to the density of the immersion liquid.

The special case of neutral buoyancy forms the basis of the flotation methods discussed in Sections 5.3.1.2 and 5.3.1.3.

5.3.1.1 Hydrostatic Weighing

Two methods of hydrostatic weighing are shown schematically in Figure 5.4. Method 1 is the classic technique capable of relative uncertainty below 10^{-6} in favorable cases. Method 2 suffers from a greater minimum uncertainty but is more convenient when one is using a servocontrolled top-loading balance.

Let x_1 be the ratio of the balance reading when the sample is placed on the pan in air to the reading when immersed in the liquid bath; ρ_w and ρ_a the density of the water bath and the ambient air; and ρ the unknown density to be determined. It

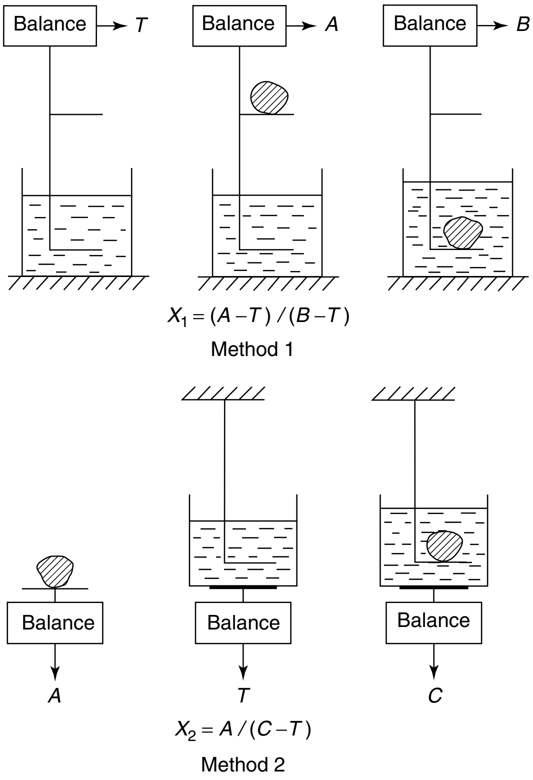

Fig. 5.4 Two methods for determining the density of a solid sample relative to an immersion liquid. The dimensionless quantities x_1 and x_2 are used in Equations (5.13) and (5.14).

is then easy to show that

$$\rho = \frac{x_1\rho_w - \rho_a}{x_1 - 1} \text{ (Method 1)} \qquad (5.13)$$

For Method 2, let x_2 be the ratio of the balance reading when the sample is placed on the pan in air to the difference in readings upon immersion. Then

$$\rho = x_2(\rho_w - \rho_a) + \rho_a \text{ (Method 2)} \qquad (5.14)$$

Note that x_1 and x_2 are dimensionless ratios so that the balances used need not be calibrated to any particular unit of mass (although their linearity must be assured). This feature is often cited as an advantage to using the same balance for both the air and water weighings. The two methods will only be sensitive if the balance is precise compared to $\rho_w V$. In addition to the obvious requirements of knowing ρ_w and ρ_a, achieving accurate results depends on careful attention to the suspension wire and prevention of gas bubbles adhering to the sample. The report of Bowman and Schoonover (1967) still serves as a useful introduction to these subjects and a paper by Fujii (2006) shows the present state of advancement. The method can also be used to determine the density of the surrounding liquid if the density of the solid is known. Techniques to measure the density of mass standards of various nominal values are described in OIML (2004a).

The suspension wire must be eliminated when determining the density of fluids far from ambient conditions (under high pressure, for instance). In such cases, the solid can take the form of a magnet that is servocontrolled to a position within the liquid by means of external coils (see the review by Wagner and Kleinrahm, 2004 and included references). Analogs of both Methods 1 and 2 shown above are practical.

It may happen that water is not suitable as an immersion liquid for a given sample. In this case, a different liquid is used and its density at the time of the measurements determined from published tables, either by performance of an auxiliary experiment or by means of a solid density reference standard (Bowman *et al.*, 1974). There are obvious advantages if the reference standard has approximately the same mass and density as the unknown.

5.3.1.2 Flotation Methods

As density is an intensive quantity, it should be possible to determine very small samples to high accuracy. Flotation methods accomplish this feat. When a sample of volume V whose density ρ is to be determined is immersed in a liquid of density ρ_L, the vertical force on it will be $(\rho - \rho_L)Vg$. The sample will, in general, rise or sink depending on whether this quantity is negative or positive. If the value of ρ_L can be adjusted so that the sample does neither (neutral buoyancy), then $\rho = \rho_L$ and the problem then becomes that of determining the density of a relatively large volume of liquid.

The method is most easily realized with transparent liquids. Since the sample and liquid generally have different thermal expansion and compressibility, equilibrium may be achieved through temperature or pressure changes as well as by adjusting the composition of a binary liquid.

When the surrounding liquid approaches the density of the sample, it becomes increasingly difficult to determine whether the sample will ultimately rise or fall. Greater sensitivity can be achieved by the use of a centrifuge rather than gravity to produce the forces. Alternatively, one can create a uniform density gradient in a column of liquid. Samples introduced in the column will, unattended, eventually come to rest at their position of neutral buoyancy.

Flotation methods are useful in quantifying small differences in density between two objects of the same material. Objects of different sizes and shapes can be compared in this way (Bettin and Toth, 2006).

5.3.1.3 Hydrometry

Hydrometers have been used as a relatively convenient method to find the density of liquids, especially when only small differences among samples are expected. The hydrometer consists of a graduated stem with a weighted volume at the bottom. The hydrometer floats in the test liquid, with the base of its stem in the liquid and the top of the stem in the air. Depending on the desired measurand, the stem is calibrated in units of density, relative density, or a specialized quantity related to density.

The review paper by Lorefice and Malengo (2006) describes how these instruments are calibrated and includes an extensive bibliography.

5.3.2
Measurements Based on Mass and Volume

If a sample of unknown density ρ has the same volume as a known standard of density ρ_s, then the ratio of masses m/m_s of the unknown and standard must equal ρ/ρ_s, the ratio of their densities. Although the volume of the unknown and the standard must be the same, it need not be known. Thus, mass determinations constitute the only precise measurements needed. Special containers, known as *pycnometers (or pyknometers)*, are designed to hold a reproducible volume of liquid.

5.3.2.1 **Liquid Pycnometers**

A variety of liquid pycnometers have been designed over the years and marketed by laboratory supply companies. Although all these have design advantages specific to given applications, it may be sufficient to use a simple hypodermic syringe as a volume standard. In this case, the syringe is first weighed empty. If V_i is the internal volume of the syringe, V_e its external volume, m its mass, ρ_a the density of ambient air, and y_1 the balance reading, then

$$y_1 = \rho_a(V_i - V_e) + m \tag{5.15}$$

The syringe is then filled with the standard liquid of density ρ_L, usually water, and weighed again:

$$y_2 = \rho_L V_i - p_a V_e + m \tag{5.16}$$

Finally, it is filled with the sample of unknown density ρ and weighed for the third time:

$$y_3 = \rho V_i - \rho_a V_e + m \tag{5.17}$$

The desired density is then determined from the known densities of the liquid standard and the ambient air:

$$\rho = (\rho_L - \rho_a)\frac{y_3 - y_1}{y_2 - y_1} + \rho_a \tag{5.18}$$

This example suggests many of the potential problems of pycnometry: the interior volume must be reproducible to the needed precision. The chamber must be carefully cleaned between fillings. The pycnometer itself must be a suitable object for weighing. If all measurements cannot be carried out at the same temperature, then the thermal expansion of the pycnometer must be known. Liquids must be introduced without entraining air bubbles (ISO, 1999).

Some commercially available pycnometers are designed for density measurements of solids, often in the form of grains or powders. In this case, the first observation is the mass of the solid sample itself. The third observation is the mass of the pycnometer with its interior volume containing the solid sample plus enough of the standard liquid to fill the interior volume completely. The density of the solid is then determined. This technique will only work well if atmospheric gases occluded by the solid can be eliminated.

Pycnometers were traditionally designed for use with a chemist's analytical balance with a capacity of about 200 g. Thus, their interior volume is typically 25–100 ml.

The so-called gas pycnometers are available commercially for the determination of solid volumes. They are based on the fact that, at constant temperature, the pressure of a fixed number of atoms of a noble gas varies inversely with the volume to which the gas is confined. In a gas pycnometer, introduction of a sample decreases the original volume by that of the sample. The measurements can be automated to an extent. The method is especially suited to the determination of powders or samples with open pores, since noble gases penetrate better than liquids.

5.3.2.2 **Vibrating-Tube Densimeters**

Pycnometry, as developed by Gay-Lussac and refined by later investigators, has been superseded in many laboratories by the vibrating-tube densimeter. First developed by Kratky, Leopold, and Stabinger

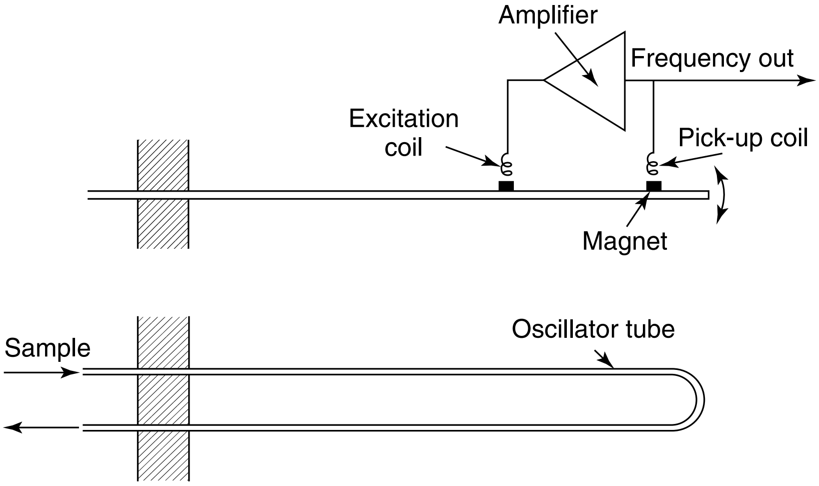

Fig. 5.5 Two views showing the principle of a vibrating-tube densimeter. The natural frequency of the hollow oscillator tube will depend on the density of the sample that fills it. Based on a sketch provided by H. Stabinger, used with permission.

(1969), this device differs from the traditional liquid pycnometer in only one fundamental respect, namely, that the inertial mass of the material within the volume chamber is sensed rather than the gravitational mass. This one conceptual change leads to many experimental advantages.

To realize the device, the liquid container takes the form of a hollow tube bent into the form of a "U" and anchored at each end (Figure 5.5). Like a tuning fork, the tube will have a mechanical resonance whose frequency depends on elastic properties, geometry, and mass. In particular, the natural period τ of the tube is proportional to $m^{1/2}$, the square root of its mass. The latter quantity is equal to the mass of the tube itself plus ρV_e, the mass of any fluid filling the vibrating region of the tube. In practice, V_e is about 1 ml, that is, much smaller than the volume of typical pycnometers. On the basis of this simple model,

$$\rho = A\tau^2 - B \tag{5.19}$$

The parameters A and B are constants, and thus the device must be calibrated at a minimum of two points over its range. Dry nitrogen and water are frequently used as standards.

The highest relative precision obtainable with such devices is of order 1×10^{-6}. Deviations from Equation (8.19) are noticeable in highly precise data, and so more careful calibration is required to achieve comparable accuracy. Devices based on the same principle of operation have been constructed for temperatures to 400°C and pressures to 40 MPa. Practical considerations are given in the ISO (1998) standard.

5.3.3
Miscellaneous Techniques

The techniques discussed above are those most generally used for density determinations. Nevertheless, myriad other methods have been developed to meet special needs.

Where volume or density appears in a physical equation, it has probably formed the basis for a determinative method. Numerous examples of traditional methods are reviewed by Davis and Koch (1992).

5.3.4
Reference Standards

Distilled or deionized tap water has a density that is known to a relative uncertainty of about 1×10^{-5} at 0.1 MPa and between 0 and 40°C and is the single most useful reference standard. Uncertainty may be improved by about a factor of 3 by correcting for or eliminating atmospheric gases dissolved in the water and by taking account of the isotopic variability of individual water samples.

A particular isotopic mix of water is designated Vienna Standard Mean Ocean Water (V-SMOW), small samples of which can be obtained from the International Atomic Energy Commission in Vienna for use in determining the relative isotopic abundances of other water samples of interest. A table of water of density suitable for typical metrological needs is given by Tanaka *et al.* (2001). A much more general formulation of the thermodynamic properties of V-SMOW has been published by Wagner and Pruß (2002).

Good use is sometimes made of the fact that the density of water has a maximum near 4°C. Problems that might be caused by convection are greatly reduced near this temperature since the density is insensitive to small changes in temperature.

The density of selected mercury samples was determined with respect to standards of mass and length by Cook (1961), who achieved a relative uncertainty of about 1×10^{-6} at 0.1 MPa and 20°C. In the succeeding years, these samples have played a key role in precision manometry, gas thermometry, and measurements of fundamental physical constants.

Glossary

Apparent Mass: The reading, uncorrected for air buoyancy, of a perfectly calibrated balance. The ratio of mass to apparent mass is a function of the ambient air density, the density of the object in question, and the density of the standards used to calibrate the balance (Section 5.2.4).

Atomic Mass Unit (Dalton): The unit mass, u, in a system where the mass of an atom of carbon-12 is taken to be exactly 12 u. One mole of carbon-12 atoms has a mass of exactly 0.012 kg.

Avogadro Constant: The number of entities in 1 mol of substance and hence the number of atomic mass units in 0.001 kg.

Balance: Originally, an ancient lever device used to demonstrate that two objects have the same (gravitational) mass. The term is now used more generally to designate almost any transducer configured to make mass measurements.

Buoyancy Correction: The correction applied to balance readings in order to eliminate the component due to air buoyancy.

Cook's Mercury (Informal): Mercury stock whose density was measured by A. H. Cook. The stock has been used to advantage in several areas of precision measurement.

Conventional Mass: At a reference temperature of 20°C, the mass of material of density 8000 kg m^{-3} that will balance an object of interest, usually a secondary standard of mass, in air of density 1.2 kg m^{-3} (Section 5.2.4).

Dalton: See atomic mass unit.

Effective Mass: The mass of an object less the product of its volume and the density of the ambient fluid, usually air (Section 5.2.4).

Gas Pycnometer: A device used to find the volume of porous solids and powders through application of the gas laws.

Gradient Column: A column of liquid whose density decreases uniformly from the bottom to the top. The densities of a sample or set of samples can be determined from their equilibrium heights in the column.

Gravitational Mass: The mass that appears in Newtonian equations for gravitational force.

Hydrostatic Weighing: A traditional method of measuring the density of a solid by weighing it both in air and submerged in a liquid, usually water (Section 5.3.1.1).

Inertial Mass: The mass that appears in Newton's second law and in special relativity.

International Prototype of the Kilogram: The artifact that defines the unit of mass in the SI.

Maximum Permissible Error: The maximum allowed absolute difference between the conventional mass of a weight (2) and its nominal mass.

Microbalance: A balance of microgram or better resolution.

Neutral Buoyancy: The condition in which an object at equilibrium neither rises nor sinks in a surrounding fluid. It is assumed that the system is subject to a uniform acceleration, usually gravitational but sometimes centripetal.

Nominal Mass: The intended mass of a standard weight (2).

Pycnometer (Pyknometer): A vessel with precisely reproducible interior volume, traditionally used to determine the relative densities of liquids.

Quartz-Crystal Microbalance: A device that measures mass per unit area in terms of the oscillation frequency of a quartz crystal (Section 5.2.4).

Relative Density: A dimensionless quantity representing the density ratio of a given sample to a standard of reference. Unless otherwise stated, the standard is assumed to be distilled water at 20°C. Relative density is the modern name for specific gravity.

True Mass: See vacuum mass.

Vacuum Mass: Another term for mass. The term vacuum mass or true mass is sometimes used to distinguish mass from conventional mass in reports of calibration.

Vibrating-Tube Densimeter: A device that measures the relative densities of fluids by a mechanical resonance technique (Section 5.3.1.2).

Vienna Standard Mean Ocean Water (V-SMOW): Water having a certain, specified isotopic composition. Distilled tap water generally has a density about 0.003 kg m^{-3} less than V-SMOW.

Weak Equivalence Principle: A basic principle of physics whose consequence for mass measurements is as follows: equivalent results are obtained independent of whether the measuring device responds to the inertial or the gravitational properties of mass.

Weighing: The process of determining mass by means of a balance.

Weight (1): The product of a mass and the local gravitational acceleration. The term *standard weight* is used to signify weight at a conventional acceleration, usually 9.80665 m s^{-2}.

Weight (2): An artifact manufactured to embody a specified nominal mass.

INTRODUCTION

The degradation of materials, more commonly referred to as corrosion, has a huge impact on modern society. Studies have shown that corrosion annually costs a nation on the order of (4–5)% of its gross national product (Payer *et al.*, 1980). Thus, for small nations, the absolute cost is small, while for industrialized nations, the cost can be staggering. For example, the U.S. gross national product for 1988 was approximately $5 trillion. Thus, the cost of corrosion to U.S. society was approximately $200 billion, or of the same order as the annual U.S. federal debt. The replacement, maintenance, and repair of chemical processing equipment, autos, ships, aircraft, and other facilties because of corrosion constitute a large fraction of this cost. While the costs of corrosion can be large, many of them are preventable. It has been estimated that $\frac{1}{3}$ of the costs of corrosion could be prevented by the proper application of present-day corrosion control measures.

Corrosion manifests itself in many ways, from the commonplace to the tragic. The replacement of automobile mufflers, while irritating to the auto owner, is usually only a minor inconvenience. However, the collapse of the Pt. Pleasant (KY) bridge in 1967 due to corrosion-related cracking of a support cost the lives of over 30 people. Corrosion diminishes the usable lifetime of components and also limits the advancements of technology. For example, in the case of advanced jet engines, the limiting technology is that of materials capable of prolonged exposure to high-temperature exhaust gases without the loss of mechanical integrity.

While the formal study of corrosion has been ongoing for over 200 years, there are still many unanswered questions. In fact, with each new material that is produced, new manifestations of degradation are observed. For example, stainless steels were hailed in the 1930s as the solution to corrosion problems. While these alloys of iron with more than 11% Cr are indeed "stainless" upon exposure to atmospheric conditions, they can undergo highly localized, high-rate attack in fairly mild environments such as seawater. Alloying can have a major effect on this sensitivity. The addition of as little as 1 at. % molybdenum increases the corrosion resistance substantially, by an as yet unknown mechanism. As another example, the new high-T_c superconductors are prone to degradation under atmospheric conditions, result-

ing in the loss of their superconducting properties. With the drive to higher component densities in the electronics industry, amounts of corrosion previously considered completely insignificant are now limiting. For example, the loss of 1 pg (10^{-12} g) of Al is sufficient to cause an interconnect failure for micron technology. These and many other applications provide a strong technological driving force for understanding corrosion processes.

In addition to the immense technological importance of materials degradation processes, they also are of great scientific interest. In part, this is because of the inherent complexity of the subject. Most degradation occurs at the interfaces between a material and its environment. It has been said that interfaces are the invention of the devil. While it is true that interfacial processes are much more complex than bulk, their satanic origin has never been verified. However, understanding interfacial behavior is critical to developing a complete view of physical processes. The interaction of a large number of variables also makes corrosion a fascinating field of scientific study. Identifying the controlling factors, and then designing experiments in which they are isolated, is a constant challenge. Theoretically, the symmetry-breaking effect of the interface provides a fruitful field for study.

At the same time, reactions that result in materials degradation provide us with vehicles to understand the fundamental nature of solid-liquid, solid-solid, and solid-gas interfaces. While our understanding of bulk effects is far from complete, the areas of surface chemistry and surface physics are two of the most challenging and fascinating research areas today. New tools are constantly being applied that provide new insights into the origins of the reactions. Because of the coupled nature of many of the phenomena, these processes are a rich area of dynamic behavior, including chaotic phenomena (Hudson and Bassett, 1991).

This article provides an overview of the phenomena involved in the degradation of materials. Because of space limitations and the extreme breadth of the field, only brief descriptions of the many important processes can be given here. However, the interested reader can find a wealth of in-depth information in the references given under Further Reading. In the first section, the physical principles of the degradation process will be presented with an emphasis on the basic thermodynamics and kinetics, the different types of degradation, and the effects of environmental variables on the processes. The second section will introduce the methods by which the relevant thermodynamic and kinetic parameters are measured. The final section consists of examples of material degradation for metals, polymers, and ceramics.

1. PHYSICAL AND TECHNICAL PRINCIPLES

1.1 Thermodynamic Driving Force

Thermodynamics dictates that materials have the tendency to reach their lowest possible free energy. A particular chemical reaction is thermodynamically allowed if the change in free energy, ΔG, for the reaction is negative. Three types of information are available in the literature in order to predict the thermodynamic stability of materials. First, the values of ΔG for possible chemical reactions can be examined directly. Some examples of the free energy of formation of common degradation products are given in Table 1; many more can be found in the literature (Goldsmith *et al.*, 1961). For most metals and alloys, the oxide, hydroxide, or sulfide is thermodynamically favored over the pure metal, as expressed by a negative free energy of formation of these corrosion products. This means that given the availability of oxygen, water, sulfides, etc. in the environment, most metals are not thermodynamically stable and should be entirely converted into the corresponding reaction products.

The free energy is $\Delta G = \Delta H - T\Delta S$, where ΔH is the enthalpy change and ΔS is the en-

Table 1. Standard free energy of formation of some degradation products.

Compound	ΔG (kJ mol^{-1})	Compound	ΔG (kJ mol^{-1})
Al_2O_3	−1576	$Pt(OH)_2$	−285
Cr_2O_3	−1047	NiO	−216
SiO_2	−805	CuO	−127
Fe_2O_3	−741	Ag_2S	−40.3
$ZnCO_3$	−731	Au_2O_3	163

tropy change in the reaction. The value of ΔS may be thought of as the change in randomness of the system. Thus for strongly ordered systems, such as fiber-reinforced composites and some kinds of polymers, a degradation of the material would result in a decrease in free energy and thus would be expected on thermodynamic grounds.

A second method of predicting thermodynamic stability is to examine the electromotive series. When a metal is immersed in a solution, a potential difference, called the single-electrode potential or half-cell potential, is developed at the metal–solution interface. In order to measure this potential, it is necessary to include another electrode in the circuit. This means that the potential cannot be measured on an absolute scale but must be measured relative to a reference electrode. The standard reference electrode is the hydrogen electrode, assigned a potential of zero. An abbreviated list of half-cell potentials is given in Table 2; very extensive lists are given in the literature (Parsons, 1959; Weast, 1991). Many degradation reactions are electrochemical in nature; that is, they consist of two coupled electrochemical half reactions. If a given degradation reaction has been divided into its two half reactions, the reaction with the higher value of E^0 would be expected to proceed in the reverse direction. For example, if an iron pipe is connected to a copper wire, the electromotive series can be used to predict that a potential difference will be established between the two metals, and current will flow, resulting in corrosion of the Fe according to the overall reaction

$$Fe + Cu^{2+} \rightarrow Fe^{2+} + Cu. \qquad (1)$$

Similarly, the corrosion reaction

$$Fe + \tfrac{1}{2}O_2 + H_2O \rightarrow Fe(OH)_2 \qquad (2)$$

can be separated into the two half reactions

$$\tfrac{1}{2}O_2 + H_2O + 2e^- \rightarrow 2OH^-, \qquad (3)$$

$$Fe \rightarrow Fe^{2+} + 2e^-, \qquad (4)$$

followed by the chemical reaction

$$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2, \qquad (5)$$

and would be expected to proceed in the direction written on the basis of the electromotive series.

Table 2. Some standard electrode reduction potentials.

Half-cell reaction	E^0 (V vs SHE)
$Li^+ + e^- = Li$	−3.045
$Al_3^+ + 3e^- = Al$	−1.706
$SiO_2 + 4H^+ + 4e^- = Si + H_2O$	−0.84
$2H_2O + 2e^- = H_2 + 2OH^-$	−0.8277
$Zn^{2+} + 2e^- = Zn$	−0.7628
$Cr^{3+} + 3e^- = Cr$	−0.74
$S + 2e^- = S^{2-}$	−0.508
$Fe^{2+} + 2e^- = Fe$	−0.409
$Fe^{3+} + 3e^- = Fe$	−0.036
$2H^+ + 2e^- = H_2$	0
$Cu^{2+} + 2e^- = Cu$	0.3402
$O_2 + 2H_2O + 4e^- = 4OH^-$	0.401
$Fe^{3+} + e^- = Fe^{2+}$	0.770
$Au^+ + e^- = Au$	1.68

Half reactions with more negative E^0 are referred to as "active" or "anodic" with respect to half reactions with a more positive value of E^0, which are termed "noble" or "cathodic." The value of E^0 is related to ΔG through the equation

$$\Delta G = -nFE^0, \qquad (6)$$

where F is the Faraday.

Thermodynamic information is also available in a Pourbaix diagram (Pourbaix, 1974). Pourbaix diagrams are a special type of phase diagram, where the potential is plotted on the vertical axis and the pH on the horizontal. They are constructed from consideration of chemical reaction equilibria, e.g.

$$Ni^{2+} + H_2O = NiO + 2H^+,$$
$$\log[Ni^{2+}] = 12.18 - 2pH, \qquad (7)$$

and electrochemical reaction equilibria, e.g.

$$Ni = Ni^{2+} + 2e^-,$$
$$E = -0.250 + 0.0295 \log[Ni^{2+}]. \qquad (8)$$

The diagrams can be used to predict the stability of elements for a large variety of conditions. Figure 1 illustrates the example of Ni in water. The two dashed lines show the equilibrium conditions for oxygen evolution and hydrogen evolution from water, as indicated on the diagram. Thus, water is ther-

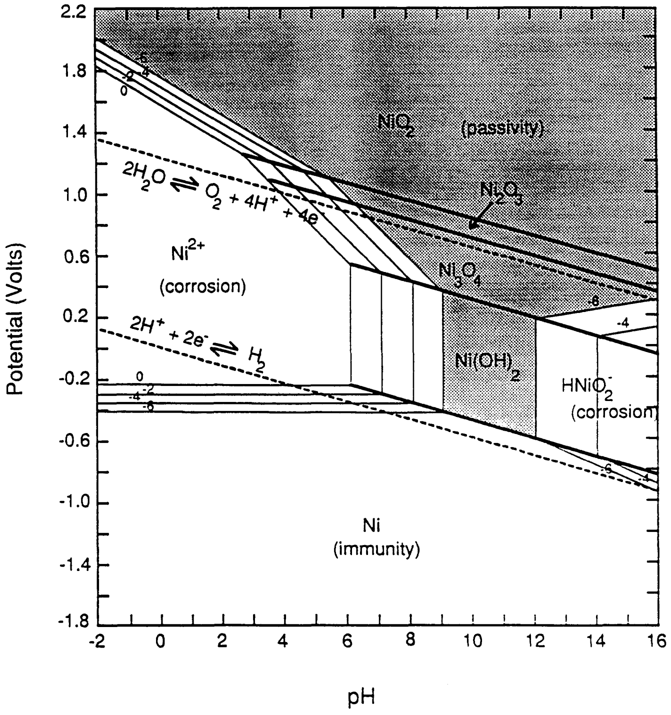

FIG. 1. A Pourbaix diagram for the system water/nickel. The potential is given relative to the hydrogen electrode. Regions of stability of various materials are shown. A thick solid line shows the equilibrium between two solid species. A thin solid line shows the equilibrium between a solid and a dissolved species, with the logarithm of the concentration of the dissolved species shown as a small number. The dashed lines indicate the equilibria for the oxygen evolution and hydrogen evolution from water. The shaded area indicates the region of passivity for nickel for a solution concentration of 10^{-6} M.

modynamically stable in the region between the two dashed lines. The thick lines indicate equilibria between two solid species; the narrow lines indicate equilibria between one dissolved and one solid species, with the small numbers giving the logarithm of the concentration of the dissolved species corresponding to each line. Thus, the diagram may be divided into regions of corrosion (dissolved species thermodynamically stable), immunity (metal thermodynamically stable), and passivity (shaded area, solid species other than metal thermodynamically stable). Thus, it may be seen that Ni would be expected to dissolve at low and high *p*H's, and exhibit passivity at intermediate *p*H values in the region where water is thermodynamically stable.

1.2 Kinetics

Although thermodynamics is very useful in predicting whether or not a given reaction is possible, it says nothing about the kinetics of a degradation reaction. For example, one would predict from Table 1 that chromium would be much more unstable than iron. However, under most circumstances, chromium is much less reactive than iron because of the kinetics of the dissolution of the corrosion products. From an engineering standpoint, the kinetics of degradation reactions are fundamentally important.

Since degradation is normally an environmentally induced process, the kinetics of any degradation process are critically dependent on the exact environmental conditions. For many systems, no general rule can be given for predicting degradation rates; however, for metals in aqueous environments, the kinetics are well understood, and thus this system will be discussed in some detail later.

As discussed above, many degradation reactions are electrochemical in nature; that is, they can be divided into two half reactions, each of which involves the transfer of electrons. In the absence of an externally applied potential, the currents for each half reaction are the same, and equal the so-called corrosion current density, which is proportional to the corrosion rate. The open-circuit corrosion potential is determined by the intersection of the lines describing the rates of the two reactions. Kinetically, the two half reactions can be examined individually by the application of an external potential (or alternatively by application of an externally applied current). This allows the construction of a mixed potential diagram, known as an *Evans diagram* for the case of corrosion reactions, as shown in Fig. 2. For a single electrode, the theory of electrode kinetics predicts that (Bockris and Drazic, 1972)

$$\eta = b \log(i/i_0), \tag{9}$$

where η is the overpotential, i.e., the difference between the reversible potential and the actual potential; b is the Tafel slope; i is the measured (or applied) current density; and i_0 is the exchange current density for the reaction. The Tafel slope is the slope of the straight-line portion of a polarization curve, usually occurring at more than 50 mV from the open-circuit potential, when presented in a semilogarithmic plot in terms of voltage per logarithmic cycle of current density (commonly referred to as volts per decade). This equation is analogous to the Arrhenius equation

$$\text{rate} = A \exp(-E_a/RT) \tag{10}$$

where A is the pre-exponential factor and E_a is the activation energy. As in the kinetics of thermally activated processes, electrochemical kinetics are plotted on semilogarithmic axes.

Thus, for $\eta = 0$, the potential is the reversible potential, and the extrapolated current is equal to the exchange current for the reaction. For each of the half reactions of interest, this point is indicated on Fig. 2. The open-circuit potential and current for the corroding system are determined by the intersection of the two lines of the half reactions (the slope of each being the Tafel slope for that half reaction). Thus, the corrosion rate is established by the individual kinetics of the two half reactions.

FIG. 2. A diagram showing the kinetic equations governing an electrochemical corrosion reaction for the metal M.

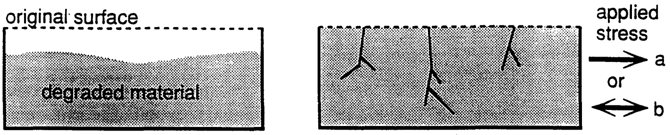
The diagram shown in Fig. 2 is directly applicable to the case of general corrosion, where the entire metal surface can be considered as the anode for the metal oxidation reaction and the cathode for the hydrogen evolution reaction. In this case, it is appropriate to plot the logarithm of the current density on the horizontal axis, and the diagram may be used to predict the degradation rate. In the case of localized corrosion, the anode and cathode will be of different sizes. In this case, the total current should be plotted. In addition, the relevant conditions will not be those in the bulk solution, but those within the confines of the local area of interest.

In conclusion, Evans diagrams are useful for predicting the kinetics of degradation reactions under a wide variety of conditions (Narayan, 1983).

1.3 Types of Degradation

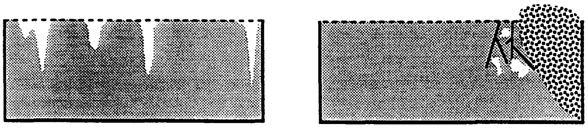
Degradation may, for convenience, be divided into eight types, illustrated schematically in Fig. 3. While the mechanisms can be very different, the classification is, in general, based on the appearance of the attack. The types are as follows:

1. General, or uniform, attack. This is a very common form of corrosion and can result from exposure of materials to the atmosphere or to solutions which are aggressive toward the material. This form of degradation can be relatively benign since its rate can often be predicted. Examples are rusting of iron and steel, and tarnishing of brass, silver, and aluminum. Often the oxidation products of the degradation reaction must be removed to ensure that the underlying surface is generally corroded (Parsons, 1982; Narayan, 1983).
2. Pitting attack. The material remains passive and stable over most of the surface but at other points is rapidly degraded,



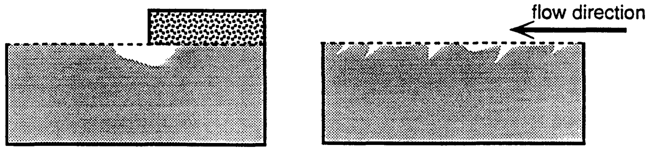
1. General attack

5. a. Stress corrosion cracking
b. Corrosion fatigue



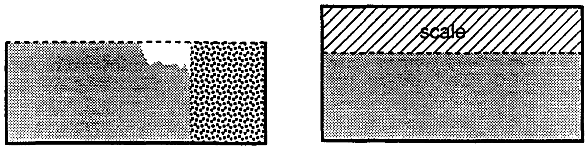
2. Pitting attack

6. Intergranular corrosion (at a weld)



3. Crevice corrosion

7. Corrosion - erosion



4. Galvanic corrosion

8. High temperature attack

FIG. 3. Schematic pictures of various types of degradation phenomena.

resulting in a very dangerous form of attack. Visually, it may be difficult to identify pitting corrosion until complete perforation of the material has occurred (Szlarska-Smialowska, 1986).

3. Crevice corrosion. When confined spaces or crevices are present in a structure, localized corrosion may occur in the occluded area. The crevices may be caused by geometric arrangements or merely by surface deposits of corrosion products (Butler and Ison, 1966).
4. Galvanic corrosion. Galvanic corrosion occurs when there is electrical coupling of two dissimilar metals that are placed in an electrolyte, resulting in corrosion of the less noble metal. The rate of galvanic corrosion is directly proportional to the ratio of the exposed areas of the cathodic and anodic metals (Narayan, 1983).
5. Stress corrosion cracking and corrosion fatigue. Stress corrosion cracking or corrosion fatigue results from the combined action of a tensile or periodic stress, respectively, and a corrosive environment on a material. For both types of degradation, the rate is accelerated over the case where either the aggressive environment or the stress is present alone. Unless a complete failure of the material has occurred by fracture, it can be difficult to identify these dangerous forms of degradation without microscopic examination (Sedricks, 1979; Narayan, 1983).
6. Intergranular corrosion. The grain boundaries of an alloy are usually physically and chemically different from the interior of the grain. Thus, they may be more susceptible to attack, resulting in a deep and rapid penetration of the metal and subsequent failure. Often welding or improper heat treatment of the metal can re-

sult in intergranular attack (Sedricks, 1979; Uhlig, 1948).

7. Erosion-corrosion. An increase in the corrosion rate may result from the relative motion of a metal surface and the aggressive environment surrounding it. Such attack is usually characterized by bright surfaces, free from corrosion products, but with distinct, localized pits or grooves oriented parallel with respect to the direction of solution flow (Butler and Ison, 1966). Often this attack results from the constant stripping of a protective film.
8. High-temperature attack. Since most metals and alloys react with air at ambient temperatures, it is expected that the rate of the reaction will increase, sometimes to a dangerous level, at elevated temperatures. The surface becomes covered with a scale, which may consist of oxides, sulfides, nitrides, etc. The damage caused by the attack depends on whether the scale is protective or nonprotective, and may often be predicted by the Pilling-Bedworth ratio, which is defined as the volume of scale formed from a unit volume of metal (Benard, 1964).

1.4 Environmental Variables

Some environments are more corrosive than others. High levels of acidity (or basicity in some cases), large concentrations of aggressive anions, such as the halides, and high levels of dissolved oxygen are conducive to degradation processes. However, since the different types of degradation are influenced in different ways by the environment, this discussion will follow the general types of degradation as shown in Fig. 3.

1. General corrosion is a result of exposure of metals to aggressive solutions or to the atmosphere. Thus, the rate will be determined by the aggressiveness of the solution in the former case and by the composition of the ambient atmosphere in the latter case. The variables include temperature, rainfall, wind conditions, and the concentration of corrosive pollutants such as ammonia, hydrogen sulfide, sulfur dioxide, etc.
2. Pitting, which results from a local disruption of the passive film, is usually caused by appreciable concentrations of chloride, bromide, or thiosulfate ions.
3. Crevice corrosion is most detrimental when the crevice is wide enough to permit the entry of the corrosive fluid but sufficiently narrow to maintain a stagnant zone. It may be attributed to lack of oxygen, change in acidity, buildup of a corrosive species, or depletion of a beneficial species within the crevice.
4. Galvanic corrosion. Environmental factors usually do not influence the reaction rate to any large extent, provided that the electrolyte has sufficient electrical conductivity.
5. Stress-corrosion cracking (SCC) occurs in specific environments, which depend on the metal alloy involved. However, it is difficult to predict SCC for a specific system without experimental data. Corrosion fatigue depends on the composition, temperature, *p*H, and oxygen content of the environment.
6. Intergranular corrosion can occur in most metal alloys and is dependent on the composition of the solution. However, the most important factors determining the susceptibility to intergranular corrosion are the composition and microstructure of the alloy.
7. Erosion-corrosion depends on the relative motion between the material surface and the corrosive environment. The nature of the movement and the corrosiveness of the environment are the main variables. However, factors such as the concentration of suspended impurities in the environment are also important.
8. High-temperature attack occurs in the absence of a liquid at elevated temperatures. The nature of the scale depends on the composition of the environment; the presence of sulfides or chlorides may result in nonprotective scales under conditions where an environment containing only oxygen would result in a protective scale.

1.5 Prevention

The detrimental effects of material degradation could be largely prevented through the proper application of existing knowledge, specifically by the following procedures:

1. A proper choice of materials for a given application. In this case, the mechanical strength, cost, and other properties must

be weighed against the material's resistance to degradation.

2. Proper geometric design of the material. In general, simpler forms, without crevices, should be used. Residual moisture should be avoided, as should unnecessary mechanical stress and galvanic coupling that will lead to degradation.
3. Elimination of corrosive materials from the environment. This includes lowering the humidity, the oxygen level, and the concentration of aggressive ions, reducing the acidity, reducing pollution levels, etc.
4. Protection of the chosen material by using inhibitors, coatings, cathodic or anodic protection. Inhibitors are materials added to the solution or to the vapor phase. They interact with the surface of materials, reducing the rate of one or both of the half reactions. Coatings act to form a physical barrier between the material and the aggressive environment. Cathodic protection, which relies on adjusting the potential of the metal into the immunity region of a Pourbaix diagram (see Fig. 1), may be accomplished through the sacrificial-anode method (Morgan, 1987), or by the impressed-current method, where an external power supply is used. Anodic protection relies on passivating the material, that is, forcing the potential into the passive region as shown in a Pourbaix diagram.

2. METHODS AND EQUIPMENT

2.1 Measurement of Thermodynamics

In the previous section, the fundamental thermodynamic and kinetic parameters were introduced. However, in order to use this knowledge, we must make measurements of the important parameters, or quantities that are directly related to them. In this section, the approach used for such measurements will be presented. The section will be divided into two major subsections dealing with the measurement methods and equipment for thermodynamic measurements and those used to determine reaction kinetics. Within each subsection, specific techniques for measurements in solutions and gaseous atmospheres will be presented.

Thermodynamic measurements are vital since they allow the problem to be divided in two: those reactions that can occur, and those that cannot. By quantifying this information, the driving force for a reaction can be determined. As discussed above, however, an understanding of the thermodynamics of a materials degradation phenomenon is a necessary, but not sufficient, state of understanding. Nonetheless, careful measurements of the important thermodynamic parameters provide a starting point for understanding corrosion.

In order to make electrochemical thermodynamic measurements in solution, a reference electrode is required. A reference electrode consists of a material–electrolyte interface that is in thermodynamic equilibrium. Thus, the conditions at this interface do not change with time and can be used as a guidepost for changes that occur at other interfaces. An extremely common reference electrode is the saturated calomel electrode, which consists of mercury in contact with Hg_2Cl_2 in a solution saturated with KCl. This interface is kept in equilibrium by containing it and its surrounding solution in a vessel with a porous plug on one end (see Fig. 4).

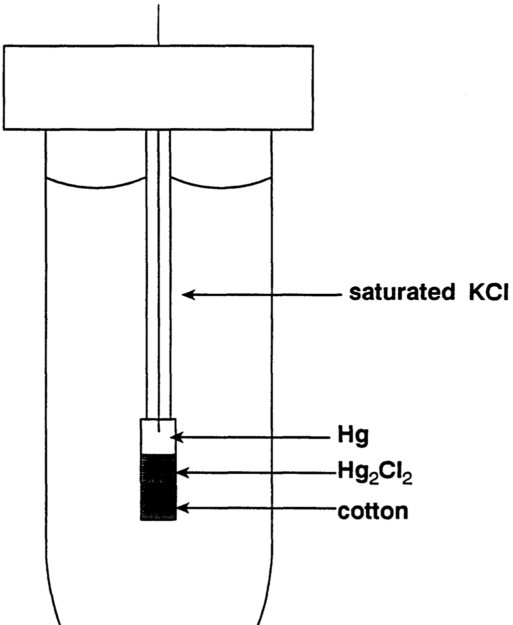


FIG. 4. Schematic of a saturated calomel reference electrode showing the component parts. The entire electrode is immersed in solution, allowing the potentials of other interfaces to be compared against it.

The porous plug allows ionic contact between the reference electrode and the test environment but prevents bulk movement of solution either into or out of the reference electrode chamber, preserving its equilibrium condition. A variety of other reference electrodes is used, as shown in Table 3. Any potentials measured with these electrodes can be referred to the standard hydrogen electrode (SHE) discussed earlier. However, these reference electrodes are far easier to construct and operate than the SHE, which requires a constant flow of pure hydrogren gas at 1 atm pressure.

Often the conditions for equilibrium measurements are extremely difficult to achieve. However, we will see that the ability to measure electrochemical potentials is critical in kinetic measurements as well. In this way, the driving force for a reaction can be related to the reaction rate. While some measurements of thermodynamic quantities can be made electrochemically, the vast majority of free-energy measurements for chemical reactions are made via calorimetry (Atkins, 1982). However, potential measurements are widely used for the determination of solubility products as well as for the determination of ionic concentrations, including H^+ detected by *p*H meters.

Measurements of thermodynamic properties of interfacial reactions when the environment is gaseous are inherently more difficult. Equilibrium conditions are more difficult to establish, especially at elevated temperatures. In most cases, the partial pressure of gases is the critical parameter to determine. In most instances, oxygen is the gas of greatest interest. Ellingham diagrams use an approach similar to the Pourbaix diagrams mentioned previously to illustrate graphically the most thermodynamically stable phases as a function of temperature and oxygen partial pressure (Lou and Heuer, 1990).

Table 3. Common reference electrodes.

Type	Voltage vs SHE (*V*)
Saturated calomel ($Hg_2Cl_2 + 2e^- = 2Hg + 2Cl^-$)	+0.241
Mercury–mercurous sulfate [$HgSO_4 + 2e^- = 2Hg + (SO_4)^{2-}$]	+0.615
Silver–silver chloride ($AgCl + e^- = Ag + Cl^-$)	+0.222
Copper–copper sulfate [$CuSO_4 + 2e^- = Cu + (SO_4)^{2-}$]	+0.318

2.2 Measurement of Kinetics

While thermodynamic considerations are a necessary first step in understanding materials degradation, they are by no means sufficient unto themselves. The fact that all materials (except gold) are *thermodynamically* unstable under ambient conditions does not prevent their successful use technologically. It is the kinetics of their reversion to their most thermodynamically stable form that is limiting. This section will provide an overview of three aspects of kinetic measurements: in solution, in gaseous atmospheres, and as a loss of mechanical properties.

The quantity to be measured that characterizes the kinetics of corrosion depends directly on the type of degradation considered. In solution, the forms of corrosion can be divided into two groupings: uniform material loss and localized attack. These two types of degradation require different approaches to the measurement of their kinetics. Uniform material loss is the simplest form of corrosion and the easiest to measure quantitatively. The most common engineering approach to measuring uniform corrosion rate is the use of coupon exposure tests in which small (e.g., 50 × 150 cm^2) panels of the material of interest are immersed in the solution of interest for a set period of time. Afterward, they are cleaned, and the loss of material is determined by the loss of specimen weight. Standard practices and methods have been developed for such tests (Jones, 1992). Usually, inspection of the surface morphology is performed with both optical and scanning electron microscopy. Surface analysis with x-ray photoelectron spectroscopy, Auger-electron spectroscopy, or secondary-ion mass spectroscopy may also be used. These postexposure tests can provide information on both the mechanism and rate of corrosion attack.

However, the main difficulty involved with exposure tests is the time required for measurable weight loss to occur. In most cases, the time constraints on materials selection decisions require answers in shorter times. It is for this reason that electrochemical methods have become increasingly popular for determining corrosion rate. The electrochemical nature of metallic corrosion is apparent from the earlier sections of this article. The utility of electrochemical measurements for the estimation of corrosion rates relies on the relation between the electrochemical potential and the reaction rate, measured as a current density. The potential has been discussed and relates to the driving force for the reaction to occur. For an oxidation reaction, an (algebraic) increase in the potential increases the driving force in the same way that an increase in temperature increases the driving force for a chemical reaction. The rate of the reaction is exactly the flux of the species:

$$i = nFJ. \qquad (11)$$

This relation allows extremely accurate measurements to be made. Currents in the μA range can be routinely measured. A simple calculation shows that 1 μA cm^{-2} corresponds to a flux of 10^{12} atoms/s. A surface contains approximately 10^{15} sites. Thus, at a current of 1 μA cm^{-2}, it would take approximately 1000 s to remove a monolayer of material. Thus, the sensitivity of electrochemical measurements makes them an attractive addition to longer-term weight-loss experiments. Exposure tests of the materials of interest to the environments cannot be ignored, as these are the most relevant measure of performance and can exhibit rates and types of degradation that were not expected.

Just as one cannot measure the absolute potential across a single interface, one can only measure the net current. At the corrosion potential, the cathodic sites are using all of the electrons liberated during the anodic process. No current needs to be applied by an external measurement device in this case. In fact, no current could be measured by an external device since all of the charge is circulating locally on the same surface, as shown in Fig. 5. No electrons would move through an external connection. However, in order to determine the corrosion rate, we need to disturb the surface and measure the applied current necessary to do so.

The device used to perturb the surface is a potentiostat. It operates like an ideal operational amplifier, as shown in Fig. 6. The interface of interest (called the working electrode) is connected to one of the inputs. The reference electrode is connected to the other. Since the potentiostat has a very high (ideally, an infinite) impedance between these electrodes, no current passes between them, and the reference electrode is maintained in thermodynamic equilibrium. In order to polarize the interface to a set potential vs the reference electrode, a voltage offset (V_{set}) is imposed between the working and reference electrodes (in this case, by a battery and a variable resistor). The potentiostat reacts to this by increasing the voltage at its output in order to return the voltage difference between its inputs to zero. This output is connected to the counter electrode, an inert electrode immersed in the same solution. This causes a current to pass between the counter electrode and the working electrode. The current changes the potential across the working electrode–solution interface until it reaches the desired value. In this way, applied current–potential curves can be generated, as shown by the solid lines in Fig. 2. If both the anodic and cathodic reactions obey Tafel kinetics [i.e., the current–potential behavior follows Eq. (9)], an extrapolation of the linear portions provides an estimate of the corrosion rate (i_{corr}). This current density can be converted to a penetration rate by standard formulas (Jones, 1992). These proce-

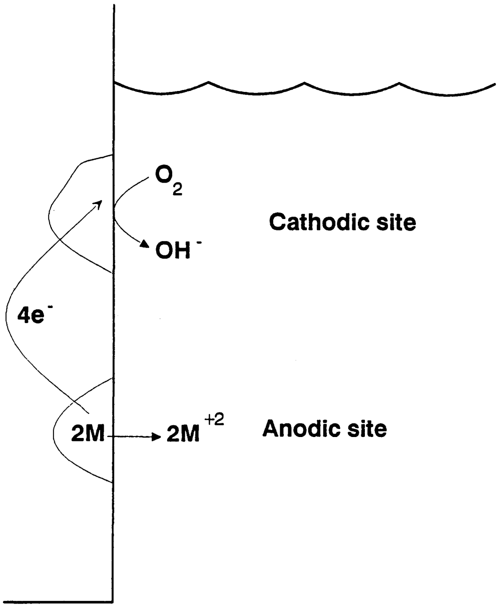

FIG. 5. Schematic of one cathodic and one anodic site communicating on an immersed surface at its free corrosion potential. The electrons liberated during the oxidation of the metal are consumed by the reduction of oxygen.

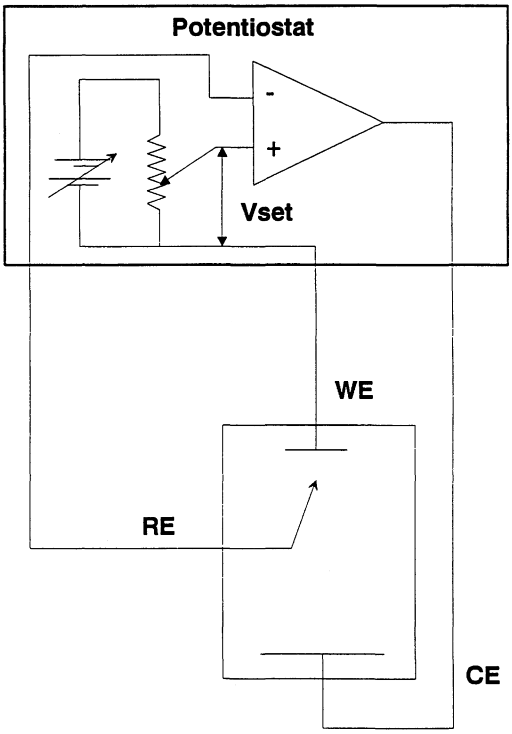

FIG. 6. Schematic of circuit and connections for a potentiostat. The working electrode (WE) is the interface of interest, while the reference electrode (RE) and counter electrode (CE) are used to control the potential of the WE at the desired level (V_{set}).

dures are easily automated and allow a large number of alloys and environmental variables to be studied.

Another method to measure corrosion rate relies on the fact that the equations describing the coupled electrochemical reactions can be linearized in the potential range near the corrosion potential. Stern and Geary (1957) showed that the corrosion rate can be directly related to the slope of the plot of applied current vs potential, as shown in Fig. 7. This approach forms the basis for the polarization-resistance method of corrosion-rate determination. Many commercial corrosion rate monitors make use of this approach.

Localized attack is a much more difficult type of degradation to analyze quantitatively. Its apparent stochastic nature and the simultaneous existence of areas of low and high corrosion rate on the same surface make it theoretically difficult to address. Its dependence on local geometry (as in crevice corrosion) adds an additional level of complexity. Besides exposures to determine the amount or probability of localized attack, electrochemical measurements have been widely used to determine the potential dependence of both the initiation and propagation phases as a function of alloy content and environmental conditions. The application of these measurements to corrosion engineering estimates of performance is at this time controversial. There is growing acceptance that carefully made measurements can be applied to specific field conditions. One area of current interest is the application of electrochemical monitoring for localized corrosion. While localized corrosion rates are not determined, conditions conducive to the development of localized corrosion can be monitored.

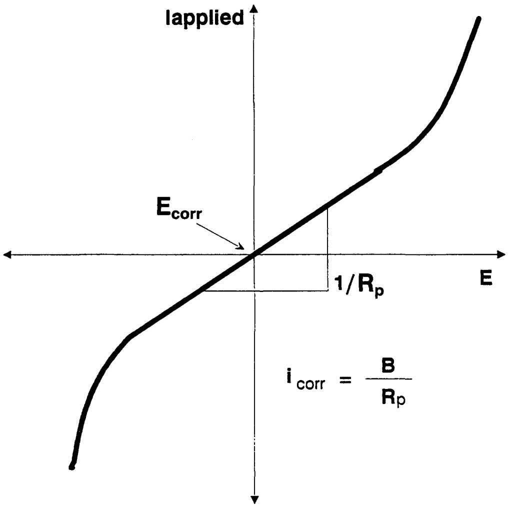

FIG. 7. Schematic plot of applied current vs potential for a polarization resistance measurement. The slope of the line at the corrosion potential is directly related to the corrosion rate.

Atmospheric corrosion kinetics have traditionally been determined by long-term exposures of coupons to the relevant conditions. For example, coupons have been exposed to industrial, urban, and rural atmospheres for up to 50 yr. Similarly, corrosion of materials in hot gases, such as in aircraft engines (exhausts), has been most extensively studied with the exposure approach. In recent years, the application of microbalance techniques has provided additional information.

The quartz-crystal microbalance (see MASS

AND DENSITY, MEASUREMENT OF) is an adaptation of the technology used in the monitoring of thin-film deposition. A thin, *AT*-cut quartz crystal is used as the substrate for the deposition thin film of the material of interest. It is then exposed to the atmospheric conditions of interest, and the resonant frequency of the crystal is followed. Since its initial resonant frequency is in the MHz region and can be measured to an accuracy of less than 1 Hz, changes in mass of less than 10 ng cm^{-2} can be observed (Deakin and Buttry, 1989). These changes are nearly equivalent in sensitivity to the electrochemical current measurements discussed above and open a new avenue to questions concerning atmospheric degradation mechanisms. This approach has been used to show quantitatively that Ni exposed to slightly polluted air corrodes at a much higher rate when both SO_2 and NO_2 are present than when either one is present alone (Zakipour *et al.*, 1986).

2.3 Measurement of the Loss of Mechanical Properties

One of the most important ways in which localized corrosion manifests itself in failures is through the loss of mechanical properties. Stress-corrosion cracking (SCC) and hydrogen embrittlement (HE) result in the loss of mechanical integrity of a wide variety of structures. The failure of the Pt. Pleasant bridge discussed above occurred as a result of hydrogen-embrittlement cracking of a support member. While a great deal of work is focused on the prevention of the conditions under which SCC and HE can occur, measurements of crack growth rate are also important to allow damage tolerance of structures to be evaluated properly. A variety of test methods is available for measuring the susceptibility of materials to SCC and HE, and many have been standardized. The tests fall under two broad categories: those that test susceptibility to both initiation and propagation, and those that quantify the propagation stage. In many cases, alloys are screened for susceptibility by exposing stressed samples to either the service environment or a simulated environment made more aggressive by increasing some environmental variable (e.g., temperature, acidity, etc.). For these tests of both initiation and propagation susceptibility, specimens are usually in the form of C rings or U bends. After a defined exposure time, the samples are removed and checked for signs of cracking. Because of the ill-defined mechanics of such a specimen, very little information of use to designers results. However, such testing is very popular for screening and ranking alloys.

More quantitative information is available from dynamic testing. Two types of approaches are used. In slow strain-rate testing (SSRT), a smooth sample of material is dynamically strained while exposed to the environment of interest. This straining is usually performed at a low rate (e.g., 10^{-5}/s). The increasing strain is necessary to fracture the protective films on the materials repeatedly and allow any crack initiation that will occur to take place. The strain is applied at a slow rate in order to provide the time necessary for the environment to interact with the material. The measured mechanical properties (ultimate tensile strength, strain to failure, etc.) and the fracture surface morphology are compared to those produced in tests performed in an inert environment such as high vacuum or oil. Fracture mechanics testing uses specimens with precracks, often initiated by fatigue. These methods use well-defined specimen geometries to relate the measured cracking to the stress state at the crack tip. Crack growth rates on the order of 10^{-5} cm/s can be measured. However, the equipment and specimen costs are much higher than the SSRT method.

3. SPECIFIC EXAMPLES FOR DIFFERENT CLASSES OF MATERIALS

3.1 Metals and Alloys

In this section, several common and important types of degradation are discussed. Much more information is available elsewhere (Uhlig, 1948; Fontana and Greene, 1967; Parsons, 1982).

Iron and low-alloy steels are well known to be susceptible to general corrosion in the atmosphere or under damp conditions, giving rise to "rusting." The composition of ordinary, red-brown rust is $Fe(OH)_3$, although layers of $Fe_3O_4 \cdot nH_2O$ and $Fe(OH)_2$ may also be present. Rusting results from the concerted action of water and dissolved oxygen on the metallic iron. It is accelerated by an increase in temperature and by appreciable concentrations of halides and acids. A special case occurs under anaerobic conditions when sulfate-reducing bacteria are present. This phenomenon is known as microbiologically induced corrosion.

Stainless steels, which are iron alloys containing at least 11% chromium, are generally resistant to atmospheric corrosion; however, they are susceptible to many other important forms of degradation, including pitting, SCC, and intergranular attack. In this section, a brief review of some of these effects will be given.

The superior corrosion resistance of stainless steels is due to the formation of a stable, highly protective, passive film. The composition of this film is still debated in the literature but is usually thought to consist of a mixture of chromium and iron oxides and hydroxides, enriched in chromium with respect to the bulk metal (Marcus and Olefjord, 1988). Many different stainless steel alloys have been developed for different applications. For example, carbon, molybdenum, titanium, aluminum, and copper are added for strength, nickel and molybdenum for corrosion resistance, sulfur and selenium for machinability, and nickel for formability and toughness (Sedricks, 1979).

Pitting attack results from a local disruption of passivity. The mechanism of the initiation of pitting is hotly debated in the literature (Mansfeld, 1987; Szlarska-Smialowska, 1986); however, for stainless steels, significant evidence exists to suggest that the sites of pit initiation are associated with defects in the film due to the presence of impurities in the alloy (Sedricks, 1979). The propagation of pits is somewhat better understood and is thought to result from a localized acidification within the confines of the pit, leading to a local increase in the dissolution rate and thus autocatalytic growth of the pit (Fontana and Greene, 1967).

Stress-corrosion cracking occurs in the presence of a tensile stress and a specific corrodant. It results in a failure of the steel at much lower stress level than in the absence of the corrodant. Again, the mechanism of this form of degradation is still not well understood. It has been variously proposed that the crack propagates by local dissolution of the metal at the crack tip enhanced by the plastic deformation of the metal, or that atomic hydrogen (produced by the reduction of water or H^+ during the corrosion) accumulates within the metal in the crack tip region, lowering the cohesive strength, or by combinations of these two mechanisms. The specific corrodants that can produce SCC in stainless steels include chloride, sodium hydroxide, and sulfides.

Intergranular attack usually occurs as a result of the segregation of alloying elements or precipitation of electrochemically active phases at the grain boundaries. The segregation often results from heat treating, aging, or welding, though equilibrium segregation can also occur. Mechanistically, either the grain boundary can be actively dissolving itself while the remainder of the material remains passive, or the precipitated phase can be actively dissolving.

The atmospheric corrosion of copper and bronze can be considered a beneficial degradation reaction, since it results in a decorative and protective coating for the metal. In contrast, silver corrodes to produce an unsightly tarnish (Uhlig, 1948; Evans, 1963). The green patina formed on copper roofs consists of a basic copper sulfate [$CuSO_4 \cdot 3Cu(OH)_2$], except near a source of chloride, when it also contains copper oxychloride [$CuCl_2 \cdot 3Cu(OH)_2$]. Sulfur-containing pollutants are necessary for the development of the patina. The patina formed on bronzes also depends on the atmosphere. In industrial areas, greenish-black and black films are formed, while bright green films and reddish-brown films are formed near the ocean and in dry rural areas, respectively. Bronze is also subject to an interesting periodic tarnishing, with alternate layers of red cuprite (Cu_2O) and green malachite [$CuCO_3 \cdot Cu(OH)_2$] formed on the surface. This phenomenon is due to a fluctuating supply of CO_2 in the environment. The tarnish on silver is again due to sulfur pollution and is not observed unless traces of H_2S are present in the atmosphere.

3.2 Polymers

Unlike for most materials, the degradation of polymers can be either detrimental or beneficial. For polymeric materials that are used in structural components (such as advanced aircraft skin), the design life is usually such that degradation is viewed as a problem. For applications in which the object is used for only a short time (such as a beverage container), rapid degradation of the polymer afterward would be advantageous, especially for easy recycling. The degradation of polymeric materials usually results from chemical reactions that break bonds, rather than electrochemical oxidation reactions as is usually the case for metallic materials exposed to solution. Because of the huge number of polymers, generalities are difficult, but all polymers show some sensitivity to heat, radiation, oxygen, and solvents. The degradation reactions damage the properties of the polymers, including their mechanical, optical, and electrical properties. Common examples of degradation include the chalking of automobile paint, embrittlement of rubber hoses, cracking and peeling of vinyl tops on automobiles, the fading of fabrics and paints, and the failure of electrical wire insulation.

Bond breaking results in a change in both the average molecular weight and its distribution, as well as a change in the chemical character of the polymer molecules. Since the molecular weight characteristics of polymers determine many of their properties, uncontrolled changes in these characteristics usually lead to a loss in performance. Degradation reactions include the cleavage of main chains, cross-linking, and the cleavage of side groups. These reactions occur via free-radical pathways, which allow both chain scission and cross-linking to occur. These three examples are shown in Fig. 8. In addition to the reduction in molecular weight caused by these processes, the products of the degradation reaction can be deleterious to the polymer's properties as well, making the process essentially autocatalytic. Chemical oxidation often occurs by exposure of the material to a combination of heat, oxygen, and uv radiation. Impurities in the polymer, which are a remnant of the manufacturing process, often act as catalysts for these reactions. Oxygen has an accelerating effect since it is reactive toward both the polymer and the degradation intermediates, leading to the formation of more free radicals.

Additives to polymers are included to stabilize them against uv radiation. In general, these antioxidants act as radical scavengers, reacting with the free radicals or the agents that form them before the polymer can be further degraded. Thus, they do not prevent damage altogether but simply lessen its rate to acceptable levels. For example, carbon black acts by absorbing uv radiation before it penetrates the bulk of the polymer. Thus, black polyethylene (PE) lasts longer when exposed to sunlight than does clear PE (Kelen, 1983).

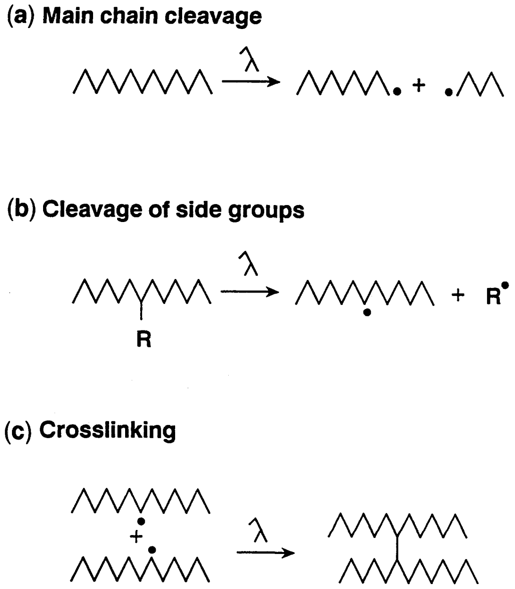

FIG. 8. Schematic showing three types of polymer degradation reactions resulting from the absorption of radiation (λ). Similar reactions can occur as a result of other active agents such as O_2.

Depolymerization of linear polymers is essentially the reverse of the reaction that forms them. The repeat units of the molecule (sometimes referred to as the "mers") start to come apart, starting with the end groups of each chain. This process is usually initiated by heat, but radiation can induce it as well if the end groups are able to absorb at the wavelength of interest. Polymers are also susceptible to a type of degradation analogous to the SCC of metallic materials.

With the recent increase in the desire for recyclable products, polymer degradation has been studied in terms of methods to generate reusable raw materials from the wide variety of plastic packaging currently used. The technological difficulties are significant, in part because of the expense of collecting and transporting the large volumes (but small weights) of polymeric materials. While it is necessary to remove the product labels from the plastic packages, the difficulties involved make it economically unattractive given current costs of landfills. In essence, it is far cheaper to throw these materials away than it is to recycle them. Incineration is typically not an option, as many commercial plastics have combustion products that are harmful or extremely corrosive. However, as landfill costs increase, the economics of plastic recycling are bound to change, and many of the technological difficulties will be overcome. Present applications for biodegradable polymers include mulch fillers and seedling holders used during tree planting. Caprolactone polyester has been found to dissolve completely in soil after 12 months, supporting the seedling tree while it takes root (Potts, 1978).

3.3 Ceramics

While ceramics are often used in situations where corrosion of metals and alloys prohibits their use, these materials are also susceptible to degradation. In most cases, the degradation rates for ceramics are much lower than for metals and alloys, even under elevated temperature conditions. However, there are a number of applications in which ceramic degradation is an important factor. One of the most important applications of ceramics is as a refractory material in the containment of molten salts, slags, and metals. For example, magnesium oxide impregnated with carbonaceous material is used to line vessels for steelmaking in basic oxygen furnaces. During the casting operation, the MgO reacts with the FeO in the slag to form a solid solution with a low melting point (compared to the operation temperature). This leads to dissolution of the refractory.

Nonoxide ceramics (such as SiC and Si_3N_4) are of interest for automotive engine and gas turbine applications because of their maintenance of strength at high temperature as well as their excellent wear resistance. However, these materials can be attacked by oxygen, hydrocarbons, NO_x, and sulfur contamination in fuel. Si_3N_4 densified with additions of Al_2O_3 and Y_2O_3 is of interest in coal gasifiers. However, it is found to degrade rapidly under conditions of high temperature (greater than 1200 °C) and in the presence of sulfur species (Oliveira *et al.*, 1990). The formation of silica-rich protective scale is thought to be important. A variant of SCC can also be observed under application conditions (Weisskopf and Morgenthaler, 1990).

Other applications of ceramics in which degradation can be a problem are hot corrosion (termed *fluxing*) during contact with molten ionic condensates such as encountered in the effluent of coal combustion plants, aqueous corrosion of ceramic containers in the containment of nuclear wastes, and the preferential leaching of stabilizers such as MgO, CaO, and Y_2O_3 from stabilized zirconia.

GLOSSARY

Many definitions of terms related to corrosion can be found in ASTM Standard G-15 (ASTM, 1992). Some of these are listed below.

Anode: The electrode in an electrochemical cell at which oxidation is the principal reaction. Electrons flow away from the anode in an external circuit.

Cathode: The electrode in an electrochemical cell at which reduction is the principal reaction. Electrons flow toward the cathode in an external circuit.

Exchange-Current Density: The rate of charge transfer per unit area when an electrode reaches a dynamic equilibrium at its reversible potential in a solution; that is, when the rate of anodic charge transfer (oxidation) balances the rate of cathodic charge transfer (reduction).

Overpotential: The change in potential of an electrode from its equilibrium or steady-state value when a current is applied.

Passive: The state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal.

Tafel Slope: The slope of the straight-line portion of a polarization curve, usually occurring at more than 50 mV from the open-circuit potential, when presented in a semilogarithmic plot in terms of voltage per logarithmic cycle of current density (commonly referred to as volts per decade).

INTRODUCTION

The word *material* for the purposes of this article refers to the physical matter from which useful objects are engineered. The preparation of materials begins (at least for the purposes of this discussion) after a mineral or other natural resource has been converted into a raw material. The process of forming a raw material through the refinement of mineral or organic precursors is not discussed, since these processes vary greatly depending on the final application and the degree of chemical change necessary to realize the final product. To illustrate this point, consider the production of a metal (such as Fe or Cu) from the mineral state (usually either a sulfide or an oxide). The product of the mining process is essentially rock (gangue) with a relatively low concentration (0.1–1 wt %) of mineral in the form of metal oxides and sulfides. This material must be mechanically ground to a fine powder to allow separation of the useful minerals from the surrounding rock. The mineral is concentrated by mechanical separation (based on differences in density and surface properties and on chemical dissolution) of the mineral from the waste rock. The concentrate is then chemically treated [typically at high temperature in a *blast* (for Fe) or *smelting* (for Cu) furnace] to reduce the oxide (e.g., FeO) or sulfide mineral (e.g., CuS) to an impure elemental state. The material of interest then undergoes purification or refining to eliminate undesirable impurities (e.g., S, P, Si and C in Fe), and other constituents are added (alloyed) to modify the physical properties of the material. For metals, the process of refinement can include dissolution of the impure metal in an electrolyte followed by electrochemical plating (e.g., electrorefining of Cu) or chemical treatment of a molten metal to incorporate impurities selectively into a oxide slag (e.g., CaO/O_2 treatment of Fe to form steel). In contrast, many useful engineering materials such as wood receive relatively little preparation other than drying and milling before they find engineering application. In this dis-

cussion, the preparation of materials that require only crude chemical preparation steps before being shaped into a useful form (e.g., bricks, wood, stone, and natural fibers) is neglected.

This article addresses, in general terms, materials preparation steps between those in which a raw material is produced through a refining or mineral processing technology and the final shaping process (such as machining or lithographic patterning). The emphasis is on processing raw materials into a near-final chemical and local-microstructural state immediately prior to the assembly or shaping of a final material into a useful device, structure, or component. These materials preparation steps will be subdivided into three principal categories based on the primary matter transport mechanism that participates in the preparation of the final solid. As such, the main headings will include vapor-state, liquid-state, and solid-state processing. A fourth category, polymer processes, is added since the preparation of a polymer begins with gaseous precursors (e.g., ethane) and passes through either or both liquid and solid states during the course of its preparation for engineering application. Representative examples of common process(es) in each of these major headings are provided; no effort has been made to survey exhaustively all materials preparation technologies since new methods are constantly being developed. In many cases, detailed information on a particular materials preparation process may be found under a more specific heading.

1. VAPOR-STATE PROCESSES

In this section, a selection of materials preparation processes that employ the vapor phase as the primary material transport mechanism are discussed. After deposition *via* any one of several vapor-state methods (some of which are discussed below), the material is typically thin (10 nm to 1 mm) relative to the substrate dimensions. All of the methods selected for this section are used in the fabrication of integrated-circuit devices in which a variety of conducting, semiconducting, and insulating materials are sequentially deposited. These methods form the basis for all modern microelectronic technologies ranging from integrated circuits to solid-state flat panel displays to modern magnetic- and ferromagnetic-based memory devices. Vapor-phase deposition is also widely used for the deposition of decorative and abrasion- and wear-resistant coatings. All vapor-deposition techniques, by definition, take place under controlled atmosphere conditions onto a suitable substrate. In evaporative, sputter, and chemical vapor-deposition processes, the material is deposited onto a substrate. In ion implantation, the material is deposited into the near-surface region of the substrate.

1.1 Physical Vapor Deposition

1.1.1 Common Themes The two principal methods of physical vapor deposition (PVD) are sputtering and evaporation. These methods are used to deposit thin films of material on a substrate to a thickness that is typically less than 1 μm and, less commonly, up to several millimeters. Thicker films may be removed after deposition to become free-standing foils. In all PVD processes, the coating material is passed from a source to the substrate *via* the vapor phase. The interaction of the source molecules with the atmosphere as they travel to the substrate must be avoided, and for this reason, the deposition chamber is usually evacuated by vacuum pumping. The chamber pressure must be low enough during deposition to prevent molecules leaving the source from colliding (and therefore reacting) with residual gas molecules (e.g., O_2) before landing on the substrate. The pressure necessary to achieve this aim is actually quite modest. At atmospheric pressure (1.013×10^5 Pa), the molecular density at 25 °C is about $2.5 \times 10^{25}/\mathrm{m}^3$, while at 10^{-3} atm (100 Pa), the vapor-phase density is three orders of magnitude lower, $2.5 \times 10^{22}/\mathrm{m}^3$. Attaining this vacuum level is easily achieved with a modern rotary vane pump. An important parameter is the mean free path λ, which is defined in the kinetic theory of gases as the average distance traveled by a gas atom between collisions with another gas atom. The mean free path decreases with decreasing pressure since the spacing between molecules increases. For example, the average distance traveled by a N_2 molecule at 25 °C can be calculated from its molecular diameter, $\delta = 0.368$ nm, the temperature (i.e., kinetic energy of the molecule), and the pressure by the following relation:

$$\lambda = \frac{kT}{\pi\delta^2 P}, \tag{1}$$

where k is Boltzmann's constant, P is the gas pressure, and δ is the molecular diameter. Using appropriate units, the mean free path at 1 atm (1.013×10^5 Pa) can be calculated to be 9.5×10^{-8} m, while at 100 Pa, it is 10 mm.

The second (and more important) reason for establishing a decreased pressure of reactive species in the deposition chamber is associated with the impingement of nonfilm species (i.e., impurities) on the growth surface during deposition. If these non-film species are incorporated into the growing layer, then the composition of the deposited material will be seriously contaminated by the impurities in the deposition system. In reactive deposition processes, a gaseous impurity is purposely introduced into the vacuum system, as is widely done in the deposition of oxides (e.g., indium oxide using O_2 and an in source) from metal sources. The surface impingement rate (I) can be calculated from the kinetic theory of gases and is given, approximately, by

$$I = \frac{2^{0.5}P}{(\pi mkT)^{0.5}} \tag{2}$$

where P is the pressure in Pa, m is the molecular weight, and T is the temperature in Kelvins.

On the basis of the above considerations, it is possible to see that when layer-by-layer atomic control of the composition of a deposited layer is important, then low pressures are required ($10^{-9} < P < 10^{-7}$ Pa is typical). Consider the case where an evaporation process is being performed in a chamber that was initially evacuated to 1.3×10^{-4} Pa. The deposition rate is 1 monolayer/s, and we will assume for simplicity that the deposited atoms are 0.3-nm-diam hard spheres that are packed in a square array. With this information, it is easy to calculate the composition of the film in terms of the ratio of impurities (i.e., air molecules) to film species. The 1-monolayer/s rate corresponds to a deposition of 1×10^{15} atoms/cm^2 s. The surface impingement rate from impurities left over after evacuation of the deposition chamber is about 7.6×10^{16} atoms/cm^2 s. Note that the ratio of impurity atoms to film atoms exceeds unity. Actually, this gives an exaggerated (<1 at. % is more typical at this background pressure) view of the importance of a low background pressure since, in reality, not all atoms that impinge on the surface stick. The ratio of the number that stick to the total impingement rate (known as the sticking coefficient) is typically much lower than unity and is dependent on the incident species and changes with the composition of the deposited material.

The microstructure of a deposited film depends on the materials being deposited, the substrate, the temperature of the substrate, and the energy of the incident material flux. The resultant film may be amorphous, fine- or coarse-grained polycrystalline, or single-crystal. The film may contain either compressive or tensile stresses depending on the thermal expansion difference between the substrate and the deposited film and, particularly in sputter deposition processes, is dependent on the background pressure. In the case of a single-crystal substrate and the deposition of a material with like crystal structure but different natural lattice parameter, a single-crystal layer with a commensurate or coherent interface may grow in a process known as epitaxy. In this case, the difference in lattice parameter is accommodated either entirely elastically (if the mismatch is small) or by a combination of elastic strain and the presence of strain-relieving interfacial dislocations.

1.1.2 Evaporation In evaporative processes, the deposit is formed by heating a source material so that its equilibrium vapor pressure is locally raised. This causes the evaporation or sublimation of the desired species into the vapor phase that passes through the apparatus and condenses on the substrate, which is at a much lower temperature. A schematic view of this process is shown in Fig. 1. The source material is heated by any one of a wide variety of methods including simple resistance heating, induction, or electron-beam or laser heating of the source material. The advantage of this method of thin-film preparation is that extremely high-purity materials can be formed since the process takes place in vacuum (typically less than

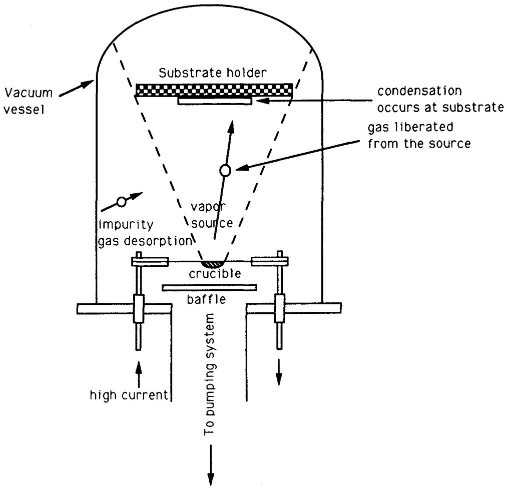

FIG. 1. Schematic view of a evaporative deposition process. The source is heated to a temperature sufficient to raise the equilibrium vapor pressure of the source material. The entire assembly is contained in a vacuum chamber.

1.3×10^{-4} Pa), and high deposition rates (relative to the surface impingement rate) can be achieved. This can also be a cost-effective thin-film deposition choice since relatively simple heating sources can be used. For example, plastic wrapping material used to protect moisture-sensitive food or electronic products is made by depositing a few tens of nanometers of Al on the surface of a polyethelyene or polypropylene polymer sheet. This is done by passing the polymer sheet (100s of meters long and up to 10-m wide) past a set of Al evaporation sources arranged in a line so that the entire width of the plastic sheet is coated as it passes by the evaporation source. In this common industrial procedure, the rolls of thin plastic sheet are placed in a large vacuum chamber, which can accommodate both the feed and take-up rolls of plastic.

The transport of species in the gas phase occurs under molecular flow conditions at low pressures (below 1.3×10^{-3} Pa). Molecular flow implies that the molecules in the gas do not interact with each other because the mean free path of the gas species is much larger than the distance between the substrate and the source. For this reason, typical evaporative deposition processes only allows the substrate areas that are in the line of sight of the source to be coated. This means that shadowing and poor step coverage are typical of evaporative processes. To alleviate this problem, inert gases are sometimes introduced so as to modify the conditions in the chamber from molecular to viscous (cooperative flow involving interaction between molecules) flow. The problem can also be reduced by rotating the object that is to be coated in a way that allows all parts of it to be exposed to the source.

Heating the source material causes an increase in the local equilibrium vapor pressure of the evaporated species. A pressure gradient in the source molecules leads to gas-phase transport to cooler surfaces where condensation occurs. The rate at which atoms pass into vacuum from a heated source is given by the Hertz-Knudsen equation

$$W = \frac{\alpha_v(P^{\mathrm{eq}} - P)}{(2\pi mkT)^{0.5}}, \tag{3}$$

where W is the rate of evaporation per unit area, P^{eq} is the equilibrium vapor pressure of the source material, P is the actual pressure in the chamber, and α_v is an emission or evaporation constant. For a pure source materials with an atomically clean surface, α_v is unity; if the surface is contaminated, then it may be three orders of magnitude lower. Consequently, a low background pressure P is more important for maximizing the emission constant than for providing a diffusion gradient. Note that the equilibrium vapor pressure is extremely sensitive to temperature since $P^{\mathrm{eq}} = \exp(-\Delta G^0/kT)$ where ΔG^0 is the Gibbs free energy for either sublimation or boiling. The equilibrium vapor pressures for a variety of elements and materials are shown in Fig. 2. In general, in order to establish a reasonable deposition rate at the substrate, an equilibrium vapor pressure of about 1×10^{-2} Torr is required. For some materials such as Al, this pressure requires that the metal be melted (T = 1220 °C at $P^{\mathrm{eq}} = 10^{-2}$ Torr while T_{melting} = 659 °C), while for others such as Cr, sufficient pressure is achieved by heating the solid below its melting point (T = 1400 °C at $P^{\mathrm{eq}} = 10^{-2}$ Torr while T_{melting} = 1900 °C). Relatively few compounds decompose into the vapor congruently (i.e., composition of the gas is not identical to the composition of the compound). Materials such as CdSe develop an equilibrium vapor pressure of 10^{-2} Torr at 660 °C where the melting

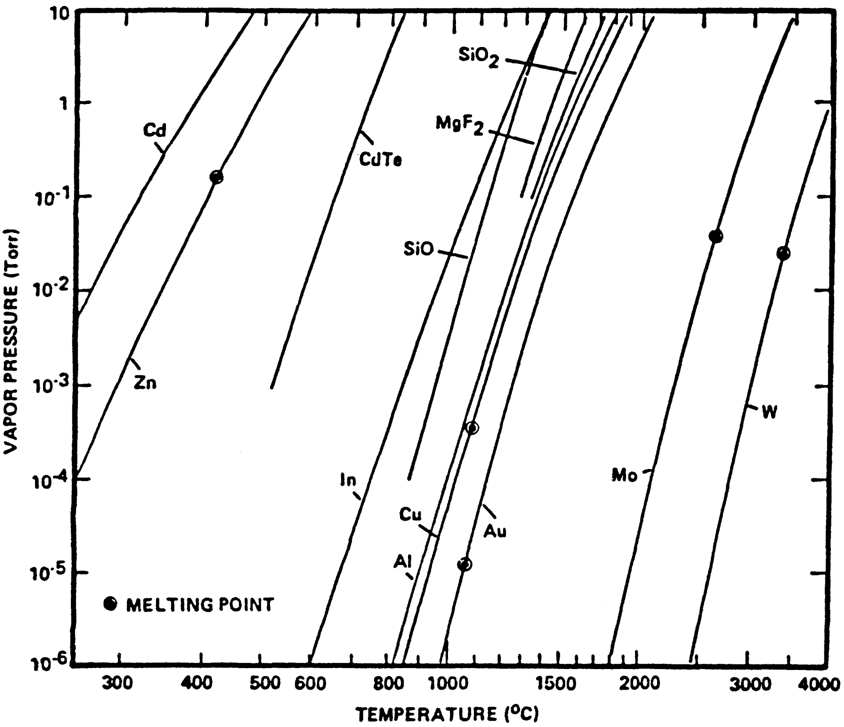

FIG. 2. Equilibrium vapor pressure of selected elements and compounds.

point of CdSe is 1250 °C, although the gas that evolved from the surface is not congruent since it is composed primarily of Se_2 and Cd. An important electronic oxide is WO_3 that melts at 1473 °C but can be volatilized into WO_3 and $(WO_3)_3$ at 1140 °C. Note that in any evaporation technique the crucible must be carefully selected since the support material must not react with the heated source material.

Conventional evaporation techniques do not allow the direct deposition of multicomponent alloys. Multicomponent films require the use of separate sources for each component, since they will typically have different equilibrium vapor pressures and, hence, different evaporation rates. Different evaporation rates, in turn, lead to an enrichment in the source crucible of the slower evaporating species and, hence, can result in compositional nonuniformities in the thickness of the deposit. In addition, great care must be taken to ensure compositional uniformity laterally across the substrate since the material flux decreases with increasing distance from the source. The deposition of compounds such as oxides and nitrides usually involves the introduction of a gaseous species into the deposition chamber. For example, the evaporative deposition of In_2O_3 from In metal involves heating the relatively low–vapor-pressure In species to volatilize it into an oxygen-containing atmosphere.

More sophisticated methods are also available for depositing multicomponent materials. One example is the use of a multiple hearth system in which a separate source (or hearth) for each component allows the temperature of each source to be adjusted in a way that sets the vapor pressures, and hence the evaporation rate, of the individual species. The equilibrium vapor pressure can be set over the source material independently from the pressure in the deposition chamber by limiting the orifice through which the evaporating species can escape. This is the principle employed in a Knudsen cell where vapor-solid (or -liquid) equilibrium is established inside the cell independent of the pressure in the deposition chamber, and at a particular temperature, the rate at which the vapor species pass into the vacuum chamber is controlled by the size of the orifice and the temperature of the cell. *Molecular beam epitaxy* (MBE) (*q.v.*) is a specialized, ultrahigh-vacuum technique that typically uses multiple hearths and Knudsen cells. Another approach is known as flash evaporation and avoids the problem of differential evaporation rates by completely and rapidly vaporizing the source material with a single high-power pulse. In this way, the composition of the source material and that of the deposited film are sure to be the same. This approach has the disadvantage of requiring exact control over the amount of material in the crucible, since it is all evaporated and hence defines the final thickness of the film. A variation on this approach is known as *pulsed laser deposition* or *laser ablation* where a small portion of the source material is evaporated by a high-power laser pulse that results in the ablation of the small region of the target that is heated by the focussed laser.

1.1.3 Sputtering In sputter deposition processes, atoms are stripped from the surface of a cathodically biased solid source material (also known as the target), which is placed in close proximity to an energetic plasma containing positively charged inert gas atoms. The plasma is generated using either a dc or an rf field and back filling the vacuum chamber with an inert gas (usually Ar). The positively charged ions (typically Ar^+) are accelerated toward the target by the bias (50–500 V), and secondary momentum transfer processes result in the ejection of atoms from the near-surface region of the target. The general setup for sputter deposition is shown in Fig. 3. The energy of the sputtered target atoms (50–500 eV) is much higher than the thermal energy ($kT < 0.1$ eV) possessed by an evaporated molecule. This allows the formation of crystalline deposits at lower substrate temperatures than would be needed for evaporative deposition of the same material. Further, the deposition rate is, to some degree, controllable, and is typically much higher than can be achieved by evaporation methods. In addition, sputter deposition techniques are available for the deposition of essentially any metal or insulator, compound or alloy.

The mechanism by which target atoms are sputtered into the vapor phase involves a two-step momentum-transfer process. This two-step process is required because a single incident-ion/target-atom collision cannot impart momentum to the target that is opposite to the incident ion momentum. Instead, a collisional cascade must occur where a primary knock-on atom reflects off a lower plane of atoms to collide (from below) with a second target atom in the top monolayer. The process is shown schematically in Fig. 4. The choice of Ar to form the plasma is mandated by simple conservation-of-momentum considerations since it is obvious that the greatest exchange of momentum occurs between particles of equal mass. Argon, with mass 40, is suitable for many sputter-deposited materials. Heavier inert gases such as Kr or Xe have advantages for some applications (with larger atomic mass targets) but are, in general, too rare and expensive for typical applications. If the mass of the incident ion is larger than that of the target material, then the incident ion will not be back-reflected by a single collision. If the mass of the incident ion is less than that of the target, then, in the case where there is a direct impact, the reflected ion may possess significant energy. Although ionized Ar ions are accelerated toward the target, a large fraction of them are neutralized immediately prior to impact by secondary electrons that are emitted from the surface of the target. As a consequence, the reflected particles are often uncharged and possess significant kinetic energy, which is imparted to the growing film in a process

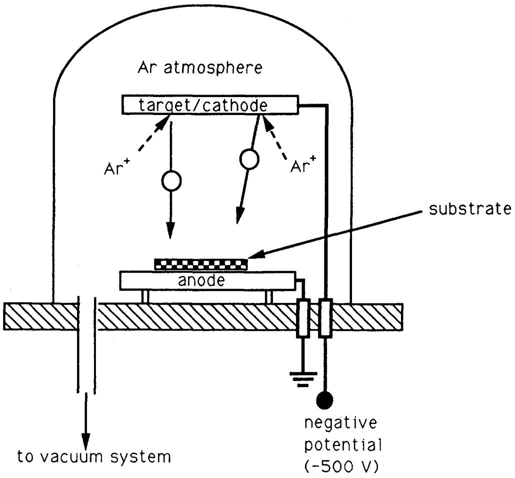

FIG. 3. Schematic view of a dc diode sputtering system.

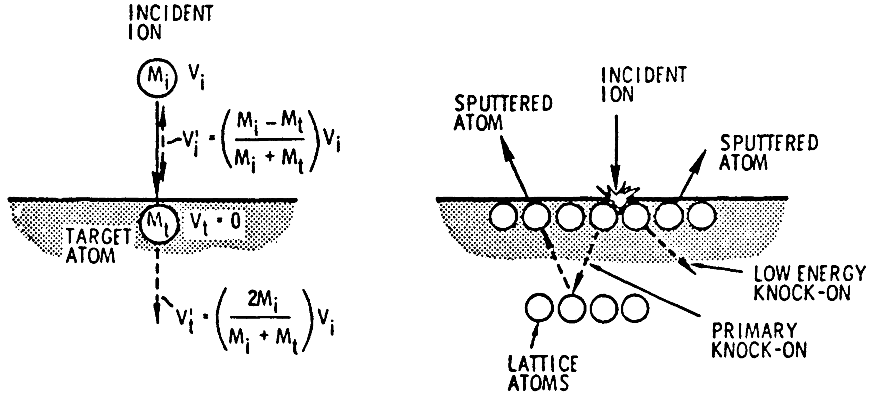

FIG. 4. Schematic view of the momentum transfer processes that take place in the target during sputtering. V_i is the ion velocity, V_t is the target atom velocity, and the prime denotes velocities after the collision (Thornton, 1982).

known as ion-peening. This has a significant effect on the microstructure and physical properties (mechanical strain, resistivity, etc.) of the film and results in the entrainment of Ar in the deposited layer.

The binding energy of a surface atom in the source material is typically in the range 5–10 eV, while the energy needed to displace a bulk atom from its lattice site is about 25 eV. The kinetic energy of an atom that has been sputtered from the source into the vapor phase depends on its molecular weight but typically ranges from 5 to 40 eV. The sum of these energy terms is significantly less than the 500 eV that the incident Ar^+ ions possess as a result of being accelerated from the plasma to the cathode/source by an applied bias. The excess energy is consumed by multiple collision/ejection events that produce a number of atoms ejected from the target per incident Ar^+ ion that is typically greater than unity. The ratio of target atoms ejected to incident ions is called the sputter yield. The sputter yield depends on the target species, target surface topography, bombarding species, energy of the bombarding species, and angle of incidence of the bombarding species. It does not depend upon the temperature of the target or the ionization of the incident particle immediately prior to collision. Experimentally determined sputter yields are given as a function of incident Ar energy for a number of species in Fig. 5.

The compositional uniformity of sputtered alloys and compounds in the through-thickness direction is assured if the target is sufficiently cooled to prevent heating and subsequent diffusion or vaporization of the constituents. It is also necessary that there are no reactive contaminants present in the deposition chamber. Variations in the composition of the target compared to the deposited film occur in multicomponent systems when vapor-phase transport is not the same for all constituents and when their sticking coefficients are different.

Although the sputter yields of the various elements are rarely the same, the film de-

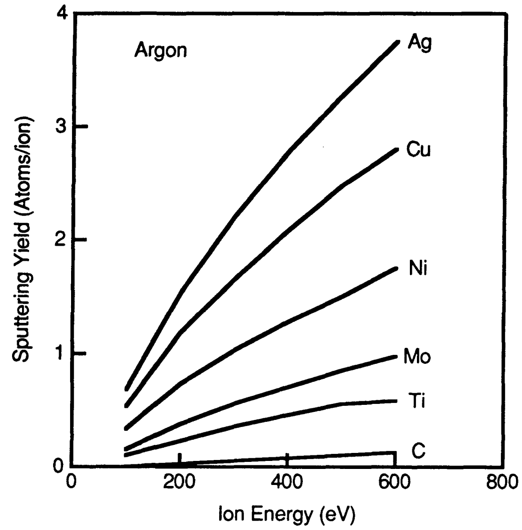

FIG. 5. Plot of sputter yield versus incident Ar^+ ion energy for various target species and normal incidence (McGuire, 1982).

posited on the substrate has, in general, the same composition as the target, provided that the constituents of the target do not diffuse or decompose and if the sticking coefficients of the various species at the substrate are the same. This is dictated by simple conservation of mass which requires that, under steady-state conditions, the composition of the flux of material leaving the target must be the same as the bulk composition of the target. The explanation can be seen by considering the following. Initially, the surface of the target has a composition that is equal to that of the bulk. After some period of time, the component in the target that has a higher sputter yield is depleted so that the composition in the near-surface region of the target (typically 3- to 10-nm thick) is enriched in the component with the lower sputter yield. The flux of a particular component leaving the surface is equal to its sputter yield multiplied by its surface concentration. Those elements that have a lower sputter yield become increasingly enriched at the surface until the product of the sputter yield and the steady-state surface concentration of a particular component is equal to its concentration in the bulk. The effective sputter yield of a constituent in an alloy or compound is not, in general, the same as that of the constituent by itself. This is due to different binding energies and to different atomic masses involved in the atomic collision sequence within the alloy or compound.

The composition of the material flux leaving the target is, at steady state, the same as the composition of the bulk target. The stoichiometry of the deposited film, however, will not necessarily be the same as the target if the film contains a volatile component. This is due to the volatilization of one of the species at the substrate surface as a result of a low sticking coefficient. Examples include O-, N-, and H-based compounds which are typically deficient in these elements when sputter deposited. The solution is found by adding a make-up gas containing the volatile species in a process known as reactive sputtering. This technique is similar to reactive evaporation and has the advantage that many complex compounds may be formed from easily manufactured targets and the introduction of a suitable gas. This technique differs from reactive evaporation in that, in addition to the reactions that occur at the substrate, reactions also occur on the target surface and in the gas phase at high reactant-gas working pressures.

In all sputter deposition processes, a target with appropriate composition must be fabricated. For metal targets, vacuum casting (see below) is typically used, while hot pressing and slip casting are used for the formation of high–melting-point metal and ceramic sputter targets. An alternative approach is to produce a mosaic target that consists of tiles of two or more elements. The ratio of the area of tiles of one kind to tiles of another provides compositional control.

1.2 Chemical Vapor Deposition

This technique is based on the use of chemical reactions to deposit solid films or coatings from gaseous precursors on heated substrates. The gas-phase reactions that result in the deposition of a solid include thermal decomposition and reduction of fluorides, chlorides, bromides, iodides, hydrides, organometallics, and hydrocarbons. These reactions are used to deposit all types of materials including metals, alloys, intermetallics, oxides, carbides, and nitrides. All CVD (chemical vapor deposition) (*q.v.*) processes take place in an enclosed CVD reactor vessel at either atmospheric or low-pressure conditions. The details of each process are extremely involved and required detailed descriptions of the thermodynamics, kinetics, and gas-flow dynamics to model fully. The CVD system includes a vessel, often made of quartz, which is used to contain the reactive gases and the substrate, a gas delivery system, and a source of heat. Some methods use a simple resistively heated tube furnace and are called hot-wall processes, while others use radiant (IR lamp heating) or induction heating and are called cold-wall systems. In the cold-wall systems, the substrate sits on a susceptor (often made of graphite) that absorbs radiant energy from the heat source.

Four examples of atmospheric-pressure CVD reactor vessel configurations are shown in Fig. 6 and include vertical tube, horizontal tube, turret, and barrel reactor types. Gases are brought into the vessel in a controlled ratio at a fixed flow rate. The reaction occurs in the hot zone of the vessel and the resultant effluent gases are passed out of the vessel. The design of a CVD system is determined in part

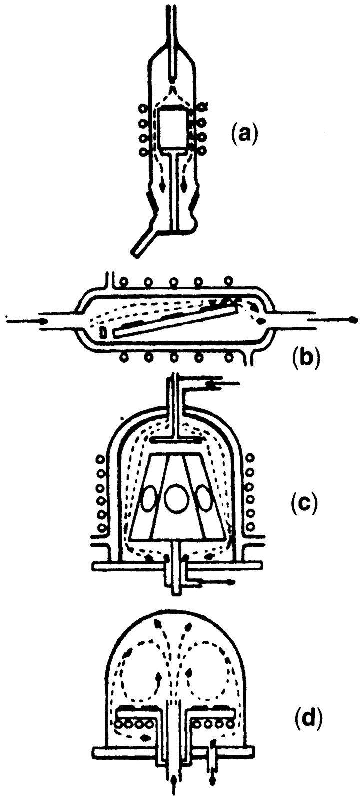

FIG. 6. Four examples of CVD reactor configurations: (a) vertical tube; (b) horizontal tube; (c) turret; and (d) barrel type.

by the physical state of the starting materials, which can be gases, volatile liquids, or volatile solids at room temperature. The use of liquids and solid sources complicate CVD reactor design, since these materials must be vaporized at the source and must remain in the vapor state as they are transported to the deposition zone.

A technologically important CVD process that is widely used (in one form or another) is the deposition of silicon from silane at either atmospheric or low pressure. The reaction can proceed *via* pyrolysis (thermal decomposition) from silane alone but is most often accompanied by a carrier gas. The reaction is written as

$$SiH_{4(g)} \leftrightarrow Si_{(solid)} + 2H_{2(g)}, \tag{4}$$

and the deposition occurs by simply passing $SiH_{4(g)}$ (diluted with a carrier gas such as H_2 or N_2) over a heated substrate.

Most useful CVD systems are of the open variety where there is a constant flow of fresh reactant gas over the substrate. There are two principal types of open reactor systems that are categorized on the basis of the total pressure in the chamber during deposition. The atmospheric system has the advantage of being relatively simple without the need for elaborate vacuum pumping systems but must be carefully designed with careful consideration given to the dynamics of the gas flow. In atmospheric deposition systems, the growth rate is typically limited by the transport of reactants to the wafer surface. Thus, the positioning of the substrate with respect to the gas flow is important. This is not the case for low-pressure CVD systems (LPCVD), since at relatively modest pressures, say 100 Pa, the gas-phase diffusivity increases by 1000-fold since the diffusivity is inversely proportional to pressure. This allows the wafers in a LPCVD deposition process to be stacked relatively close to one another without regard to the gas-flow conditions. Thus, some of the benefits associated with the increased cost of an LPCVD system are larger loads and better uniformity.

The kinetics of the CVD process can be modeled by the series of sequential steps shown schematically in Fig. 7. The steps are

1. transport of reactants to the deposition region;
2. transport of reactants by diffusion from the main gas stream through a stagnant boundary layer to the growth surface;
3. adsorption of reactants on the growing surface;
4. surface reaction: chemical decomposition, surface migration, and site incorporation;
5. desorption of by-products;
6. transport of by-products through the stagnant boundary layer and back into the main gas stream; and finally,
7. transport of by-products away from the deposition region.

The steps listed above can be further subdivided to accommodate various additional reaction kinetic models. Whichever step is the slowest will determine the overall rate of the deposition process and is known as the "rate-limiting" step. When a process is limited by steps as in **3–5** listed above, it is known as surface-reaction-rate limited while all other steps represent mass-transport limiting steps.

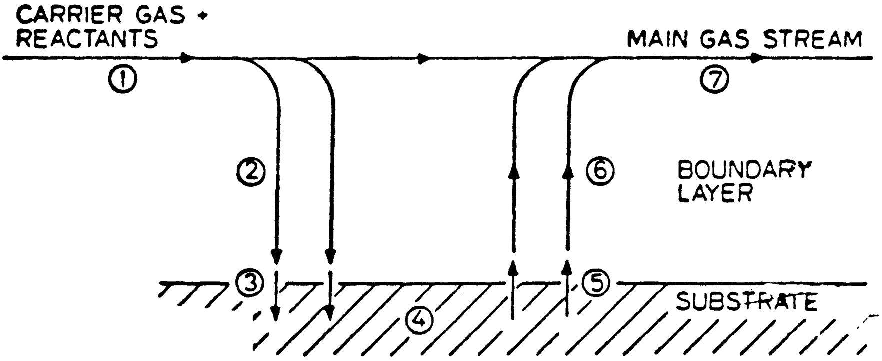

FIG. 7. Schematic view of the CVD deposition mechanism showing seven sequential steps, any one of which may be rate limiting.

To illustrate the notion of the rate-limiting step, consider the case where the input reactants to the CVD process are relatively low, the gas velocity (i.e., flow rate) is low, and the temperature (and hence the surface reaction rate) is high. Under these conditions, the initial mass transport step (step **1** above) will control the rate of the deposition process. In most cases, mass transport conditions will eventually dominate as the temperature of the reaction is increased since the activation energy for surface reaction mechanisms is larger than the activation energy for mass transport processes. Thus, at higher reaction temperatures, surface reactions proceed rapidly and mass transport becomes rate limiting. If, on the other hand, the concentration of the reactants and the gas velocity is high but the reaction temperature is low, surface kinetics usually take over as the controlling step. In general, low temperatures, and low pressures where gas-phase diffusivity is large (as in LPCVD), tend to favor surface-reaction rate control.

1.3 Ion Implantation

Ion implantation is extensively used for the introduction of impurities into the near-surface region of a single-crystal electronic material such as Si. It is also now being used in the modification of surface properties of structural and magnetic materials (see ION-BEAM MODIFICATION OF MATERIALS). Ion implantation involves the introduction of atoms into a substrate with sufficient energy to penetrate beyond the surface. To introduce specific elemental impurities into the near-surface region of a substrate, the species of interest are accelerated through a high accelerating potential, pass through a mass spectrometer that selects only those ions with a characteristic energy, and are directed into the substrate. Atoms from the lattice of the target substrate are displaced from their lattice positions through momentum transfer processes between the energetic incident impurity ions and the atoms of the substrate. Under conditions that depend on the substrate and ion species, implant dose, energy, and substrate temperature, an amorphous region can be created by this process. For example, the surface of a Si wafer can be amorphized by implanting 50- to 200-keV $^{28}Si^+$ at a dose greater than $10^{15}/cm^2$ at room temperature or below. At 200 keV, this process amorphizes the Si surface to a depth of about 380 nm, where the peak of the implant dose (R_p) is located at a depth of 266 nm, and the projected deviation (ΔR_p) is about 78 nm. Immediately below the amorphous-crystalline interface, a narrow region of crystalline material exists that has suffered lattice damage due to ions that, although they are near the end of their range, still possess sufficient energy to cause lattice displacements. This damage and the amorphous region can be fully recrystallized by a relatively low-temperature annealing procedure. If the implantation is performed at elevated temperature, or if the ion dose is relatively low, then the displaced substrate atoms can refind their lattice positions during the implantation process.

2. LIQUID-STATE PROCESSING

Preparation of solid materials from the liquid phase is widely applied to metal and semiconductor materials and includes such technologically important processes as ingot casting, continuous casting, foundry processes, single-crystal growth, and fusion welding. This approach to the shaping of metals into useful objects has been in use since 4000 B.C. and continues to this day to be the most versatile and flexible process available for forming complex shapes out of metal. In fact, nearly all metals are cast at some point in their processing sequence. An example is the process of steel making (see STEEL). To make steel (i.e., Fe-C alloys), iron ore [hematite (Fe_2O_3), limonite ($Fe_2O_3 \cdot xH_2O$), or magnetite (Fe_3O_4)] is chemically reduced to form impure iron metal. The reduction is performed in a blast furnace that produces an iron metal (known as pig iron) that contains about 7 wt % impurities such as C, S, Mn, S, and P. The formation of steel from pig iron involves the refining of the metal to remove undesirable impurities such as S and P, and the purposeful introduction of alloying elements to improve the physical properties of the metal. Finally, the steel is continuously cast into billets or ingots, which are used for further (solid-state) forming processes.

The solidification process requires that the liquid be cooled to below its equilibrium melting temperature T_m enough to overcome kinetic barriers to the formation of solid. The magnitude of the driving force necessary to create a small volume of solid (called a nucleus) in a liquid is given by nucleation theory, which balances the decrease in the Gibbs free energy (G_v) of the system due to the formation of solid against the energy increase due to the formation of a solid–liquid interface (γ_{SL}). The interfacial energy contribution represents a barrier to the formation of the solid phase from the liquid, which must be overcome by providing additional driving force through supercooling (cooling the liquid below its natural melting point). The degree of supercooling required to nucleate a solid in the liquid depends mostly upon the availability, and effectiveness, of heterogeneous nucleation sites. These sites reduce the surface energy cost when the solid forms from the liquid and can be purposely introduced in a process known as seeding.

For homogeneous nucleation (in the absence of heterogeneous sites) of spherical particles with isotropic solid–liquid surface energy, the degree of undercooling (and hence the amount of driving force) is readily calculated by minimizing the free energy of a particle of radius r, which is found by summing the volume free-energy decrease (volume × ΔG_v) and the surface free-energy increase (surface area × γ_{SL}):

$$\Delta G_r = \tfrac{4}{3}\pi r^3 \Delta G_v + 4\pi r^2 \gamma_{SL}, \tag{5}$$

where ΔG_r is the total free energy of a particle of radius r formed from a liquid that is undercooled. The effect of undercooling on the volume free energy can be seen from

$$\Delta G_v = (G_L - G_S) = \Delta H_f \Delta T / T_m, \tag{6}$$

where ΔH_f is the latent heat of fusion, $\Delta T = T_m - T$ is the undercooling, and T_m is the melting temperature. Note that the interfacial term (which is positive) increases as r^2, while the volume term (which below T_m is negative) increases as r^3. This implies that there is a critical particle radius r^* above which a particle is stable (i.e., will tend to increase in size) and below which it is not (i.e., would remelt into the liquid if such a sized particle were to form in the melt at a given undercooling). This critical radius is easily found by differentiating the above expression and setting the result equal to zero:

$$r^* = 2\gamma_{SL}/\Delta G_v, \tag{7}$$

which is given in terms of undercooling by

$$r^* = 2\gamma_{SL} T_m / \Delta H_f \Delta T \tag{8}$$

where γ_{SL} is the solid/liquid free energy.

Expression (7) reveals that the critical nucleus radius decreases with increasing undercooling. The larger the critical radius, the lower the probability that a cluster of this size will form as a result of random thermal motion of the atoms of the liquid. The liquid is thought of as containing particles that are constantly changing their positions and in which transient clusters form and disappear that briefly have the crystalline arrangement. The maximum-sized cluster that is likely to form in a given volume of liquid increases with decreasing temperature since the solid arrangement of atoms is more favored as the temperature is lowered. As the undercooling increases, the critical particle size decreases and the maximum-sized cluster that is likely to form in a liquid of a fixed volume in reasonable time increases. The formation of clusters of atoms with dimension r in the liquid occurs with a probability that is exponentially dependent on the energy of the particle (ΔG_r) so that the number of clusters of size n_r in a volume containing n_0 atoms is given by

$$n_r = n_0 \exp(-\Delta G_r/kT). \tag{9}$$

As the undercooling increases (i.e., T decreases), the maximum-sized cluster that has a reasonable likelihood of forming in the volume of liquid increases while, at the same time, the critical radius r^* decreases with increasing undercooling. This is shown in Fig. 8, which shows the critical particle size r^* and the maximum cluster size $r_{\max}$ that has reasonable probability of being found in a given volume of liquid as a function of undercooling. At ΔT_N, the critical radius equals the size of the largest probable cluster found in the volume and rapid nucleation takes place.

The undercooling predicted by the homogeneous nucleation theory for typical metals can be hundreds of degrees Celsius, but this behavior is only seen under carefully controlled experimental conditions. In reality, the solid does not typically nucleate homogeneously in the melt but at energetically more favorable heterogeneous nucleation sites.

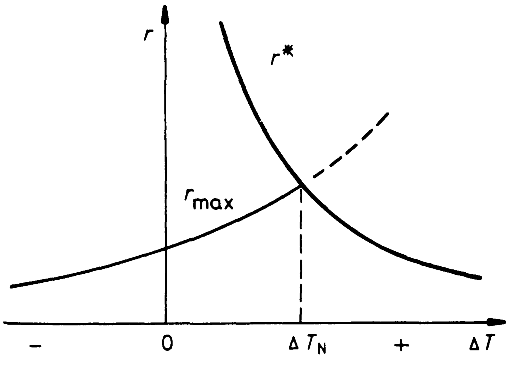

FIG. 8. Schematic plot showing the effect of undercooling (ΔT) on critical radius size (r^*) and the maximum cluster size likely to be found in a fixed volume of liquid (Porter and Easterling, 1987).

After nucleation has occurred, the rate at which the solidification proceeds and solid–liquid interface planarity are controlled by the diffusion of heat or impurities away from the solid–liquid interface. The heat that is present at the solid–liquid interface is a result of the latent heat that is released during solidification and the heat that is thermally conducted toward the solid–liquid interface from the melt. In most systems undergoing solidification, there are impurities and alloying elements that must be rearranged so that the difference in composition between solid and liquid in thermodynamic equilibrium can be accommodated. This compositional difference is given for a two-component system by the schematic binary phase diagram shown in Fig. 9. Consider an imaginary binary system of A and B species. Above the melting point of A, T_m^A, the two species are completely miscible and exist as a single liquid condensed phase. If a liquid of composition X_0 is cooled, the first solid will appear at $T = T_1$. The compositions of the liquid and solid phases that coexist at this temperature are different: the liquid has composition X_0 while that of the solid that is in thermodynamic equilibrium with this liquid is kX_0. As the temperature of the system is lowered further, say to $T = T_2$, both the compositions of the liquid and the solid change as defined in Fig. 9 by the solidus line for the solid and the liquidus line for the liquid. Thus, these lines give the equilibrium compositions of the coexisting liquid and solid phases as a function of temperature. The compositional difference between solid and liquid that coexist at equilibrium results in both macroscopic and microscopic chemical inhomogeneities because solid-state diffusion rates are too slow to establish equilibrium in the bulk of the crystal.

The final microstructure of a solid formed by solidification depends on heat flow, impurity diffusion, convective mixing in the remaining liquid, and the imposed cooling rate. Detailed description of these processes is beyond the scope of this article; however, there are three situations that will be considered briefly below. First, typical casting processes have a relatively slow cooling rate ($<10^2$ °C/s) and shallow temperature gradients, which result in both microscopic and macroscopic compositional gradients. Relatively local

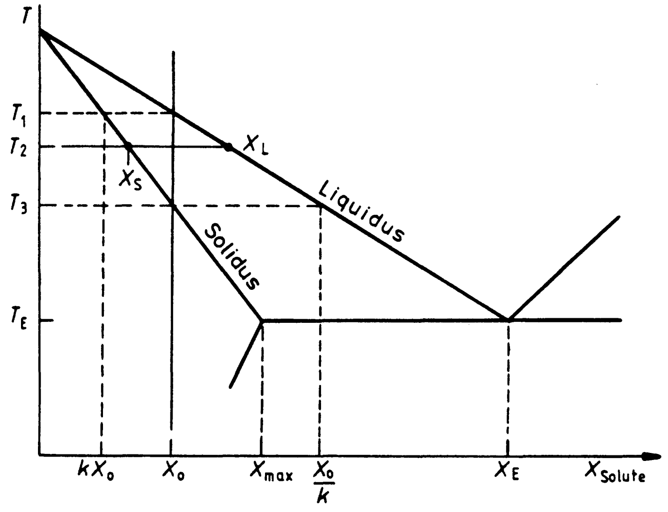

FIG. 9. Binary phase equilibrium diagram (temperature versus composition) showing the equilibrium concentration of solute when solid (X_s) and liquid (X_l) coexist at a fixed temperature (Porter and Easterling, 1987).

compositional gradients (over 10 to 100 μm) appear in the final microstructure of a cast object as *dendrites*. Dendrites are rodlike and armlike features that project into the solidifying liquid as shown in Fig. 10. The cooling rate and rate of diffusion and convectional mixing in the liquid determine the dimensions of these features, which can range from <1 to 100s of microns in size. Unfortunately, solid-state diffusion alone is usually an impractical method for homogenizing the compositional variations in cast alloys.

A second scenario is discussed below in which crystallographically textured and single-crystal materials are grown. This microstructure results when temperature gradients at the solid–liquid interface are steep and a single-crystal seed is employed. In this case, the liquid is not cooled below T_m except at the solid–liquid interface where the amount of undercooling is extremely small. Finally, extremely rapid cooling (10^3 to 10^6 °C/s) dramatically decreases compositional segregation and is used for the synthesis of powders with uniform composition. Even faster cooling (10^6 to 10^{10} °C/s) of some alloys results in the formation of amorphous metals. Metallic alloys that can be cooled so that they are solid but retain the liquid amorphous state usually have a temperature-composition phase diagram that is characterized by an alloy solidification temperature that is much lower than either of the pure components (known as a deep eutectic phase diagram).

2.1 Casting Methods

The basis for all casting processes is the feeding of molten metal into a cavity of the required shape (a mold) followed by cooling to produce a solid object. In most casting methods, the mold walls have a large number of heterogeneous nucleation sites and solidification proceeds close to (but below) the melting point by heat transfer through the mold walls to the exterior. The resulting microstructure is often described as columnar and may contain large compositional variations. These compositional variations may be neglected, or they may be eliminated by further processing. For example, the solid-state process of forging can be applied to cast ingots to breakup these compositional inhomogeneities.

The various casting processes (and there are many) differ principally in the way in which the mold is formed. In some cases, a nonreusable mold is created for each casting and is subsequently broken up to remove the cast object. The two most common forms of casting processes are called *sand casting* and *investment casting* (*lost wax*) and are described below. In other cases, a permanent mold is used repeatedly for a succession of casts and the casting is removed after each pouring without damage to the mold. A common example is called *die casting*. In all cases, some provision for feeding metal into all parts of the mold is required. All alloy castings processes produce materials with microscopic and macroscopic compositional variations that can affect the mechanical strength and performance of the cast object.

2.1.1 Sand Casting To form an object using the sand-casting approach a *pattern* of the object to be cast is manufactured using an easy-to-work-with medium such as a soft wood or plastic. The pattern is shaped into an exact model of the desired object. A mold is then made by packing sand around the pattern. The mold is typically made in two parts, an upper section, which is known as the *cope*, and a lower part, which is known as the *drag*. The two parts together contain the full mold, and the container holding the sand is called the *flask*. Where the cope and drag meet is called the *part line*. If the final form is to have a hollow section, separate mold parts known as *cores* are made and placed inside the cavity left by the pattern. A pathway is created to feed the liquid to all parts of the mold cavity. This pathway is called the *gating* system and consists of *sprues*, *runners*, and *risers* which, respectively, feed the molten metal, distribute the metal laterally, and provide liquid to replace the volume lost because of the decrease in molar volume of the solid compared to the liquid. A schematic view of the mold along with representations of the various parts of the system is shown in Fig. 11. After the liquid is completely solidified, the rough casting is removed from the mold, any cores that were included are knocked out, and the risers, sprues, and runners are cut off.

During the solidification process, the direction of motion of the solid–liquid growth front is controlled by carefully designing the mold so that the direction of heat flow leaves

no region of liquid that is isolated from the riser. Metal inserts called *chills* are sometimes included in the mold to promote heat extraction and solidification in some parts of the mold, while insulating materials are used to delay the onset of freezing in regions of the mold that would leave other sections isolated from the risers. The careful design of the mold with respect to heat flow is essential for the making of pore-free castings. Corners, for example, are hot spots, which commonly cause casting defects that result from slower heat transfer at internal corners compared to straight runs.

The advantages of sand casting are that it is cheap, it is simple, it is very flexible from a design viewpoint, and it can be used to manufacture objects over a wide range of size scales from about 10 g to 1 ton. Its disadvantages include poor surface finish and low dimensional tolerances, making thin sections and intricate shapes impossible to produce.

2.1.2 Investment (Lost-Wax) Casting Investment (also known as lost-wax) casting is a technique that has been used for centuries for the fabrication of decorative objects. Today it is used when the as-cast form must have fine dimensional tolerances. An example of an industrial application of this method is in the fabrication of some types of aircraft turbine blades. The process for creating a lost-wax mold and casting an object is described briefly in what follows.

An expendable pattern is manufactured using wax. If the pattern is to be used repeatedly, it is often economical to fabricate a mold that can be repeatedly used for casting the wax pattern in a process similar to die casting (described in Sec. 2.1.3). The wax pattern in its final shape is coated with a refractory ceramic slurry in a process known as investing. The ceramic mold is fabricated by repeatedly dipping the pattern into a ceramic slurry (often plaster), allowing it to set between dips. A fine-particle slurry is used for the first dipping in order to give a smooth surface to the cast object. A coarser slurry is used in later dippings in order to strengthen the mold. Finally, the ceramic shell is dried and fired in a furnace to melt and/or volatilize the wax pattern so that a cavity is left in the ceramic mold. The molten metal is poured into the mold and, after solidification, the ceramic shell is broken up to recover the casting. Steps in the production of a ceramic shell investment casting are shown in Fig. 12. As the description implies, this process requires a large investment in the preparation of the mold and pattern, which limits the use of this process to large–value-added objects like jewelry or aircraft parts.

The expense of the mold-making process can be reduced on a cost-per-cast-unit basis by creating many different objects (or many copies of the same object) in wax and then attaching these smaller features *via* runners to a central sprue. In this way, a single investment will yield many castings. Preformed cores can be used if hollows are needed as part of the cast structure. For example, cooling channels are created in turbine blades by incorporating into the wax pattern silica rods, which are chemically dissolved using HF acid after the blade is cast.

2.1.3 Permanent-Mold Castings Processes that make use of metal molds and simple hydrostatic pressure to introduce the liquid metal are called permanent-mold castings. The mold must be designed in two or more parts that free the casting when separated. Processes that use metal molds are limited to low–melting-point alloys such as those that are based on Zn, Al, Mg, and Cu (leaded yellow brass). The molds are economical since they can be used for up to 100 000 castings. Consequently, these permanent-mold processes are commonly used for the fabrication of metal parts for almost every commercial application such as automobile parts (e.g., carburetor) and camera bodies.

When molten metal is forced under pressure into a steel mold (known in this process as a die) the process is known as die casting. As shown in Fig. 13, the molten metal enters the die under pressure when a plug or valve is released. The rapid introduction of the metal into the mold combined with preheating of the die assembly helps prevent nonuniform heat flow and the consequent generation of casting defects. Injection of the liquid also allows much thinner-walled castings to be formed. For example, cast Al can be produced with a 0.8-mm minimum wall thickness by die casting. Once solidified, the die is separated at the part line and the object is forced out of the mold with pusher rods as is shown in Fig. 13.

2.2 Oriented or Single-Crystal Growth

The principal driving force for the development of single-crystal growth techniques (see CRYSTAL GROWTH) continues to be the demand for solid-state electronic and optoelectronic materials. The largest commercial demand is for single-crystal Si for use in integrated-circuit devices. Compound semiconductors (most notably GaAs) make up about 2% of current semiconductor single-crystal growth and are used for high-speed, laser, and detector device applications. In the case of electronic device substrates, wafers are typically cut from cylindrical boules grown by the Czochralski method. Single-crystal (or strongly oriented) growth is also used when high-temperature creep (time-dependent permanent deformation of a loaded structure) resistance is desired. An example of this is high-performance turbine blades, which operate at temperatures greater than half the melting point of the material on the Kelvin scale. Since grain boundaries provide rapid diffusional paths, their elimination drastically decreases the creep rate of materials. This effect does not require perfect

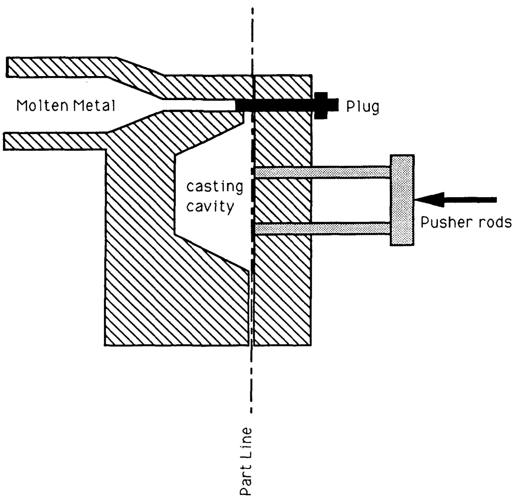

FIG. 13. Cross-sectional view of a die casting. When the plug is removed, the molten metal is forced under pressure into the steel mold. After solidification, the die is parted at the part line and pusher rods remove the casting.

single crystals and, in many applications, highly textured or directional growth is adequate for the reduction of creep.

2.2.1 General Single-Crystal Growth Considerations Most single-crystal growth processes begin with an oriented seed crystal (i.e., a crystal that contains only one crystallographic orientation) that is appropriately oriented and provides the template for the arrangement of atoms during controlled crystallization of the melt. The temperature of the molten material is carefully controlled so that undercooling, and spontaneous nucleation of randomly oriented crystals, is avoided. All methods are based on the simple principle that the extraction of the latent heat of solidification must be achieved without allowing the melt to supercool enough for random nucleation of solid to occur in the melt away from the seed crystal. This is usually done by extracting heat by conduction through the solidified single crystal. In practice, a heat sink is provided at the seed end of the crystal, and a heat source is provided at the melt so that the heat flow away from the interface through the solid is exactly balanced by the heat flow from the liquid plus the latent heat of solidification that is generated at the interface.

Ultrahigh-purity feed material is required for crystals grown for electronic applications. In the case of Si, the refining process proceeds as follows. First quartz (SiO_2) is placed along with carbon in the form of coal or wood in a submerged electrode arc furnace. Several reactions take place under these conditions, including

$$SiC_{solid} + SiO_{2(solid)} = Si_{(solid)} + SiO_{(gas)} + CO_{(gas)}. \tag{10}$$

This process produces metallurgical-grade Si, which is used as the feedstock for further chemical-refining processes. The first step is the reaction of Si powder with HCl gas to form trichlorosilane ($SiHCl_3$) *via* the following:

$$Si_{solid} + 3HCl_{gas} = SiHCl_{3gas} + H_{2gas}. \tag{11}$$

At room temperature, the $SiHCl_3$ is a liquid and can be purified by the fractional distillation method. The distilled $SiHCl_3$ is then reacted with H_2 *via*

$$2SiHCl_{3gas} + 3H_{2gas} = 2Si_{solid} + 6HCl_{gas}, \tag{12}$$

and the solid thus produced becomes the feedstock for the growth of single-crystal Si.

2.2.2 Structural Components: Bridgman Technique Single-crystal growth for the preparation of structural components (or highly textured, directionally solidified crystals) require that the as-grown object be close to the final shape. The most common example of the application of the techniques used to form highly textured or single crystals of arbitrary shape is in the fabrication of high-performance turbine blades. These objects are grown from high-performance, Ni-based alloys using the Bridgman technique in which a boat (or crucible) is created with the appropriate shape and is filled with molten metal. The boat is slowly translated out of the hot zone of the furnace so that solidification begins at a seed crystal. If a particular orientation is not required, it is possible to form a single crystal by using a boat with a pinched end. If the pinched end is slowly passed through the temperature gradient, a single crystal may nucleate in the heterogeneous site provided. This single crystal then acts as a seed crystal for the rest of the solidification process. A schematic view of the Bridgman technique is provided in Fig. 14.

2.2.3 Float-Zone (Zone-Refining) Method

In this technique, a rod-shaped sample is passed through a localized heat source (e.g., a rf coil or a focussed electron beam), which melts a section of the rod. The setup is shown schematically in Fig. 15. The molten zone is held in place between the solid region above and below by the surface tension of the liquid. The rod is slowly lowered through the heat source so that melting occurs on one side of the molten zone while solidification occurs on the trailing side. This method can be used to produce large grained, textured, or single-crystal metals but is primarily used for the creation of extremely pure materials by zone refining.

The principle of zone refining can be seen by again referring to the temperature–composition phase diagram presented in Fig. 9. The thermodynamic equilibrium composition of the binary liquid in equilibrium with the solid at a particular temperature is given by the tie line that connects the liquidus and solidus curves as shown in the figure. Note that the composition of the liquid is richer than that of the solid which means that under equilibrium conditions, the solid that freezes from a liquid with composition x_l will contain a lower concentration x_s than the starting liquid. For this reason, the solidifying solid rejects impurities into the molten zone, which tend to remain in the liquid as the molten zone moves up the length of the rod. Only the very last solid to form contains a higher concentration of impurities than that of the initial rod. This end of the rod may be cut off and the process repeated numerous times to decrease further the impurity concentration in the rod.

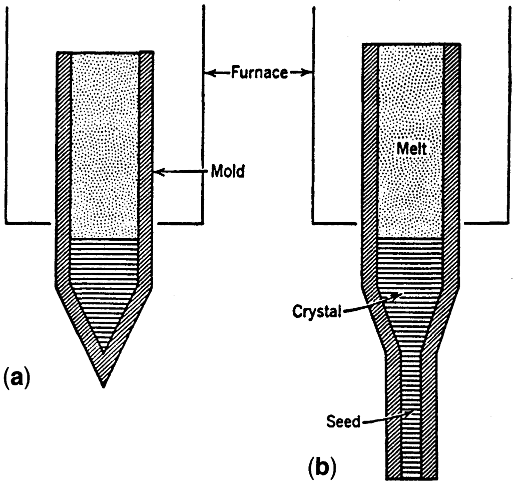

FIG. 14. Schematic view of the Bridgman technique for oriented crystal growth. (a) The pinched end and (b) the seed methods (Flemings, 1974).

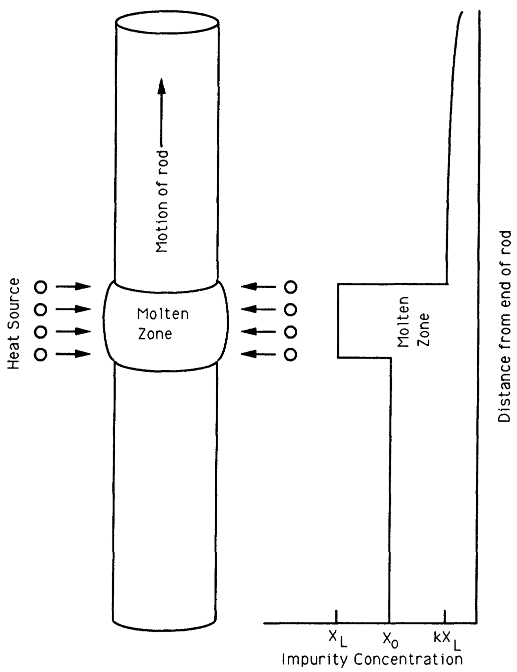

FIG. 15. A schematic view of float-zone crystal growth and refinement. In this operation, the rod is slowly lowered through a localized heat source that melts a region of the rod. The molten zone is supported by the surface tension of the liquid.

2.2.4 Semiconductor and Optical Materials

The vast majority of single-crystal material grown for the semiconductor industry is grown by the Czochralski crystal-pulling method. The setup is shown schematically in Fig. 16. A seed crystal of suitable crystallographic orientation is attached to a *puller* and is dipped into a melt that is contained in a *crucible*. The seed is rotated (to ensure uniform interfacial temperature and composition) and slowly withdrawn from the liquid so that the rate of crystal motion equals the rate of crystal growth. The rate of crystal growth, in turn, is determined by the rate at which the latent heat of solidification is removed through the crystal, seed, and puller.

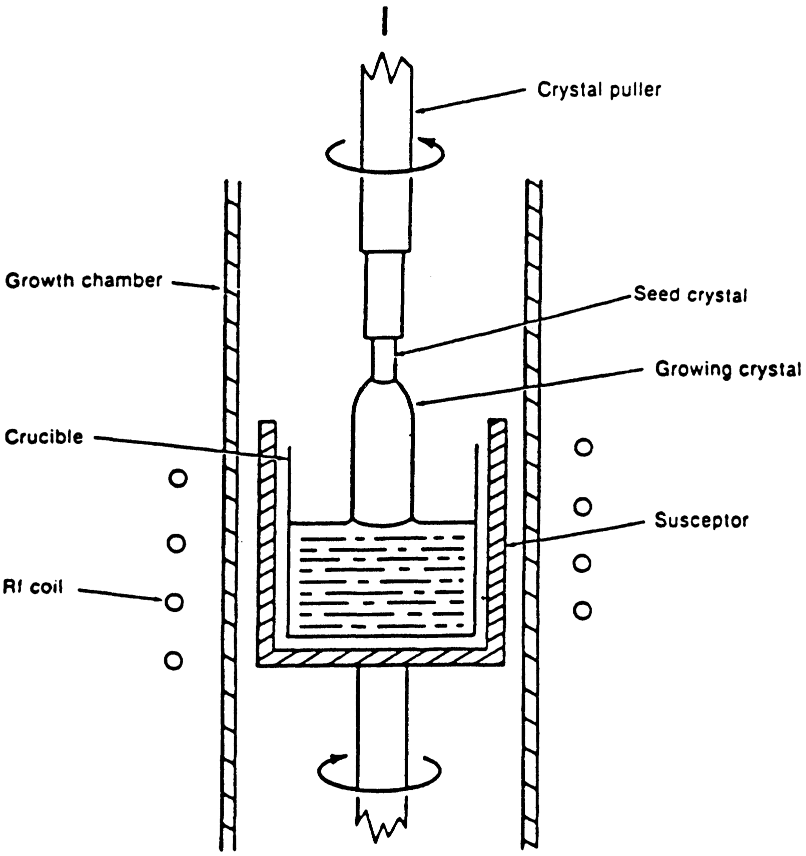

FIG. 16. The Czochralski method for the growth of single crystals from the melt.

The solid single crystal that is drawn from the melt is called a *boule.*

The latent heat of solidification must be carried away from the solid–liquid interface *via* the grown crystal. The temperature gradient down the length of the crystal is more or less fixed. Since heat flux is given by $q = -kdT/dx$ and since the temperature gradient (dT/dx) and the thermal conductivity (k) are fixed, so too is the heat flux (Q). This means that the latent heat evolved by the solidification process must equal Q at steady state. If it is greater, the amount of solidifying material decreases; if it is less, the amount increases so that steady state is reached. Consequently, the crystal growth rate for a boule of fixed diameter is limited by the rate at which latent heat is carried away from the solid–liquid interface.

The composition of the as-grown semiconductor crystal must be carefully controlled. For example, the composition of the crystal can be affected by contamination and, in compound crystal growth, by the preferential loss of a more volatile component. Furthermore, wafers that are cut from different parts of the boule must have similar dopant concentrations to allow reproducible characteristics in electronic devices made from them. Contamination other than that from the initial feed material comes from the atmosphere and/or the crucible. While it is easy to use a vacuum or inert gas to control the atmosphere above the melt, it is necessary (except in float-zone growth) to contain the melt in a crucible, which can contaminate the melt. Preferential evaporation of one or more species from the melt can be suppressed by applying an over-pressure or by providing an encapsulant. In the case of GaAs crystal growth by the Czochralski method, As tends to evaporate from the melt leaving it rich in Ga and deficient in As. This is eliminated by providing an atmosphere of As gas above the melt at a pressure that is selected so that the vapor and melt are in thermodynamic equilibrium. Compositional nonuniformities also can result from the rejection of solute at the solid–liquid interface. As the crystal is drawn from the melt, the composition of the melt changes as a result of the buildup of rejected solute. When dopants (*n* or *p* type) are added to the melt, their concentration is a function of position in the boule, with the highest dopant concentration in the material that was the last to be pulled from the melt.

A crystal grown carefully from the melt by the Czochralski method should be free of crystallographic defects other than point defects, and the number of line defects (e.g., dislocations, which are linear discontinuities in the periodic crystal lattice) should be minimal. There are two possible mechanisms for the introduction of dislocations that must be carefully monitored during single-crystal growth. First, they can propagate from the seed crystal, and second, they can be introduced as a result of large temperature gradients in the boule during growth or thermal shock to the boule after growth. It is possible to eliminate dislocations that propagate from the seed by causing the diameter of the crystal to decrease as it is drawn from the melt so that dislocations can run easily to the nearby outer surfaces where they terminate. This process of necking down the crystal diameter by increasing the pull rate is done shortly after the crystal growth begins. Since energy considerations demand that dislocations minimize their length in a crystal, there is a tendency for the dislocations that propagate from the seed to be drawn to the surface. Thus, if the crystal is made narrow enough, the dislocations that start in the seed will be grown out of the crystal.

2.3 Rapid Solidification

When the rate at which a liquid is cooled is slow relative to the rate of diffusional and convective mixing in the liquid, then the solid–liquid interface is relatively close to thermodynamic equilibrium, and the solid product is a near-equilibrium phase. As a consequence, as a multicomponent liquid is cooled through the liquidus line, there is a separation of the components in the system since the equilibrium concentration of impurity in the solid is not typically the same as that in the liquid (as shown previously in Fig. 9). Consequently, when solidification occurs on a time scale that allows equilibrium to be maintained at the solid–liquid interface, say at a rate of 1 K/s, macroscopic segregation of impurities is observed in the final microstructure. If the rate of cooling is increased so that the melt is brought into a highly supercooled state (i.e., $T < T_m$), then the microstructure of the solid is dominated by nucleation of individually oriented solid particles rather than by their growth into the liquid.

In one application of rapid solidification, small-particle-diameter powders are produced from a metal alloy melt with a high degree of chemical homogeneity. For compositional uniformity, it is necessary that the particles formed by the rapid cooling process be small relative to typical segregation distances. For example, the synthesis of 10- to 100-μm diameter powders of a particular alloy ensures that if these particles are fused together through the process of sintering (see Sec. 3.1.2), the scale of the compositional segregation remains the same as the scale of the particles.

Cooling rates of 10^3 to 10^5 K/s can be achieved by gas atomization processes in which an inert gas of N_2 or He is blown into a stream of molten metal. If ultrasonic methods are used, particle diameters as small as 20–30 μm may be achieved. More rapid cooling may be obtained by directing of a stream of molten metal onto a spinning, water-cooled, copper wheel to form 100-μm-thick amorphous metal tapes with a cooling rate of 10^5 to 10^9 °C/s. These amorphous metals find application in transformer cores and magnetic recording devices.

2.4 Electrochemical Processes

Surfaces can be coated by the process of electroplating, which is similar in concept to electrowinning of metals during the refining process. Copper is electroplated on large cathode substrates for the synthesis of high-purity Cu, which is then drawn into wire for electrical applications. Coatings of Cr, Ni, Cu, Zn, Cd, Sn, and Mo are deposited to thicknesses up to 0.25 mm for corrosion prevention, wear protection, and decorative purposes. The process is performed in an electrolyte that contains the metal ions of interest. Sulfates and nitrates are commonly dissolved in appropriate acidic baths to form the electrolyte. A potential is applied between the part to be plated (the cathode, negative potential) with respect to an anode placed in the electrolyte. The concentration of plating ions, the bath temperature, and the applied voltage must be carefully controlled in order to optimize the microstructure (planarity, porosity, adhesion to the substrate) of the deposit. Deposit uniformity is dependent on maintaining a uniform current density over the entire cathodic region to be plated. The basis for the deposition can be described using Faraday's law, which says that the amount of electrochemical reaction occurring at an electrode totals 1 g equivalent for each 96 484 A·s of electricity that passes through the electrode, where 1 g equivalent equals the atomic weight in grams of the deposited species divided by the charge on the ion. One consequence of Faraday's law is that overvoltage (i.e., a voltage larger than that needed to cause the reaction to proceed) at the electrodes must be avoided, since the application of a potential that is greater than is necessary results in increased creation of H_2 at the cathode. This has two negative effects: First, it causes the incorporation of H into the deposited metal, which in some metals results in embrittlement. Second, the creation of H_2 means that the amount of material that is being deposited is decreased since Faraday's law applies to the total electrochemical reaction (both the plating reaction and the hydrogen reaction).

3. SOLID-STATE PROCESSING

Solid-state processing generally can be subdivided into processes in which the solid undergoes plastic deformation (i.e., metal forming), materials removal (i.e., machining), or solid-state consolidation and densification (i.e., powder processing). In this section, the processes of material removal are not discussed since these methods do not generally affect the bulk microstructure of the final product. Plastic deformation, on the other hand, usually is applied to metals and results in profound changes in the microstructure and mechanical properties of the deformed material. Solids that cannot be plastically deformed at reasonable temperatures are typically prepared from powders of the appropriate composition in powder consolidation and sintering processes. These processes take advantage of high temperatures to cause mass transfer of material *via* diffusion that allows the fusing of particles and filling in of interparticle voids. In this section, powder processing and mechanical forming of materials are discussed in a materials preparation context.

3.1 Powder Processing

Powder processing is an important technology for the manufacture of useful objects from ceramic materials that, in general, do not exhibit ductility and, hence, cannot be deformed by conventional metal stamping, forging, or rolling processes. Powder-processing methods are also widely applied to high–melting-point metals (W, 3400 °C; Ta, 2996 °C; Mo, 2620 °C) and highly reactive metals (e.g., Ti and Zr) and in the preparation of alloys without the macroscopic segregation that results when casting methods are used. Other applications of powder-processing methods include the formation of porous structures for the fabrication of filters, and porous surface coatings for forming a permanent bond between natural bone and prosthetic devices (e.g., hip replacements) *via* in-growth of bone into the pores of the coating. In powder processing, a nearly fully dense object is produced from loose ceramic or metal powder by compaction of the material in a die followed by sintering (heating) the compact at high temperatures. The compaction step establishes the basic shape of the object while the sintering step densifies the material through diffusional transport of material into voids.

Traditionally, powders of naturally occurring ceramic materials in the form of clay (hydrated aluminosilicates) have been used directly for the preparation of ceramic materials. These naturally occurring minerals are layered structures with strong primary bonding within the layers but weak van der Waals bonding between layers. As a result, the addition of water to these materials makes them pliable and easily formed. Nonlayered ceramic materials are not as readily formed and require powder-processing methods and careful precompaction powder preparation. Most simple oxide powders, such as Al_2O_3, ZrO_2, ThO_2, BeO, MgO, and $MgAl_2O_4$, are formed as a product during the refinement of the metal from metal-bearing ores. For example, Al_2O_3 is formed from bauxite (a mixture of aluminum hydroxide and iron hydroxide) in the Bayer Al refinement process. More complex ceramic materials such as $PbFe_{12}O_{19}$, $ZnFe_2O_4$, and $Y_6Fe_{10}O_{24}$, and ferroelectric ceramics such as $BaTiO_3$ are formed by reaction between simpler oxides at high temperature. Nitrides such as Si_3N_4, carbides such as SiC, and borides such as TiB_2 have become interesting for high-temperature structural applications. An example of the production of one of these powders is the *Acheson* process for the synthesis of SiC powder. In this process, silica and carbon are piled around a central graphite electrode. Current is passed through the electrode to produce temperatures in excess of 2000 °C, which allows the solid state reaction $SiO_2 + 3C = SiC + 2CO$ to proceed. The central mass of SiC powder is then cleaned with HF acid to remove remaining silica and is placed in a rolling mill to be processed into powder.

Metal and alloy powders with a mean particle size of 25–100 μm are formed by atomization of the liquid metal in a stream of inert gas (as described briefly in Sec. 2.3). Some metals, and all ceramic materials, can easily be pulverized by grinding in ball mills to produce powders that have the peak of the particle size in the range 1–25 μm. Finer powders may be formed using more sophisticated powder synthesis, milling, and particle separation and sizing methods.

3.1.1 Powder Compaction The first step in every powder process is compaction of the powder to form a "green body." Compaction methods include simple die compaction where pressure is uniaxially applied using a press, isostatic compaction in which the powder is placed in a flexible mold and then hydrostatically compressed using a fluid (liquid or inert gas), or slip casting in which compaction is achieved through capillary action of a liquid. By applying pressure to a powder, the particles are forced to rearrange themselves in a way that tends to lock or key the particles together mechanically. This provides strength to the green (unheated) compact sufficient to preserve the shape imparted by the die. If the powder is a ductile metal, the particles will plastically deform during compaction and bonding will occur between particles. The final density of a cold-pressed powder and the postsintering tensile strength of the structure are dependent upon the amount of pressure applied during compaction and on the powder used.

In many powder compaction processes, organic or inorganic binders (e.g., kaolinite in the form of common clay) are added to the powder to provide additional strength to the green body. A plasticizer is also added to the powder to improve the pliability of the binder. Other additives include lubricants, which reduce the friction between particles and between the compact and the walls of the die.

Slip casting allows compaction of powders without the direct application of pressure through capillary interaction between the porous walls of the mold and a liquid slurry. In this process, the particles of the powder are suspended in a suitable liquid to form a slurry called a slip. The slip is then cast into a mold made of plaster, which contains pores that draw the liquid out of the slurry by capillary action. There are many forms of slip casting, including simple casting into a single- or multiple-piece mold and drain casting. Drain casting is a commercially important process that is used for fabricating common porcelain sinks and many other products. The method is shown schematically in Fig. 17. The slip is poured into the mold, and nearest the wall of the mold, the water is drawn into the pores of the plaster mold. The dried region of the slip consists of a relatively close-packed compact that grows as more water is wicked into the mold. When a suitable compact thickness is established, the excess liquid is drained from the mold leaving behind a powder compact shell that can then be sintered.

Uniaxial pressing involves the compaction of powder into a die by applying pressure in a single axial direction with a mechanical or hydraulic press and a suitably designed die (see Fig. 18). The powder feed may be either dry (less than 4% moisture) or, if a clay binder is used, 10 to 15% moisture. Nonuniform stress distributions in the compact during loading result from friction at the die wall and nonuniform particulate flow before and after loading (known as rebound), which may result in the formation of cracks and density inhomogeneities. Isostatic pressing allows greater flexibility in the selection of the final shape of the solid. It also results in improved

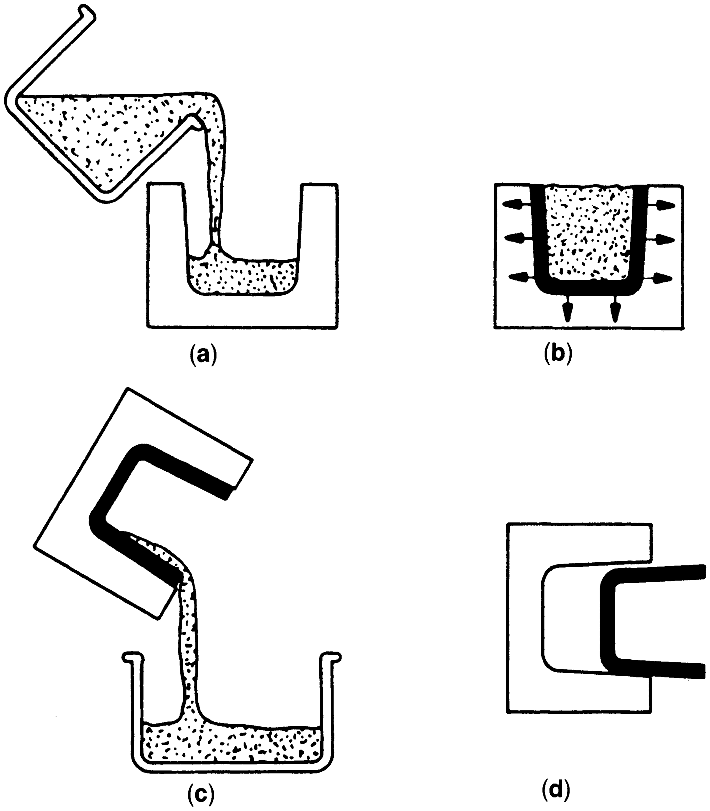

FIG. 17. The drain-casting approach to slip casting. (a) The slip is poured into a plaster mold, (b) the pores of the mold draw water out of the slip near the mold wall, (c) the excess liquid is drained off, and (d) the compacted form is removed after partial drying (Richerson, 1992).

compaction uniformity. In these processes, the powder is loaded in hydrostatically (equally loaded in all directions) by sealing the powder in a flexible bag and applying pressure using a liquid or a gas. This results in improved compaction uniformity.

Hot pressing (and hot isostatic pressing) combine the processes of compaction and sintering (described below). The application of pressure at the sintering temperature accelerates the compaction process by increasing the driving force for densification by mass transfer. These effects are described below.

3.1.2 Sintering A powder compact that is heated to below the melting point ($T/T_m > 0.75$) of the solid undergoes densification by a process known as sintering. The driving force for densification during sintering is the reduction of internal surface area. The amount of surface area obviously scales inversely with the size of the particles that make up the powder. Consequently, coarse powders densify more slowly than do fine powders. Upon heating, a variety of diffusion-based mass transfer processes (initially dominated by surface, then grain-boundary, then bulk diffusion) result in the fusion of particles and the filling in of the pores between particles. Initially, the porosity will be fully interconnected in a three-dimensional network, and the primary change in microstructure will be the smoothing of the particle surfaces and the fusion of connecting particles. After moderate times at temperature, the particles become fused and begin to form a three-dimensional network of solid material consisting of individually oriented grains, with pores present mostly at the grain boundaries. Grain growth occurs concurrent with the reduction in pore size and the increase in pore spacing. When pores become trapped within individual grains, they become difficult to remove by further annealing, because grain boundaries provide a rapid diffusional path for vacancies away from the void. Consequently, after long times at temperature, the density may not change with time, but entrapped voids make the actual density less than that of the fully dense structure.

The mechanisms of material transport that

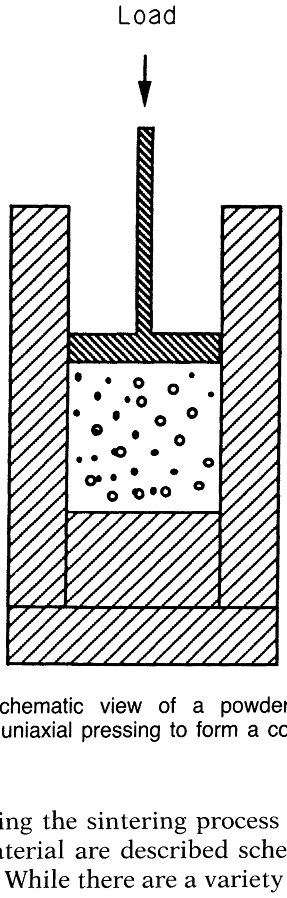

FIG. 18. Schematic view of a powder in a die undergoing uniaxial pressing to form a compact.

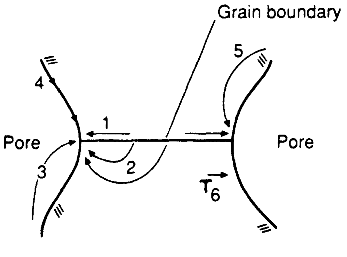
occur during the sintering process of a crystalline material are described schematically in Fig. 19. While there are a variety of matter transport mechanisms that can operate during sintering, there are only three that directly contribute to densification by removing material from between grains and depositing it on a void surface. Densification requires material transport paths that cause grains in the structure to move closer together. These three mechanisms are grain-boundary diffusion, volume diffusion, and dislocation motion. The transport mechanisms that do not directly result in densification, and actually compete against the densification processes, are evaporation/condensation at and to pore surfaces, surface diffusion (which results in the smoothing of the particle surfaces), and grain coarsening by volume diffusion (i.e., movement of material from one grain to another rather than to a pore surface).



Mechanism	Densifying	Non-densifying
1. Grain boundary diffusion	X	
2. Volume diffusion	X	
3. Evaporation/condensation		X
4. Surface diffusion		X
5. Coarsening by volume diffusion		X
6. Dislocation (T) creep	X	

FIG. 19. Densification occurs by material transport to the pores of the compact. Six mechanisms for densification are shown schematically (Evans and Jonghe, 1991).

At some time *t*, there will be grains surrounding a pore as shown in Fig. 20. The atom flow can be calculated if the diffusivity of the atoms of the material is known. Empirically, it has been seen that the rate at which a compacted specimen undergoes densification (as measured by the reduction in length of the compact) is given by $\Delta L/L_0 = Kt^m$, where ΔL is the change in length, L_0 is the initial length of the compact, *t* is the time, *m* is a constant that lies between 0.3 and 0.5, and *K* is a factor that is constant in time but depends inversely on the cube of the particle size. As the compact gets to be within 85% of the full density, the rate decreases from that which is predicted by this expression since the pores become completely closed, and, as more of them become isolated within individual grains (i.e., with no grain-boundary intersection with the pore), the rate of densification goes to zero. Consequently, it is necessary to use additional driving force—say, by the application of pressure, as in hot pressing—to produce fully dense materials.

The compaction of a powder and subsequent annealing of the compact at between 0.5 and 0.8 of the melting point is sufficient to produce a free-standing object from a powder. Annealing for long times at these temperatures will cause a 1-μm powder to produce a structure that has no interconnected porosity and a grain size of 10–100 μm. If one is not concerned about the mechanical strength of the object produced, then this may be sufficient. Otherwise, additional steps, such as the application of a repressing step before additional sintering, may be necessary. More rapid densification and more fully dense materials may be formed if multicomponent materials are sintered at temperatures above

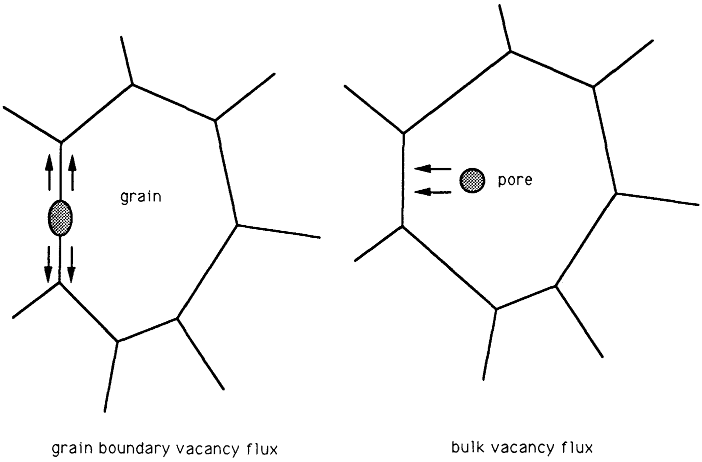


FIG. 20. Schematic view of pores present in and out of grain boundaries.

the melting point of one of the components. This results in the formation of a liquid that wets the grain boundaries of the material and provides a more rapid diffusion path for densification. This is routinely done in ceramic and cemented carbide (for hard-tool materials) sintering processes and is known as liquid-phase sintering.

3.2 Mechanical Forming

Mechanical forming is a process that is applied to those materials that can tolerate significant amounts of plastic deformation. Plastic deformation occurs in polymers by the flow of the molecules that make up the plastic and in metals by the motion of dislocations. A dislocation is a line defect that represents a boundary between atomic planes that have been displaced relative to one another in response to external forces. Plastic deformation of metals can be appreciated from a plot of engineering stress (force per unit initial cross-sectional area) versus strain elongation, $(L_f - L_0)/L_0$, as shown schematically in Fig. 21 for a bar that is loaded in tension. The initial deformation is elastic (i.e., fully recoverable), but above a critical stress (called the yield stress) the strain induced is no longer linearly proportional to the applied load, and it is not recoverable. The shape of the stress-strain curve depends on the material (both composition and microstructure) that is being loaded.

A feature of the plastic deformation behavior of crystalline materials is that the yield strength decreases at higher temperatures, and hence the energy necessary to perform mechanical shaping by plastic deformation also decreases. Consequently, most initial metal-forming operations (known as finishing operations) are performed at elevated temperatures. Ceramics cannot sustain any plastic deformation at reasonable temperatures and hence must be formed by powder methods. Hot-working processes are defined as those in which the deformation takes place under conditions of temperature and strain rate such that recovery processes take place

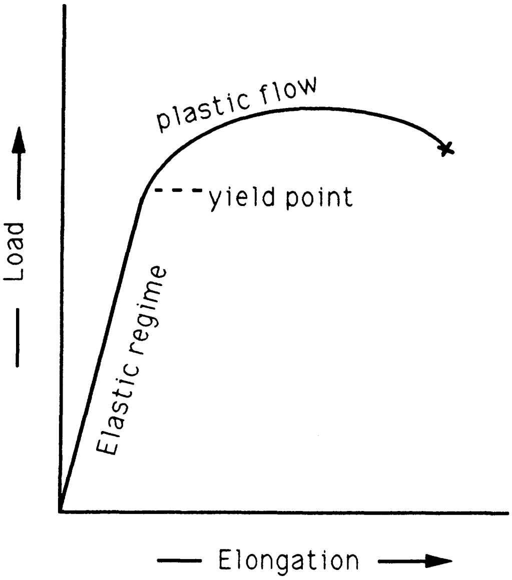

FIG. 21. Schematic illustration of load versus elongation for a metal.

simultaneously with the deformation. Recovery processes leave the grains of the metal relatively large and equiaxed and free of dislocations. Deformation at low temperatures (at $T \ll 0.3T_m$) is called cold-working and results in dramatic changes in microstructure and mechanical response of a material.

The mechanisms of plastic deformation are discussed elsewhere (e.g., Dieter, 1986); only a few essential concepts are discussed here. For instance, the process of strain hardening can be seen in Fig. 21 which shows that the stress necessary to continue deforming a material past its initial yield point increases with increasing strain. The load at which a material initially yields, and its strain-hardening behavior, is easily determined under uniaxial conditions by a uniaxial tensile test. The loads applied during metal forming are, however, rarely simply uniaxial but instead include a combination of stress components. Consequently, a criterion for yielding is required. Metals deform by crystallographic slip (*via* dislocations) in specific slip planes and in specific directions. In polycrystalline materials where the bulk is considered to be isotropic and homogeneous and in which volume is conserved, a criterion for yielding can be developed based on distortion–energy considerations and is called the von Mises yield criterion:

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = C, \tag{13}$$

where C is a constant and $\sigma_{1;2;3}$ are the principal stresses. Principal stresses are found by rotating the orthonormal coordinate system with respect to the applied stresses so that the stress state can be described in terms of just three axial stress components that act normal to the three planes defined by the new axes (i.e., no shear components). With tension conventionally noted as positive and compression negative, it is easy to show that for uniaxial tensile loading where σ_1 is positive and $\sigma_2 = \sigma_3 = 0$, yielding will occur when σ_1 = yield strength (σ_{ys}) as defined for pure tension in Fig. 21 and $C = 2\sigma_{ys}^2$. For pure torsional loading, $\sigma_1 = -\sigma_3$ and $\sigma_2 = 0$, and yielding occurs when the applied torsional stress exceeds the shear yield strength ($\sigma_{ys\ shear}$) and the von Mises criteria is $C = 6(\sigma_{ys\ shear})^2$.

3.2.1 Bulk Forming Operations that cause shape changes in a plastically deformable material through the application of compressive stresses to an ingot are referred to in this article as bulk-forming methods. In these processes, there is a large degree of contact between the tool and the work piece (ingot). Flat rolling is used to generate plates, sheet, and foil by the reduction of the plate thickness and, although the forces are applied to the surface of the work piece, the metal flows at right angles to the applied load. These operations are performed in a rolling mill, which consists of cylindrical rolls that are set a fixed distance apart. When the width-to-thickness ratio of the original piece is large (>10:1), then the piece is constrained to deform only in the length direction. Constraint in both the width and thickness directions results in the development of stresses only in these directions and not in the unconstrained length direction. The geometry of the rolling process for a simple one-roll pair is shown in Fig. 22. Instead of using rolls with parallel surfaces, it is also possible to use rolls with complex shapes so as to prepare I-beams, rails, and other sections.

Metal that can be made to flow can also be formed by extrusion, which is a process in which the metal is forced (by application of compressive pressure) to flow plastically through a restricted orifice (known as a die) of arbitrary shape. The pressure is applied by a piston that, along with the chamber that surrounds the metal, applies compressive stresses to the work piece. The basic layout for the extrusion process is shown in Fig. 23. A related process is known as drawing, which is the method used to make wire or rod from bulk metal. In this process, the metal is pulled through the die so as to develop tensile stresses in the material after it passes through the die. In drawing processes, it is necessary to remain in the region of the stress-strain curve where homogeneous deformation occurs. If the reduction in cross section is too large, the tensile stresses that are required to pull the metal through the die cause necking (i.e., localized reduction in cross section) and fracture. By selecting a sequence of dies with an ever-decreasing diameter, extremely large reductions in cross section can be achieved, and, consequently, extremely long lengths of wire or rod can be formed.

Forging is a method that is roughly described as the mechanical working of a metal into a useful shape by hammering or press-

ing. This method is widely used to form very large pieces from cast steel ingots (hot forging). Steel-forging operations take place at elevated temperature in equipment that is designed to apply blows to the sample in one of two ways. A forging hammer (or drop hammer) is set up to repeatedly deliver rapid impacts to the metal. A forging press subjects the metal to slow-speed compressive force. In both cases, direct compression is applied by driving two patterned dies toward each other. An example of items that are fabricated by forging include drive shafts for large stationary engines and turbines. On a smaller scale, it is also used to form heads on nails and to produce the relief pattern observed on coins. An example of a forging machine is shown in Fig. 24. Forging also is very important for reducing the dendritic microstructure of an as-cast ingot into a finer, more equiaxed and less segregated structure with superior mechanical and corrosion properties.

known as bulk forming by the application of forces that result in inhomogeneous stress states. For example, the simplest sheet-forming processes imaginable are those that involve bending to form simple objects (e.g., brackets, metal boxes, cabinets) by taking a piece of sheet metal and applying bending moments. In this case, the top surface of the material experiences tension while the bottom surface experiences compression, and hence, the piece experiences inhomogeneous stress during deformation. More complex sheet-forming processes include deep drawing, which is used to form the familiar aluminum beverage can. The formation of a beverage can begins with a round slug of Al that is clamped in a hold-down device over a die. Pressure is then applied to the central region of the slug using a punch to cause the material to flow (at room temperature) into the die. The flange of the blank is subjected to compressive forces due to the hold-down device, while the wall of the cup experiences tensile stresses. The process is shown schematically in Fig. 25.

4. POLYMER PROCESSES

The creation of a plastic product or structure requires two principal steps: the first is the chemical manufacture of long-chain car-

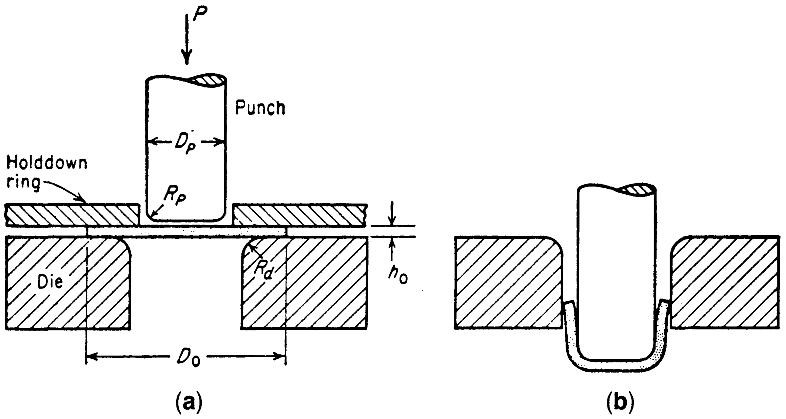

FIG. 25. Deep drawing of a cylindrical cup or can showing the material before and after drawing.

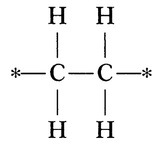
bon-based polymeric molecules, and the second is the arrangement of these molecules into a near-final solid shape. The shaping of polymeric materials depends to a large extent on the class of polymer to which the material belongs. The three classes are thermoplastics, thermosets, and elastomers. Thermoplastics flow when heated and therefore can be formed by any one of a variety of flow processes (such as extrusion) that were described earlier for mechanical forming of metals. The only difference between metal and thermoplastic forming is that thermoplastics flow at much lower stresses at close to room temperature. Thermosetting polymers are formed from polymeric precursor molecules that undergo cross-linking when subjected to heat or to a catalyst. As a consequence, thermoset materials must be in their near-final shape before they undergo the cross-linking process, during which they transform irreversibly from a liquid to a solid state. Thermosets are widely used as the matrix in polymer-based composites while thermoplastics, owing to the ease with which they are formed, are the basic material from which most low-cost packaging and consumer goods are formed.

4.1 Polymeric Materials

Most polymers (or plastics) are based on some form of synthetic organic resin that is a long-chain compound molecule containing carbon as the central element. The carbon atoms in each molecule are covalently bonded together, and the molecule is saturated with hydrogen and subunits known as radicals, which typically contain nitrogen, oxygen, and chlorine. The size of the basic molecule that forms the polymer, known as a polymer macromolecule, depends on the number of atoms in the carbon backbone. This quantity, known as the degree of polymerization, has a profound affect on the properties of the material. Polymer macromolecules are formed by the bonding together of much smaller subunits called monomers. For example, the thermoplastic polymer known as polyethylene is formed by the linear addition of activated ethylene monomer units:



$$\begin{array}{ccccccc} & & H & & H & & \\ & & | & & | & & \\ * & - & C & - & C & - & * \\ & & | & & | & & \\ & & H & & H & & \end{array} \qquad (14)$$

where the * represents an activated site. Hundreds of these ethylene monomer units add together in what is known as an addition reaction to form the long (>500 monomer units) chain macromolecule. There is no by-product formed during an addition reaction.

The properties of these materials greatly depend upon the size of the polymer macromolecules and the interaction and arrangement of the molecules in the solid. For instance, as base units are added, the stable form of the molecule at room temperature changes from a simple gas, to a liquid, to a solid. Polymer molecules can contain up to thousands of monomers. The polymer macromolecule can be made up of a single type of monomer as is the case with polyethylene, or it can be made in a process known as copolymerization from two or more monomers.

Thermoplastic materials are composed of chemically separate long molecules that are held together by secondary chemical bonds. While the primary covalent bonds of the backbone of each molecule remain strong upon heating, the secondary ones are weakened at elevated temperature and ultimately dissociate. Thermoplastics, therefore, can flow at elevated temperatures because the macromolecules of the polymer are not bonded to each other and can respond to an applied stress by sliding past one another.

When the molecules of a polymer are randomly arranged, the material is called an amorphous (or glassy) polymer. Examples of amorphous polymers include polystyrene, polymethyl methacrylate, and polycarbonate. Other plastics are called crystalline because their molecules are locally aligned in a pseudoregular array to form structures called spherulites. The spherulites are surrounded by amorphous material but are interconnected by small fibers of crystalline material. Examples of crystalline polymers include polyethylene, isostatic polypropylene, acetal, and nylon. Crystalline polymers tend to have the strongest secondary bonds and hence are able to withstand higher temperatures than amorphous polymers. The arrangement of the radical groups on the long-chain molecule affects the crystallization behavior of some polymer materials. For example, if the radical groups are arranged randomly along the length of the molecule, then the packing of the macromolecules is less efficient and the polymer is less likely to crystallize. The increasingly organized arrangement of radical groups is referred to as the tacticity of a polymer. The higher the tacticity, the more likely the molecules will arrange themselves in a crystalline form. Tacticity also affects the efficiency with which molecules can be packed together. In general, lower tacticity results in increased distance between molecules, weaker secondary bonds, and lower softening temperature.

A second class of plastics is known as thermosetting. Plastics in this class are composed of macromolecules that are linked together in three dimensions (as opposed to the linearly bonded carbon backbone in thermoplastics) by primary covalent bonds. An example of a thermosetting plastic is phenolic resin, which is formed by the reaction between phenol and formaldehyde. Thermosetting plastics do not soften upon heating and remain intact until they thermally decompose into smaller molecules. The thermosetting plastics are generally stronger, harder, and more resistant to heat and chemical attack, but they do not flow under loads and tend to be brittle.

A third class of polymeric materials is known as elastomers. These consist of macromolecules that are cross-linked at widely separated points into a three-dimensional network. Examples of elastomers include natural rubber, isoprene, polybutadiene, and neoprene. Elastomers can be stretched to at least twice their original length, and they preserve their ability to recover their original shape after loading over a wide range of temperatures (typically −20 to 200 °C). The elastic behavior of elastomers is permanently lost when, through exposure to heat, light, or chemical attack, the network becomes increasingly cross-linked.

4.2 Polymer Forming

Plastic objects are formed by a variety of methods, most of which are a simple application of the methods that were discussed for

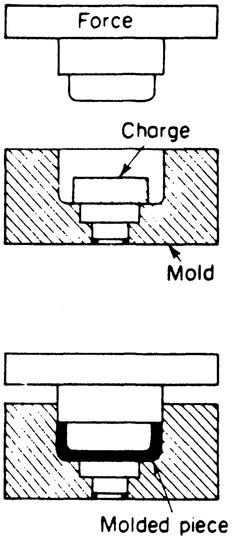


FIG. 26. Compression molding setup for forming thermoplastics (Ludema, 1987).

metal forming. These include extrusion, casting, and injection molding. Many of these processes have been discussed in the previous sections (e.g., injection molding), and only the additional details relevant to plastic forming will be discussed here. Thermoplastics are formed by mechanically forcing them to flow (typically above their softening point). Most of the thermoplastics that are commonly used are formed at temperatures between 120 and 250 °C. Thermosets are not plastically deformable and hence must be formed from the liquid state by casting or otherwise applying the liquid in nearly its final shape before the cross-linking process proceeds to the final formation of a solid.

Thermoplastics can be produced in any cross-sectional shape by extrusion. In plastic extrusion equipment, the feed takes the form of small plastic pellets that are heated before the application of a force that extrudes the plastic through a die. Unlike the extrusion of metal, thermoplastics can be formed at 120 to 250 °C with relatively light loads that may be applied using a screw-type auger feed mechanism. Compression molding involves the squeezing of a set amount of polymer in a cavity with a punch as shown in Fig. 26. In this process, the plastic is made to flow by the application of pressure to fill the space between an appropriately shaped piston and a mold. Blow molding is used for the fabrication of plastic bottles and is shown schematically in Fig. 27. In this process, a tube (called a parison) of thermoplastic material is heated and placed into a mold. One end of the tube is pinched closed, and gas is used to pressurize the inside of the tube so that it bulges out against the mold wall.

Direct casting can be performed with thermosets that, in their liquid state, can be cast in relatively soft molds made of rubber,

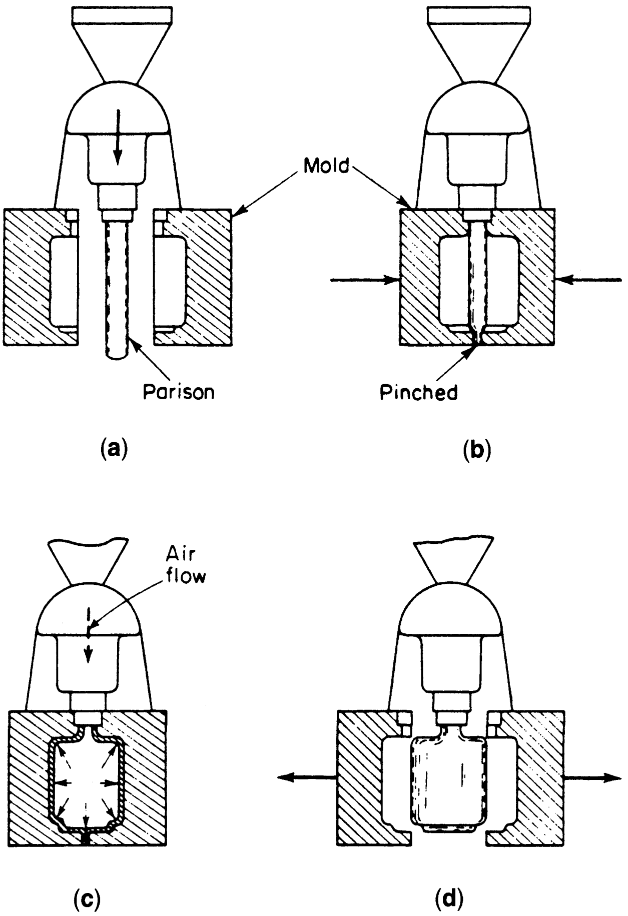

FIG. 27. Blow molding for the formation of plastic bottles from thermoplastic (Ludema, 1987).

wood, plaster, etc. A catalyst is added to the resin to speed up polymerization. Thermosets are commonly used in the formation of polymer matrix composites. Composites are materials that consist of a soft matrix material (i.e., the polymer) that is reinforced by fibers of a much stiffer and more brittle material. These two-part materials are tougher (resistant to failure by crack propagation) than either of the constituents and are stronger and stiffer than the matrix polymer. Composites may be formed by using a thermosetting polymer matrix (epoxy, for example) and mixing in fibers made from glass, carbon, or Kevlar (aramid). In all of these cases, the resulting composite material is much tougher (i.e., resistant to failure by crack propagation) than either the matrix epoxy or the reinforcing material. The mechanical properties of composites are very sensitive to the orientation of the applied load with respect to the alignment of the fibers.

GLOSSARY

Addition Reaction: The process by which bifunctional monomer units combine sequentially to form a linear polymer macromolecule.

Burgers Vector: A vector that describes the magnitude and direction of the lattice distortion associated with a dislocation.

Ceramic: A compound of metallic and nonmetallic elements that are bonded together *via* ionic bonds.

Crystalline: A solid state of matter in which the atoms of the solid are distributed in a repeating three-dimensional array.

Dislocation: A linear crystalline defect that marks the center of a localized distortion of the crystal lattice. Plastic deformation occurs by the movement of these defects.

Drawing: In metal forming, a technique used to fabricate metal wire and tubing. Deformation is accomplished by pulling the material through a die by means of a tensile force.

Elastic Deformation: Nonpermanent (i.e., recoverable) response of a material to an applied load.

Epitaxy: The coordinated arrangement of one set of atoms on a crystalline template formed by a single crystal of either the same or a different material.

Grain: An individual crystal in a polycrystalline metal or ceramic.

Grain Boundary: The interface in a polycrystalline material between two grains that have different crystallographic orientations.

Gibbs Free Energy (ΔG): A thermodynamic quantity that is a function of both the enthalpy and entropy of a system. Gibbs free energy is a minimum at equilibrium.

Lattice: A regular geometrical arrangement of points in space such that every point has identical surroundings.

Lattice Parameters: The combination of unit cell edge lengths and interaxial angles that defines the unit cell geometry.

Liquidus Line: A line on a binary phase diagram that defines a boundary between the single-phase liquid and the liquid-plus-solid regions. This line indicates the temperature at which solid will first appear when a particular alloy composition is cooled from the single-phase liquid regime.

Macromolecule: Usually a polymer molecule that consists of hundreds or thousands of atoms.

Monomer: The group of atoms that make up the repeating unit that forms a polymer macromolecule.

Plasma: A gas of positive ions and free electrons in approximately equal numbers.

Polymer: A solid, usually carbon-based, compound of high atomic weight that is composed of smaller repeating monomer units.

Plastic deformation: Change in shape, due to the application of a load, which is not recovered when the load is removed.

Solidus Line: A boundary on a phase diagram that defines the point at which solidification is complete (i.e., a single-phase solid regime is entered) when an alloy is cooled.

Strain, Engineering: The change in length of a specimen loaded uniaxially divided by the original length.

Stress, Engineering: The instantaneous load applied to a specimen divided by its cross-sectional area before any deformation.
